#### Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The editors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the editors, nor the publisher, nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete. Readers are encouraged to confirm the information contained herein with other sources. For example, and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this book is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

# Foreword to the first edition (1993)

Sport in Australia is ingrained in the national consciousness more widely, deeply and indelibly than almost anywhere else in the world. When a prominent sportsperson sustains a sporting injury, either traumatically or from overuse, becomes excessively fatigued, or fails to live up to expectations, this assumes national importance. It is even more relevant nowadays with greater individual participation in sporting activities. The same type of problems occur for recreational athletes, middle-aged people wanting to become fit, or older people wishing to sustain a higher level of activity in their later years.

In *Clinical Sports Medicine* the authors take sport and exercise medicine out of the realm of the elite athlete and place it fairly and squarely where it belongs—as a subspecialty to serve everyone in the community who wishes to be active.

The book is organised in a manner that is sensible and usable. The chapters are arranged according to the anatomical region of the symptom rather than diagnostic categories. This results in a very usable text for the sports physician, general/family practitioner, physiotherapist, masseur, or athletic trainer whose practice contains many active individuals.

Practical aspects of sports medicine are well covered—care of the sporting team and concerns that a clinician might have when travelling with a team. In all, this is an eminently usable text which is timely in its production and will find an important place among clinicians involved in the care of active individuals.

JOHN R SUTTON MD, FRACP

*Professor of Medicine, Exercise Physiology and Sports Medicine*

*Faculty of Health Sciences*

*University of Sydney*

*Past President, American College of Sports Medicine*

*This foreword was written by the late Professor John Sutton before his untimely death in 1996; we honour the memory of this champion of the integration of science, physical activity promotion and multidisciplinary patient care.*

# Foreword to the fifth edition

Twenty-four years after the publication of the first edition, the salient point made by Professor John Sutton in his foreword remains true—in *Clinical Sports Medicine* the authors take sports and exercise medicine out of the realm of the elite athlete and present it in the service of everyone in the community who wishes to remain active.

A search for the fourth edition in our university library revealed very well used and even threadbare copies and illustrated how indispensable this resource is to students and practitioners alike. This fifth edition continues the clear focus of previous editions: 'helping clinicians help patients', transcending professional boundaries to enable best practice.

The authors of *Clinical Sports Medicine: Injuries* include the very top names in sports and musculoskeletal physiotherapy, sports medicine and sport science from around the world—in short, the community that takes care of active people everywhere, including the recreational or competitive sportsperson. The truly interdisciplinary nature of professional practice in sports medicine is revealed in this book. Indeed, this fifth edition includes specific chapters on key but often overlooked aspects of professional development; namely working in collaborative teams and how to develop your career. To achieve this, it draws on real-life lessons from around the world.

*Clinical Sports Medicine: Injuries* builds on the high-quality, evidence-based content of previous editions, with 15 new or substantially revised chapters. It is beautifully illustrated, combining aesthetics and evidence in a partnership that provides accessible learning to all readers. Practice pearls and step-by-step illustrations of physical activity for every joint are supported by more than 550 new and innovative illustrations, and line drawings superimposed on selected photographs to aid understanding.

A striking feature of *Clinical Sports Medicine* has always been the authors' relentless commitment to 'clinical'. This is a useful book; one to be consulted between patients or even while the patient is with you. The colour-coded sections develop, one on another. Part A—Fundamental principles—has been completely rewritten and the cadre of expert authors added new chapters on Pain, Core stability, Patient-reported outcomes (for use in the clinic), Training and Return to sport. Each of the 24 chapters in Part B—Regional problems—stands alone, flowing logically from functional anatomy to the broader, expert clinical perspective on the specific management of more than 100 major conditions. These chapters include the key aspects of injury epidemiology, clinical risk factors and interventions across sports; they cover the common presentations but also provide commentary on the atypical. One aim and notable focus throughout the book is to make evidence accessible to busy practitioners to aid their decision making. Best available evidence, consensus statements and cautionary notes are provided throughout in an eye-catching and succinct way. Part C—Practical sports medicine—closes out Volume 1 with five chapters for those working in various sport settings.

This is a unique book. The variety of illustrations and their contribution to the understanding of form, function, concepts, intervention and management, in combination with decades of the cumulative wisdom of practitioners, teachers and researchers, ensures that this is an indispensable work.

DR EMMA K. STOKES FTCD

Associate Professor / Deputy Head

Department of Physiotherapy, School of Medicine, Trinity College, Dublin

President, World Confederation for Physical Therapy

## 14 Clinical assessment: moving from rote to rigorous

by Chad Cook 201

Why is differential diagnosis important?	201
Differential diagnosis: a three-step process	201
How to calculate an accurate diagnosis	202
Reliability	202
Sensitivity and specificity	202
Positive and negative predictive values	202
Likelihood ratio	203
Clinical utility	203
The formal diagnostic assessment	206
The role of bias in influencing diagnostic metrics	206
Challenges to making a diagnosis	206
Final thoughts and guidance	207

## 15 How to make the diagnosis

with Ali Guermazi, Jon Patricios and Bruce Forster 209

Does 'diagnosis' mean 'tissue diagnosis'?	209
Keys to accurate diagnosis	210
History	211
Allow enough time	211
Be a good listener	211
Know the sport	211
Discover the exact circumstances of the injury	211
Obtain an accurate description of symptoms, both at the time of injury and at the initial consultation	211
History of a previous similar injury	212
Other injuries	212
General health	212
Work and leisure activities	212
Consider why the problem has occurred	212
Training/activity history	213
Equipment	213
Technique	213
Overtraining	213
Psychological factors	213
Nutritional factors	213
Drugs: prescription and others	213
History of exercise-induced anaphylaxis	213
Determine the importance of the sport to the athlete	213
Differential diagnosis	213
Physical examination	213
Develop a routine	214

Where relevant, examine the other side	214
Consider possible causes of the injury	214
Attempt to reproduce the patient's symptoms	214
Assess local tissues	214
Assess for referred pain	214
Assess neural mechanosensitivity	214
Examine the spine	214
Biomechanical examination	214
Functional testing	214
The examination routine	214
Differential diagnosis	221

### Diagnostic imaging 221

The five imaging-related habits of highly effective sports medicine clinicians	221
--	-----

### Specific imaging modalities 223

Conventional radiography	224
MRI: massive blessing for active patients	224
Ultrasound scan (for diagnosis)	227
CT scanning	229
Radioisotopic bone scan	229

## 16 Patient-reported outcome measures in sports medicine

with Natalie Collins, Kay Crossley and Ewa M Roos 231

What are PROMs?	231
Why is it important to use appropriate PROMs in sports medicine?	231
Considerations for what constitutes a 'good' PROM for use in sports medicine	232
Is the PROM easy to use in a sports medicine setting?	232
Does the PROM evaluate dimensions that are relevant for the patient?	233
Do all items within a PROM measure the same construct?	233
Can the PROM be trusted to detect true change in the patient and be free from error?	233
Is the PROM sensitive enough to detect real change in the patient's condition?	234
Summary	235

## 17 Treatment of sports injuries

with Ben Clarson 239

Therapeutic exercise	241

Quotation sources	1035	Index	1039

'Helping clinicians help patients' has been the clear focus of *Clinical Sports Medicine* from its inception. This edition brings you more authors, more artwork and more evidence. We are fortunate that many reading this will already have *Clinical Sports Medicine* in their library, so you are asking, 'What's new?'

- *The complete focus on sports injuries for 1034 pages.* So many advances, we had to make a volume just for injuries. We decided to call it *Injuries*.
- *The giants of sports medicine and sports physiotherapy joining us on the front cover—our seven editors.* You know their work and now they have distilled their best for your benefit (see below and on the Editors page).
- *The artwork.* Vicky Earle's artwork is recognised the world over, the way Dr Frank Netter's was in the 1900s. You may not know the name, but you have seen the tendons, the groin entities and the *BJSM* covers. Five hundred new illustrations to clarify our field.
- *Fifteen new chapters.* (See new content, below.)
- *More than 4000 references—the solid foundation.* As Chapter 2 tells us, we do not yet have all the evidence we would like to have, and clinical advances can outpace the science, but ultimately the scientific method underpins quality care.
- *The unprecedented complementary social media—Facebook, Twitter, Instagram and the [www.clinicalsportsmedicine.com](http://www.clinicalsportsmedicine.com) website.* This content will have shelf life until 2020 and we will continually update it with the existing digital methods and those that have not yet been invented.

## Editors and authors

*Volume 1—Injuries* reflects the generosity of seven sports physiotherapy and sports medicine editors. Ben Clarsen (senior editor), Jill Cook, Ann Cools, Kay Crossley, Mark Hutchinson, Paul McCrory and Roald Bahr share their passion for helping patients and educating clearly. Our 121 chapter authors and contributors represent 19 countries. Recruited for their first edition, alongside editors Cools and Clarsen, are Rintje Agricola, Hamish Anderson, Sam Blanchard, Jeffrey Boyle, Darren Burgess, Phil Burt, Bojan Buvka, Graeme Close, Natalie Collins, Chad Cook, Adam Culvenor, Michael Davison, Stefano Della Villa, Pieter D'Hooghe, Paul Dijkstra, Sean Docking, Deborah Falla, Rodney French, Tim Gabbett, Phil Glasgow, Adam Gledhill, Alison Grimaldi, Fares Haddad, Toby Hall, Shona Halson, Roger Hawkes, Greg Hoy, Steven Kamper, Vasileios Korakakis, Alex Kountouris, Karl Landorf, Adam Meakins, Håvard Moksnes, Grethe Myklebust, Andrew Nealon, Ian Needlman, Kieran O'Sullivan, Peter O'Sullivan, Jon Patricios, Noel Pollock, Nebojsa Popovic, Michael Rathleff, Ebonie Rio, Ewa Roos, Stephen Simons, Geoffrey St George, Raj Subbu, Stephen Targett, Kristian Thorborg, Elsbeth van Dorssen, Stuart Warden, Adam Weir, Liam West and Fiona Wilson.

## New content

Five years is a long time in our field. Major advances, such as high quality evidence for physiotherapy rehabilitation in the management of acute knee injuries, new algorithms for the treatment of shoulder pain and fresh space for the biopsychosocial model are included. The shoulder and knee will remain the shoulder and knee for the next 100 years but chapters can be completely renovated between editions, by new authors. The following chapters have new authors with new diagnostic approaches and new treatments to benefit the clinician.

- Chapter 1: Paul Dijkstra and Stefano Della Villa outline the **team approach** to sports medicine.
- Chapters 3 and 4: Stuart Warden shares the latest mechanistic understanding of **acute** and **overuse injury**.
- Chapter 6: Ebonie Rio builds on Lorimer Moseley's chapter on **pain** (Chapter 5) for the clinician.
- Chapter 9: Experts in their fields share decades each of experience in assessing patients for **sport-specific biomechanical errors**.
- Chapter 10: Darren Burgess gives clinicians insight into the principles that underpin **training** at the very top level of sport and how these apply at the community level.
- Chapter 11: Paul Hodges summarises 20 years of thinking about **core stability**.
- Chapter 14: Chad Cook clarifies the numerical basis that should underpin clinical reasoning and **assessment**.
- Chapter 15: Ali Guermazi partners with fellow radiologist Bruce Forster, and clinician Jon Patricios, to simplify accurate **diagnosis** including MRI interpretation for every clinician.
- Chapter 16: Natalie Collins launches *Clinical Sports Medicine* squarely into the world of PROMs—**patient-reported outcome measures**.
- Chapter 17: Ben Clarsen threw away the fourth edition chapter and built a new **treatment** chapter with international leaders in the different disciplines.
- Chapter 19: Ian Shrier outlines the StARRT model for **return to play**.
- Chapter 21: Toby Hall brings a very practical physiotherapy focus to **headache**.
- Chapter 23: Together with Deborah Falla, Gwen Jull unravels **neck pain** and provides detailed treatment principles and tips.
- Chapter 24: Ann Cools shares her 20 years' experience in assessing and managing **shoulder pain**.
- Chapters 26 and 27: Greg Hoy led the extensive revision of the **wrist pain** and **hand and finger injuries** chapters, highlighting new treatments and new conditions.
- Chapter 29: Peter O'Sullivan incorporates the biopsychosocial approach to **back pain** assessment and management. See the very clinical patient triage outline in Figure 29.2.
- Chapter 30: Adam Meakins describes and illustrates (51 images) how to treat **buttock pain** using exercises as the foundation.
- Chapter 32: Adam Weir skilfully extracted the most useful clinical discoveries from the first world conference on **groin pain**.
- Chapter 35: Sports **knee** surgeons and physiotherapists combine to highlight what is working and what is not working for patients in this rapidly changing field.
- Chapter 43: Karl Landorf and Michael Rathleff are the world leaders on plantar fasciopathy. They provide a major new section inside the important **foot pain** chapter.
- Chapter 46: Stephen Targett applies his vast experience of **periodic medical assessment** to issues such as cardiac clearance, and giving advice that influences contracts worth millions of dollars when doing professional athlete transfer medicals.
- Chapter 47: Liam West hit the refresh button on **working and travelling with teams** and included essentials such as indemnity and emergency preparation.
- Chapter 48: Michael Davison introduces the junior clinician to the global world of sports medicine and sports physiotherapy—A 'how to' on **career development**. (Spoiler alert: hard work is involved!)

No single profession has all the answers required to treat every ill or injured athlete or enthusiast. *Volume 1—Injuries* was created by a champion team. We are confident that, whatever your training, *Clinical Sports Medicine* fifth edition will reinforce and refine existing knowledge and techniques, and introduce useful new approaches for your clinical practice as well as for your teaching of our wonderful vocation.

# About the authors

## Peter Brukner

OAM, MBBS, DRCOG, FACSEP, FASMF, FACSM, FFSEM (Ireland, Hon), FFSEM (UK, Hon)

### **Sport and Exercise Medicine physician**

Team Doctor, Australian cricket team

Head, Sports Medicine and Sports Science, Liverpool Football Club, UK 2010–12

Founding Partner, Olympic Park Sports Medicine Centre, Melbourne, Australia

Professor of Sports Medicine, La Trobe University, Melbourne, Australia

Associate Professor, Centre for Health, Exercise and Sports Medicine, The University of Melbourne, Australia

Honorary Fellow, Faculty of Law, The University of Melbourne, Australia

Adjunct Professor, School of Human Movement Studies, The University of Queensland Australia

Adjunct Professor, Liverpool John Moores University, UK

Visiting Professor, Lee Kong Chian School of Medicine, Singapore

Visiting Associate Professor, Stanford University, USA 1997

Executive Member, Australian College of Sports Physicians 1985–2000

President, Australian College of Sports Physicians 1991–92, 1999–2000

Board of Trustees, American College of Sports Medicine 2000–02

State and Federal Council Member, Sports Medicine Australia 1984–90

### **Team physician**

Socceroos 2007–10, Asian Cup Finals 2007, World Cup Finals 2010

Australian Olympic Team, Atlanta 1996, Sydney 2000

Australian Commonwealth Games team, Edinburgh 1986, Kuala Lumpur 1998

Australian team, World Student Games, Edmonton 1983, Kobe 1985, Zagreb 1987

Australian Athletics team 1990–2000, World Championships Tokyo 1991, Gothenburg 1995, Seville 1999

Australian team, World Cup Athletics, Havana 1992

Australian Men's Hockey team 1995–96

Australian team, World Swimming Championships, Madrid 1986

Melbourne Football Club (AFL) 1987–90

Collingwood Football Club (AFL) 1996

### **Books (co-author)**

*Food for Sport* 1987

*Stress Fractures* 1999

*Drugs in Sport—What the GP Needs to Know* 1996, 2000

*The Encyclopedia of Exercise, Sport and Health* 2004

*Essential Sports Medicine* 2005

*Clinical Sports Anatomy* 2010

### **Editorial boards**

*British Journal of Sports Medicine*

*Clinical Journal of Sport Medicine*

*Current Sports Medicine Reports*

*The Physician and Sportsmedicine*

### **Editor**

*Sport Health* 1990–95

### **Awards**

Medal of the Order of Australia 2006

Inaugural Honour Award, *Australian College of Sports Physicians* 1996

Citation Award, *American College of Sports Medicine* 2000

Honorary Fellowship, *Faculty of Sports and Exercise Medicine (Ireland)* 2012

## Karim Khan

MD, PhD, MBA, FACSEP, FSMA, DipSportMed (CASEM),  
FACSM, FFSEM (Ireland, Hon), FFSEM (UK, Hon)

### Sport and Exercise Medicine physician

Professor, University of British Columbia, (Department  
of Family Practice and School of Kinesiology)  
Vancouver, Canada

Co-Director, Centre for Hip Health and Mobility,  
University of British Columbia, Vancouver, Canada

Adjunct Professor: Professor, School of Allied Health,  
College of Science Health and Engineering, La Trobe  
University, Melbourne, Australia

Visiting Professor, School of Human Movement Studies,  
The University of Queensland, Brisbane, Australia

Clinical Professor, Centre for Musculoskeletal Studies,  
School of Surgery, University of Western Australia,  
Perth, Australia

Exercise is Medicine Committee, American College of  
Sports Medicine 2009–11

Medical Education Committee, American College of  
Sports Medicine 2002–04

Research Evaluation Committee, American College of  
Sports Medicine 2005–07

Director of Research and Education, Aspetar  
Orthopaedic and Sports Medicine Hospital, Qatar  
2013–15

Sports Medicine Advisory Board to the International  
Olympic Committee 2015–

### Team physician

Olympic Games Sydney 2000, Basketball Competition  
Venue

Australian Women's Basketball (The Opals) 1991–96

The Australian Ballet Company 1991–96

The Australian Ballet School 1991–96

Australian team, World Student Games 1993

Australian team, Junior World Cup Hockey 1993

Sport and Exercise Medicine Physician, South Yarra  
Sports Medicine, Melbourne, Australia; Australian  
Team Doctor, World Track and Field Championships,  
Helsinki 2005, and Olympic Games, Beijing 2008

**Greg Hoy** FRACS, FAOrthA, FACSP

Hand and Upper Limb Surgeon, Melbourne  
Orthopaedic Group, Melbourne, Australia

**Christopher Jordan** MD,

Assistant Director, South Bend-Notre Dame Sports  
Medicine Fellowship, University of Notre Dame, South  
Bend, USA

**Gwendolen Jull** AO MPhy, PhD, FACP

Emeritus Professor; Physiotherapy, School of Health  
and Rehabilitation Sciences, The University of  
Queensland, Australia

**Astrid Junge** PhD

Professor for Prevention and Sport, MSH University,  
Hamburg, Germany; Head of Research, FIFA-Medical  
Assessment and Research Centre (F-MARC) and  
Schulthess Clinic, Zürich, Switzerland

**Steven J Kamper** BSc (Hons), BAppSc, PhD

Senior Research Fellow, The George Institute for  
Global Health, Australia

**Jon Karlsson** MD, PhD

SPECIAL SURGERY CO-AUTHOR/EDITOR  
Professor of Sports Traumatology, Sahlgrenska Academy,  
Gothenburg; IFK Gothenburg football; Ortopedic  
Surgeon, Sahlgrenska University Hospital, Sweden

**Joanne Kemp** PhD, MSportsPhysio, BAppSci(Physio)

APA Sports Physiotherapist, Research Fellow, La  
Trobe Sports Exercise Medicine Research Centre;

School of Allied Health; College of Science, Health and Engineering, La Trobe University, Melbourne, Australia

**Tamim Khanbhai** MBBS, FFSEM (UK)

Sport and Exercise Medicine Physician, Defence Medical Rehabilitation Centre, Headley Court, Epsom, Surrey, UK; Club Doctor, West Ham United, UK

**W Ben Kibler** MD

Orthopedic Surgeon; Medical Director, Shoulder Center of Kentucky, Lexington Clinic, Lexington, Kentucky, USA; Team Physician, Lexington Legends/Kansas City Royals baseball teams Transylvania University, Lexington, Kentucky, USA; Medical Consultant, Women's Tennis Association

**Walter Kim** MD

Orthopaedic Surgeon, University of Illinois at Chicago, USA

**Vasileios Korakakis** PT, PhD, MSc, OMT, DipMDT

Senior Sports Physiotherapist, Aspetar Orthopaedic and Sports Medicine Hospital, Doha, Qatar

**Alex Kountouris** BAppSci(Physio), PostGradDip Sports Physio, PhD

Sports Science & Sports Medicine Manager, Cricket Australia; Physiotherapist, Australian Men's Cricket Team

**Karl B Landorf** Dip App Sc (Pod), Grad Cert Clin Instr, Grad Dip Ed, PhD

Associate Professor in Podiatry, School of Allied Health, La Trobe University, Australia

**Zuzana Machotka** MPhysio (Musc and Sports), BPhysio

Clinical Researcher/Physiotherapist, International Centre for Allied Health Evidence, University of South Australia, Adelaide, Australia; Australian Paralympic Winter Team

**Erin M Macri** MSc(Kin), MPT, MSc

Registered Physical Therapist, PhD candidate, Experimental Medicine Program, University of British Columbia, Centre for Hip Health and Mobility, Vancouver, Canada; OARSI Scholar, Boston University, USA

**Nicola Maffulli** MD, MS, PhD, FRCP, FRCS(Orth)

Department of Musculoskeletal Surgery, University of Salerno School of Medicine, Salerno, Italy; Centre for

Sports and Exercise Medicine, Queen Mary University of London, London, UK

**Michael Makdissi** BSc (Hons), MBBS, PhD, FACSP

Sport and Exercise Medicine Physician, Olympic Park Sports Medicine Centre, Melbourne, Australia; Team Doctor, Hawthorn Football Club (Australian Football League)

**Lawrence Mayhew** MSc, MCSP, FHEA

Senior Lecturer, Sports and Exercise Medicine and Physiotherapy, Musculoskeletal Health Research Group, Leeds Beckett University, Leeds, UK; Physiotherapist (Women's), England Football Association

**Adam Meakins** BSc (Hons) Physiotherapy

Lead Physiotherapist, Perform for Sport, Bushey, Herts. UK; Extended Scope Practitioner, West Herts. NHS Trust; Author of The Sports Physio Blog, <http://thesportsphysio.wordpress.com>

**Håvard Moksnes** Bachelor of Physiotherapy, PhD

Clinical Sports Physiotherapist, Norwegian Olympic Training Center (Olympiatoppen) & the Norwegian Sports Medicine Center (Idrettens Helsecenter); Co-director of the IOC Diploma in Sports Physical Therapie; The Norwegian Alpine Skiing Team 'Attacking Vikings' and Norwegian Athletics

**Hayden Morris** MBBS, DipAnat, FRACS

Orthopaedic Surgeon, Park Clinic Orthopaedics and Olympic Park Sports Medicine Centre, Melbourne, Australia

**G Lorimer Moseley** BAppSc(Phty) (Hons) PhD

Professor of Clinical Neuroscience & Foundation Chair in Physiotherapy, University of South Australia, Adelaide, Australia

**Grethe Myklebust** PT, PhD

Professor, Oslo Sport Trauma Research Center, Norwegian School of Sport Sciences, Oslo, Norway; Specialist in Sports Physiotherapy; Physiotherapist at the Seoul Olympics in 1988 and Sydney Olympics in 2000

**Andrew Nealon** BAppSc(Phty)

Principal, Aspire Physiotherapy Centre, Holgate, NSW, Australia; Head of Medical, Central Coast Mariners Football Club

**Ian Needleman** BDS, MSc, PhD, MRDRCS, FDSRCS, FFPH, FHEA

Centre for Oral Health and Performance, UCL Eastman Dental Institute, London, UK

**John W Orchard** MD, PhD, FACSEP, FFSEM, FACSM

Sport and Exercise Medicine Physician; Adjunct Professor, School of Public Health, University of Sydney; Chief Medical Officer, Cricket Australia

**Kieran O'Sullivan** BSc, M Manip Ther, PhD, Postgrad Dip Teaching & Learning

Lecturer, University of Limerick, Ireland; Lead Physiotherapist, Sports Spine Centre, Aspetar Orthopaedic and Sports Medicine Centre, Doha, Qatar

**Peter O'Sullivan** Dip Physio, Grad Dip Manip Ther, PhD, FACP

Professor, School of Physiotherapy and Exercise Science, Curtin University, Perth; Specialist Musculoskeletal Physiotherapist, Bodylogic Physiotherapy, Perth, Australia

**Jon Patricios** MBBCh, MMedSci, FACSM, FFSEM (UK), FFIMS

Sports Physician, Morningside Sports Medicine and Waterfall Sports Orthopaedic Surgery; Director of Sports Concussion, South Africa; Consultant to World Rugby, South African Rugby, Kaizer Chiefs Football Club and Team Didata cycling

**Babette M Pluim** MD, PhD

Chief Medical Officer, Royal Netherlands Lawn Tennis Association; Team Physician, Dutch Davis Cup and Fed Cup teams; Sports Physician, Amsterdam Collaboration on Health and Safety in Sports, IOC Research Centre for Prevention of Injury and Protection of Athlete Health, VUmc/AMC, Amsterdam, The Netherlands

**Noel Pollock** MBBCh, MSc, FFSEM

Sport and Exercise Medicine Physician; Team Doctor with British Athletics; Great Britain team doctor at six World Championships, the Beijing Paralympic Games and 2016 Summer Olympic Games, Rio de Janeiro

**Nebojsa Popovic** MD, PhD

Orthopaedic Surgeon and former Acting Chief Medical Officer, Aspetar Orthopaedic and Sports Medicine Hospital, Doha, Qatar; Chief Medical Officer for Yugoslavia, Summer Olympic Games, Seoul 1988 and Barcelona 1992

**Joel M Press** MD

Professor, Physical Medicine and Rehabilitation, Feinberg/Northwestern School of Medicine; Medical Director, Spine and Sports Rehabilitation Centers, Rehabilitation Institute of Chicago, USA; Reva and David Logan Distinguished Chair of Musculoskeletal Rehabilitation

**Michael Pritchard** BMedSci, MBBS (Hons), FRACS (Orth)

Orthopaedic Surgeon, St John's Hospital, Hobart, Australia

**Craig Purdam** Dip Physio, Postgrad Dip Sports Physio, MSc (Sports Physio)

Specialist Sports Physiotherapist; Adjunct Professor, University of Canberra; Head of Physical Therapies, Australian Institute of Sport; Australian Olympic Team Physiotherapist (x5)

**Michael Skovdal Rathleff** Bachelor of Physiotherapy, PhD

Senior Researcher, Research Unit for General Practice in Aalborg and Department of Clinical Medicine, Aalborg University, Denmark; Department of Occupational Therapy and Physiotherapy, Department of Clinical Medicine, Aalborg University Hospital, Denmark

**Maria Reese** MD

Specialist in Physical Medicine (Physiatry), Rehabilitation Institute of Chicago, Illinois, USA

**Ebonie Rio** B App Sci, B Physiot (Hons), M Sports Physio, PhD

Post-doctoral Research Fellow, La Trobe University Sport and Exercise Medicine Centre; The Australian Collaboration for Research into Injury in Sport and its Prevention; Victorian Institute of Sport, Australia

**Ewa M Roos** PT, PhD

Professor and Head of Research, Research Unit for Musculoskeletal Function and Physiotherapy, Institute of Sports Science and Clinical Biomechanics, University of Southern Denmark, Denmark

**Stephan Rudzki** MBBS, GradDipSportSc, MPH, PhD, FACSP

Brigadier, Australian Defence Force, Joint Health Command; Director, General Army Health Services, Canberra, Australia

**Anthony Schache** BPhysio (Hons), PhD

Physiotherapist, Olympic Park Sports Medicine Centre and Richmond Football Club (AFL); Research Fellow, Hugh Williamson Gait Laboratory, Royal Children's Hospital, Melbourne, and Faculty of Engineering, The University of Melbourne, Australia

**Alex Scott** BSc(PT), MSc, PhD

Associate Professor, Department of Physical Therapy, University of British Columbia, Canada

**Catherine Sherrington** PhD, MPH, BAppSc(Physio)

Professorial Research Fellow, George Institute for Global Health, Sydney Medical School, University of Sydney, Australia

**Ian Shrier** MD, PhD

Associate Professor, McGill University; Centre for Clinical Epidemiology, Lady Davis Institute, Jewish General Hospital, Montreal, Canada

**Karin Grävare Silbernagel** PT, ATC, PhD

Assistant Professor, Department of Physical Therapy, University of Delaware, USA

**Stephen M Simons** MD, FACSM

Director of Sports Medicine, Saint Joseph Regional Medical Center, Mishawaka, Indiana; Co-Director, South Bend-Notre Dame Sports Medicine Fellowship, USA

**Kevin Singer** PhD, PT

Emeritus Professor, School of Surgery, The University of Western Australia, Australia

**Geoffrey St George** BDS, DGD (UK), MSc, FDS (RCSEd), FDS (Rest Dent)

Centre for Oral Health and Performance, UCL Eastman Dental Institute, London, UK

**Raj Subbu** MBBCh MRCS, BSc (Hons) PGMedEDCert

Sports Research Fellow, Institute of Sport Exercise and Health, London; Watford FC & Fulham FC, UK

**Kent Sweeting** BHLthSc (Pod) (Hons)

Podiatrist and Director, Performance Podiatry & Physiotherapy; Director, Queensland Orthotic Laboratory, Brisbane, Australia

**Stephen Targett** MB ChB, FACSEP

Sport and Exercise Medicine Physician; Clinical Lead Athlete Screening, Aspetar Hospital, Doha, Qatar

**Kristian Thorborg** PT, PhD

IOC Sports Medicine Copenhagen; Sports Orthopedic Research Center—Copenhagen (SORC-C), Amager-Hvidovre Hospital, Copenhagen University, Denmark

**Michael Turner** MB BS, MD, FFSEM (UK and Ireland)

Chief Medical Advisor, Lawn Tennis Association; Chief Medical Advisor, British Horseracing Authority, UK

**Elsbeth van Dorssen** MD, MSc

Sports Medicine Physician and Team Doctor KNZB (Royal Dutch Swimming Federation), The Netherlands; Paralympic Games, Rio de Janeiro 2016

**Evert Verhagen** PhD

Department of Public and Occupational Health, VU University Medical Center, Amsterdam, The Netherlands

**Bill Vicenzino** PhD, MSc, Grad Dip Sports Pty, BPhty

Professor, Chair in Sports Physiotherapy; Director of MPhty (Musculoskeletal, Sports Pty), School of Health and Rehabilitation Sciences, The University of Queensland, Australia

**Stuart Warden** BPhysio (Hons), PhD, FACSM

Professor and Associate Dean for Research, School of Health and Rehabilitation Sciences, Indiana University, Indianapolis, USA

**Adam Weir** MBBS, PhD

Aspetar Orthopaedic and Sports Medicine Hospital, Doha, Qatar; Amsterdam Center of Evidence Based Sports Medicine, Academic Medical Center, Amsterdam, The Netherlands

**Liam West** BSc (Hons), MBBCh, ECOSEP(ac), DipSEM

Junior Doctor, Royal Melbourne Hospital, Melbourne, Australia; Head Doctor, Williamstown Football Club

**Fiona Wilson** BSc, MSc, MA, PhD

Assistant Professor & Chartered Physiotherapist, Discipline of Physiotherapy, School of Medicine, Trinity College Dublin, The University of Dublin, Dublin, Ireland

# Other contributors

**Richard Allison** BSc, MSc, PhD

Senior Sports Dietitian, Aspetar Orthopaedic and Sports Medicine Hospital, Doha, Qatar

**Ummukulthoum Bakare** PT

Sports Physiotherapist; Secretary, Nigeria Sports Physiotherapy Association; Chief Physiotherapist, Lagos University Teaching Hospital; Member, Medical and Scientific Commission, Nigeria Olympic Committee; Team Physiotherapist, All Africa Games 2015, Paralympic Team, Rio de Janeiro 2016

**Tone Bere** PT, PhD

NBA Director of Sports Medicine; Professor and Chief, Division of Sports Medicine and Non-Operative Orthopaedics, David Geffen School of Medicine, UCLA; Head Team Physician, UCLA Department of Intercollegiate Athletics, Los Angeles, USA

**Allison Ezzat** PT, MCISc, MSc, PhD candidate

British Columbia Children's Hospital Research Institute, School of Population and Public Health, University of British Columbia, Canada

**Anna Frohm** PT, PhD

Swedish Sports Confederation, Elite Performance, Head of Sports Medicine and Karolinska Institutet, Department of Neurobiology, Care Sciences and Society, Section of Physiotherapy

**Sue Mayes** BAppSc (Phty), Grad Dip Sports Physiotherapy, PhD(c)

Principal Physiotherapist, The Australian Ballet

**Francis O'Connor** MD, MPH, FACSM

Professor and Chair, Military and Emergency Medicine Uniformed Services University of the Health Sciences Bethesda, USA

**Seth O'Neill** MSc, BSc, MACP, MCSP

Lecturer, University of Leicester, UK

**Matthew Stride** MRCP (UK), DipSEM MSc, FFSEM, CES

Consultant Sport and Exercise Medicine, Isokinetic London, UK; Team Doctor Brentford Football Club

**Markus Walden** MD, PhD

Orthopaedic Surgeon, Department of Orthopaedics, Hässeholm, Sweden; Member of Football Research Group (FRG), Linköping University, Sweden; Team Physician, IFK Kristianstad (handball), Sweden

## Medical illustrator

**Vicky Earle** BSc (AAM), MET, Cert TBDL

Vicky, an international award winning medical illustrator, has worked with renowned researchers, sports medicine physicians and surgeons around the globe. She has created thousands of illustrations for medical and scientific textbooks and journals, as well as artwork for legal litigation, video, animation and websites on a variety of topics. Vicky's keen interest in *Clinical Sports Medicine* stems not only from a great appreciation of the human body and its capabilities, but also from years of racing experience as a championship rower, a world-class paddler, and a rock climbing enthusiast—and knowing first-hand the many injuries that accompany these activities.

# Acknowledgments

*Allow me to thank you for being part of this wonderful sports medical book family. I cherish the privilege to have partnered with you to blend science with practice.*

This page allows us to say 'thank you'. We open with a quote from one of our chapter authors because it captures the spirit of the large and diverse team that has created Volume 1 of this fifth edition of *Clinical Sports Medicine*. Every single colleague went beyond the call of duty during their busy lives at the peak of great careers.

This highlights that the global sports medicine and sports physiotherapy community is generous and patient focused. Our community shares the wonderful compelling goal of making life better for athletes and for recreational individuals. We share a passion: the joy of physical activity, the love of sport, the conviction that these are elements of medicine at its very best. Here we say 'thank you' to every contributor for allowing us to guide your passion into these pages and the digital elements that complement them.

On the topic of professions in our field, please indulge us a personal note from two medical doctors. To leaders in physiotherapy/physical therapy, we thank you for having embraced the value of physical activity and sport from your profession's beginnings. Physiotherapy/physical therapy has established a very substantial evidence base, along with other disciplines, so that our field—sport and exercise medicine—is recognised as a critical pillar in health. The PEDro database is just one example we can point to if people ask 'What is the scientific basis of the field?' Your profession has been generous to us personally by educating us, and by welcoming us to share our humble opinions with you. We are honoured and grateful to the President of the World Confederation for Physical Therapy for reading this edition and vouching for its value in the foreword and on the back cover. Dr Emma Stokes, we salute you and wish you every success as you execute a shared vision for a very proud, difference-making profession.

Specific thanks for this edition of *Volume 1—Injuries* go to chapter co-authors listed, with their affiliations, on pages xxx-xxxv. We are both humbled and privileged to be sharing cover authorship with seven amazing colleagues and friends: Ben Clarsen, Jill Cook, Ann Cools, Kay Crossley, Mark Hutchinson, Paul McCrory and Roald Bahr. Vicky Earle, our medical illustrator, is part of this book's DNA (three editions now).

The University of British Columbia (Department of Family Practice—Faculty of Medicine, as well as the Faculty of Education—School of Kinesiology) provided essential support (KK), as did La Trobe University in establishing the Sport and Exercise Medicine Research Centre.

We have passed the silver anniversary of McGraw-Hill writing a snail-mail letter to Peter Brukner in 1990 wondering if he thought a sports medicine book might be in order; we are very fortunate for more than 25 years of remarkable support. Nicole Meehan and Robert Ashworth are passionate about this book. Isabella Mead and Yani Silvana always reached out with offers of help. The copy-editing team have added great value for the reader.

We dedicate this fifth edition to the *Clinical Sports Medicine* community. We are proud to be in a family of clinicians who are absolutely unwavering in prioritising patient care. Lastly, to our very, very patient friends and families, 'Yes, it is finished (for now)'. Diana and Heather, thank you for the many editions you have shared us with. Let's leave the conversation about the fifth edition of *Volume 2—Exercise Medicine* (for 2018 release) for another day.

# Guided tour of your book

The principal text in its field, this first volume of the fifth edition of *Clinical Sports Medicine* continues to provide readers with quality up-to-date content. The engaging material has been contributed by leading experts from around the world. Look out for these key features, which are designed to enhance your learning.

## Premium, up-to-date content

Treatment and rehabilitation is emphasised. Part A—Fundamental Principles includes 12 chapters that are either brand new or written by new authors.

The chapters in Part B, which address regional problems, provide clinical solutions via clear text, abundant clinical photos (e.g. physical examination), relevant imaging and customised medical illustrations.

## Tables

New tables summarise vast amounts of evidence to provide take-home messages. Primary sources are readily available.

**Table 36.6c** Remote factors that can contribute to patellofemoral pain syndrome and their possible mechanisms—increased knee valgus/tibial external rotation

Increased apparent knee valgus/tibial external rotation	Possible contributing factors	Confirmatory assessments
	Structural: <ul style="list-style-type: none"> <li>• genu varum</li> <li>• tibial varum</li> <li>• coxa varum</li> </ul>	Radiographic: <ul style="list-style-type: none"> <li>• long leg X-ray</li> </ul> Clinical assessment: <ul style="list-style-type: none"> <li>• goniometer/inclinometer</li> </ul>
	Inadequate strength/control: <ul style="list-style-type: none"> <li>• hip external rotators</li> <li>• hip extensors</li> <li>• hip abductors</li> <li>• quadriceps</li> <li>• hamstrings</li> <li>• lumbopelvic muscles</li> </ul>	Clinical assessment: <ul style="list-style-type: none"> <li>• manual muscle test</li> <li>• hand-held dynamometer</li> <li>• biofeedback</li> </ul>
	Altered movement patterns	Biomechanical/gait assessment (Chapter 8): <ul style="list-style-type: none"> <li>• can the patient correct the movement pattern when asked to focus on it?</li> </ul>

## Practice Pearl

**Practice pearls** are a valuable feature that provide clinical tips and important information to keep in the forefront of your mind.

### PRACTICE PEARL

In the large majority of these hamstring strains, the injured muscle is the biceps femoris (reported as 76–87%). Semimembranosus injury is uncommon; semitendinosus injury is rare.

## Contributors

The 121 **world-renowned contributors** bring a truly global perspective to the book.

### Editors

**Ben Clarsen** PT, MSc, PhD  
Specialist sports physiotherapist,  
Norwegian Olympic Training  
Centre (Olympiatoppen),  
Postdoctoral Research Fellow,  
Oslo Sports Trauma Research  
Center, Norwegian School  
of Sport Sciences; Team  
Physiotherapist, London Olympic  
Games 2012, UCI Road Cycling  
Professional Tour 2005–07, UCI  
World Road Cycling Championships 2004–12.

**Mark R Hutchinson**  
MD, FACSM  
Professor of Orthopaedics and  
Sports Medicine and Head  
Team Physician, University of  
Illinois at Chicago, Chicago,  
Illinois; Volunteer Team  
Physician, United States,  
Olympic Games, Rio de  
Janeiro, 2016.

PART A

# Fundamental principles

# Sport and exercise medicine: the team approach

with PAUL DIJKSTRA and STEFANO DELLA VILLA

*You may have the greatest bunch of individual stars in the world,  
but if they don't play together, the club won't be worth a dime.*

Babe Ruth (1895-1948)

Sport and exercise medicine (SEM) is evolving as a specialist medical discipline that includes a variety of tasks and responsibilities.<sup>1-7</sup> These include:

- injury and illness prevention
- injury diagnosis, treatment and rehabilitation
- management of medical problems
- performance enhancement through training
- nutrition and psychology
- exercise prescription in health and in chronic disease states
- exercise prescription in special subpopulations
- medical care of sporting teams and events
- medical care in situations of altered physiology, such as at altitude, environmental extremes, or at depth
- dealing with ethical issues, such as the problem of drug abuse in sport.

SEM has been defined as the scope of medical practice that focuses on:

1. prevention, diagnosis treatment and rehabilitation of injuries that occur during physical activity
2. prevention, diagnosis, and management of medical conditions that occur during or after physical activity
3. promotion and implementation of regular physical activity in the prevention, treatment and rehabilitation of chronic diseases of lifestyle.<sup>8</sup>

Because of the growing breadth of content, SEM traditionally lends itself to being practised by a multidisciplinary team of professionals with specialised skills who provide optimal care for the athlete and improve each other's knowledge and skills. The sporting adage that a 'champion team' would always beat a 'team of champions' applies to sport and exercise medicine. This team approach

can be implemented in a multidisciplinary SEM clinic or by individual practitioners of different disciplines collaborating by cross-referral. However, the real-world application of this multiskilled team approach poses significant challenges—some of which are eloquently dealt with by the specialist SEM physician. SEM is now an official medical specialty in many countries and this has significantly changed the level of care to athletes and also patients suffering from chronic disease.

## THE SEM TEAM

The most appropriate sports medicine team depends on the setting. Clubs and sporting bodies increasingly employ specialist SEM physicians, with the primary role being the comprehensive health management of the athlete to facilitate optimal performance. This includes the diagnosis and treatment of injuries and illnesses associated with exercise to ultimately improve performance. In an isolated rural community the sports medicine team may consist of a family physician or a physiotherapist/physical therapist alone. In a populous city, the team may consist of a number of clinicians and sports scientists working together and may include:

- specialist SEM physician
- family physician
- physiotherapist/physical therapist
- soft tissue therapist
- exercise specialist for exercise prescription
- other medical specialists with an interest in SEM
- orthopaedic surgeon, rheumatologist, radiologist, cardiologist, etc.
- podiatrist
- dietitian/nutritionist

- psychologist
- sports trainer/athletic trainer
- other professionals such as osteopaths, chiropractors, exercise physiologists, biomechanists, nurses, occupational therapists, orthotists, optometrists
- coach
- fitness adviser.

In the Olympic polyclinic, an institution that aims to serve all 10 000 athletes at the games, the sports medicine team includes 160 practitioners (Table 1.1).

### Multiskilling, roles, responsibilities and communication

There are, of course, distinct differences in roles and responsibilities when clinicians are employed by sporting organisations or clubs as opposed to providing care in the form of a once-off expert opinion for a specific athlete's injury or illness. Equally, medical teams contracted by the

local organising committees (LOCs) of smaller or major events have very specific roles and skills depending on the size of the event. Multiskilling, where practitioners in the team each develop skills in a particular area of sports medicine, is important but may also pose challenges in areas of considerable amount of overlap between the different practitioners. The key is always effective teamwork with clear roles and responsibilities, leadership and communication. This 'multiskilling' might be of use if the practitioner is geographically isolated or is travelling alone with sporting teams.

The concept of effective teamwork is best illustrated by example. When an athlete presents with an overuse injury of the lower limb, the specialist SEM (or other physician) will have the diagnostic responsibility but the sport-specific therapist, podiatrist or biomechanist might have a better knowledge of clinical biomechanical assessment, the functional relationship between abnormal biomechanics and the development of the injury and how to correct any biomechanical cause. However, it is essential that all the practitioners have a basic understanding of lower limb biomechanics and are able to perform a clinical assessment.

Similarly, for the athlete who presents complaining of excessive fatigue and poor performance, the dietitian is best able to assess the nutritional state of the athlete and determine if a nutritional deficiency is responsible for the patient's symptoms. However, other practitioners such as the SEM physician, physiotherapist/physical therapist or trainer must also be aware of the possibility of nutritional deficiency as a cause of tiredness and be able to perform a brief nutritional assessment.

### The sport and exercise medicine model

The model for the delivery of effective healthcare is changing with an increased focus on individualised medical care and case managing. The traditional medical model (Fig. 1.1) has the physician as the primary contact practitioner with subsequent referral to other medical and paramedical practitioners. The early SEM model (Fig. 1.2) is different. The athlete's primary professional contact is often with a physiotherapist/physical therapist; however, it is just as likely to be a trainer, SEM physician or soft tissue therapist. It is essential that all practitioners in the healthcare team understand their own strengths and limitations and are aware of who else can improve management of the patient.

This improved SEM model recognises the multidisciplinary nature of the athlete's 'primary professional contact' but still emphasises the reductionist approach, with each discipline potentially operating

**Table 1.1 The clinical team structure at the London 2012 Olympic Games polyclinic**

Administration/organisation
<ul style="list-style-type: none"> <li>• Chief Medical Officer</li> <li>• Deputy Chief Medical Officer and Chief Athlete Services (sports physician)</li> <li>• Director of Clinical Services—polyclinic (sports physician)</li> <li>• Director of Nursing</li> <li>• Director of Physiotherapy/Physical therapy</li> <li>• Director of Remedial Massage</li> <li>• Director of Podiatric Services</li> <li>• Director of Dental Services</li> <li>• Director of Emergency Services</li> </ul>
Consulting
<ul style="list-style-type: none"> <li>• Medical practitioners: sports physicians; orthopaedic surgeons; general practitioners; rehabilitation specialists; emergency medicine specialists; ear, nose and throat specialists; gynaecologists; dermatologists; ophthalmologists; ophthalmic surgeons; radiologists; amputee clinic physicians; spinal clinic physicians</li> <li>• Physiotherapists/Physical therapists</li> <li>• Soft tissue therapists</li> <li>• Podiatrists</li> <li>• Optometrists</li> <li>• Pharmacists</li> <li>• Dentists</li> <li>• Interpreters</li> </ul>

**Figure 1.1** The traditional medical model

in its own specialist silo with little focus on holistic athlete health management, effective communication integration and understanding to facilitate decision making. The athlete and coach are often ill equipped to integrate the different contributions in these settings of increasing complexity and multispecialists. They often rely on expert case managers with a very good sport-specific understanding (in big teams the specialist SEM physician) to provide 'health leadership', effectively and efficiently communicating and integrating the contributions of all the key role players in the so-called *integrated performance health management and coaching model*.<sup>9</sup> This new model emphasises the importance of an integrated approach in communication and management to athlete health problems. The focus is on operational integration of the health management and coaching to improve performance with one accountable 'case manager'.

## THE CHALLENGES OF MANAGEMENT

The secret of success in SEM is to take a broad view of the patient and his or her problem. The narrow view may provide short-term amelioration of symptoms but will ultimately lead to failure. Examples of a narrow view may include a runner who presents with shin pain, is diagnosed as having a stress fracture of the tibia and is treated with rest until pain-free.

Although it is likely that in the short term the athlete will improve and return to activity there remains a high likelihood of recurrence of the problem on resumption of activity. The clinician must always ask 'Why has this injury/illness occurred?' The cause may be obvious, for example, a recent sudden doubling of training load, or it may be subtle and, in many cases, multifactorial.

The greatest challenge of SEM is to identify and correct the cause of the injury/illness. The runner with shin pain arising from a stress fracture may have abnormal biomechanics, inappropriate footwear, had a change in the training surface, or a change in the quantity or quality of training. In medicine, there are two main challenges: diagnosis and treatment. In SEM it is necessary to diagnose both the problem and the cause. Treatment then needs to be focused on both these areas.

## Diagnosis

Every attempt should be made to diagnose the precise anatomical, pathological and functional cause of the presenting problem. Knowledge of anatomy (especially surface anatomy) and an understanding of the pathological and functional processes likely to occur in athletes often permits a precise diagnosis. Thus, instead of using a purely descriptive term such as 'shin splints', the practitioner

**Figure 1.2** The SEM model. In professional sport the player's agent also features prominently in athlete-coach interaction

should attempt to diagnose which of the three underlying causes it could be—stress fracture, chronic compartment syndrome or periostitis—and use the specific term. Accurate diagnosis guides precise treatment.

Some clinical situations do not allow a precise anatomical and pathological diagnosis. For example, in many cases of low back pain, it is clinically impossible to differentiate between potential sites of pathology. In situations such as these it is necessary to establish a functional diagnosis, monitor symptoms and signs through careful clinical assessment and correct any abnormalities present (e.g. hypomobility) using appropriate treatment techniques.

As mentioned, diagnosis of the presenting problem should be followed by diagnosis of the cause of the problem. American orthopaedic surgeon Ben Kibler coined the term 'victim' for the presenting problem and 'culprit' for the cause.<sup>10</sup> Diagnosis of the cause often requires a good understanding of biomechanics, technique, training, nutrition and psychology. Just as there may be more than one pathological process contributing to the patient's symptoms, a combination of factors may cause the problem.

As with any branch of medicine, diagnosis depends on careful clinical assessment, which consists of obtaining a history, physical examination and investigations. The most important of these is undoubtedly the history but, unfortunately, this is often neglected. It is essential that the sports clinician be a good listener and develop skills that enable him or her to elicit the appropriate information from the athlete. Once the history has been taken, an examination can be performed. It is essential to develop examination routines for each joint or region and to include in the examination an assessment of any potential causes.

Investigations should be regarded as an adjunct to, rather than a substitute for, adequate history and examination.<sup>11</sup> The investigation must be appropriate to the athlete's problem, provide additional information and should only be performed if it will affect the diagnosis and/or treatment.

## Treatment

Ideally, treatment has at least three components: discussing the planned treatment with the athlete, coach and key role players (also in the context of the immediate and future performance goals); treatment of the presenting injury/illness; and treatment to correct the cause. Generally, no single form of treatment will correct the majority of SEM problems. A combination of different forms of treatment will usually give the best results.

Therefore, it is important for the clinician to be aware of the variety of treatments and to appreciate when their use may be appropriate. It is also important to develop as many treatment skills as possible or, alternatively, ensure access to others with particular skills. It is essential to evaluate the effectiveness of treatment constantly. If a particular treatment is not proving to be effective, it is important firstly to reconsider the diagnosis. If the diagnosis appears to be correct, other treatments should be considered.

## Meeting individual needs

Every patient is a unique individual with specific needs. Without an understanding of this, it is not possible to manage the athlete appropriately. The patient may be an Olympic athlete whose selection depends on a peak performance at forthcoming trials. The patient may be a non-competitive business executive whose jogging is an important means of coping with the stress of everyday life. The patient may be a club tennis player whose weekly competitive game is as important as a Wimbledon final is to a professional. Alternatively, the patient may be someone to whom sport is not at all important but whose low back pain causes discomfort at work.

The cost of treatment should also be considered. Does the athlete merely require a diagnosis and reassurance that he or she has no major injury? Or does the athlete want twice-daily treatment in order to be able to play in an important game? Treatment depends on the patient's situation, not purely on the diagnosis.

## THE COACH, THE ATHLETE AND THE CLINICIAN

The relationship between the coach, the athlete and the clinician is shown in Figure 1.3. The clinician obviously needs to develop a good relationship with the athlete. A feeling of mutual trust and confidence would lead to the athlete feeling that he or she can confide in the clinician and the clinician feeling that the athlete will comply with advice.

As the coach is directly responsible for the athlete's training and performance, it is essential to involve the

**Figure 1.3** The relationship between the coach, the athlete and the clinician

coach in clinical decision making. Involving the coach in the decision-making process is essential for athlete compliance. The coach will also be a valuable aid in supervising the recommended treatment or rehabilitation program. Discussion with the coach may help to establish a possible technique-related cause for the injury. Unfortunately, some coaches have a distrust of clinicians; however, it is essential for the coach to understand that the clinician is also aiming to maximise the performance and health of the athlete. When major injuries occur, professional athletes' agents will also be involved in discussions. It is therefore crucial that clinicians understand the performance environment and develop skills in communication and management to complement optimal decision making in challenging situations.

## 'LOVE THY SPORT' (AND PHYSICAL ACTIVITY!)

To be a successful SEM clinician it is essential to be an advocate for physical activity. A good understanding of a sport confers two advantages. First, if the clinician understands the physical demands and technical aspects of a particular sport, this will improve his or her understanding of possible causes of injury and facilitate development of sport-specific rehabilitation programs. Second, it will result in the athlete having increased confidence in the clinician. The best way to understand the sport is to attend training and competition and ideally to participate in the sport. Thus, it is essential to be on site, not only to be available when injuries occur, but also to develop a thorough understanding of the sport and its culture.

### The case manager approach

**The Isokinetic group of sports medicine clinics in Italy and the United Kingdom adopt the case manager approach to rehabilitation of the injured athlete. Here the group's founder, sports physician Dr Stefano della Villa, explains the Isokinetic philosophy.**

The final result of our job, as a sport physician, is when the athlete is able to play again; as fast, as strong and as powerful as before. Everything in the middle is just a ring in the chain. Despite everyone being aware of this, in real life the situation is completely different.

Most of the time, sports physicians are unable to follow the patient during the long process from injury to return to play. A long list of practical issues may become obstacles along the way, including:

- the length of the process, especially if it is post-surgery
- the number of professionals involved, from the surgeon to the team coach and all those in the middle
- logistical issues during the recovery process—the needs of the patient during recovery to use different facilities and environments such as consultation rooms, gyms, pools and pitches, all of which may well be located in different areas
- pressure from the outside—family, friends, agent, manager, other players, coaches, fitness team, traditional media and social media.

In my opinion, this long list is not the biggest obstacle to overcome. That obstacle is our way of thinking as doctors. The key is to change this paradigm: we need to forget the injury and to re-focus on the recovery from the first moment after the injury. We must do it, from the very beginning, when we explain the recovery process to the patient.

#### Medical training and its influence

Studying at university does not help the sports physician to follow the approach described above. During our time at university we learn a lot about anatomy and symptoms of diseases. The real challenge for a student is to be prepared and ready to make the right diagnosis. However, the right diagnosis does not have value without a strategy to ensure the patient returns to sport. The right diagnosis is crucial, but it is only the first step. Then the process begins and the patient goes through different steps, such as in the following example of an injury that requires surgical treatment:

- imaging
- surgical procedure
- pain management and prevention of deep venous thrombosis
- post-surgical protocols
- recovery of activities of daily living (ADL)
- recovery of range of motion
- recovery of strength
- recovery of coordination and proprioception
- recovery of match fitness
- restoration of specific sports skills
- prevention of re-injury.

We believe the sports physician should always be in charge and control all of these steps (Fig. 1.4). This, however, is not what happens in the sports medicine community. Apart from a few examples in professional sports, most of the time responsibility is shared during the recovery process, without central coordination. In the end this means that no one person is responsible. Many professionals are involved in this process, as it must be, but each of them is focused only on

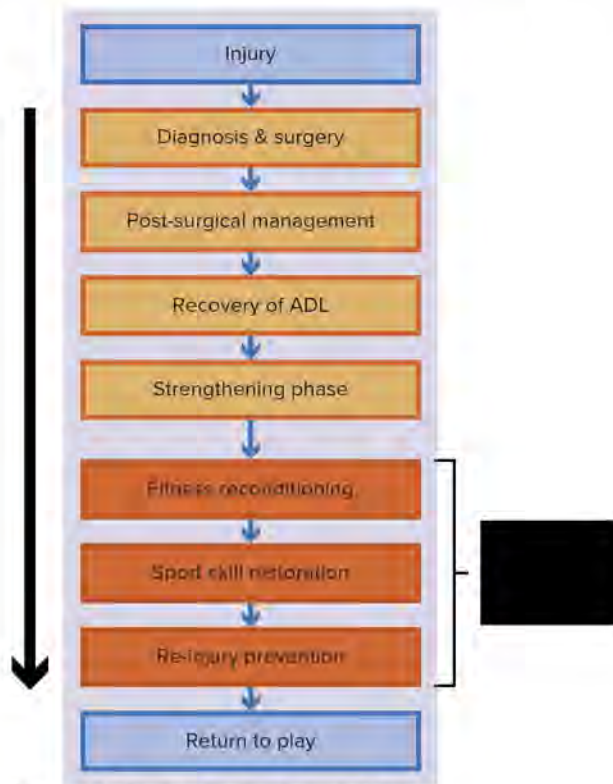

Figure 1.4 From injury to return to play

their single job and there is a need for a leader to coordinate all of them.

#### The case manager concept

We believe that the management of sports injuries can be visualised like a symphony. Many musicians are involved, but they need a conductor—a director of the orchestra. This person is able to deal with the first violin and all the other elements. Based on our experience, our medical group has defined this role as that of the ‘case manager’—the manager of each specific patient and their recovery from injury.

We strongly believe in the concept ‘patient first’ and we put the patient at the centre of our attention. We also understand that after a bad injury the patient needs a project, a plan and a conductor who is able to drive them through the potentially long recovery process.

#### The facilities for the sports recovery process

Utilising this new approach, sports physicians should always be a step ahead in the process. During the diagnosis process they must look ahead to the next possible steps. They need to have a vision of the future for the patient and understand where there could be obstacles on the road to recovery. They need to anticipate problems but, more importantly, consider

when there will be key decision points. This will include the times when the path and speed of the recovery can change, such as the options for surgery and the surgeon. Both before, and at the time of, the surgery they must plan the post-surgical management, right up to completion of the final phase. This can include seeking activities that may ordinarily appear in a future phase of rehabilitation and bringing them forward to operate in parallel with earlier phase activities. An example might be using a pool early to maintain cardiorespiratory fitness, while working to regain strength in the injured limb. Therefore, having the appropriate facilities is a first and major step in planning effective rehabilitation.

We believe for an athlete to fully complete their rehabilitation, they need access to a proper facility consisting of medical offices, rehabilitation gyms, rehabilitation pools and sports fields. The use of these specific areas at well-defined moments in the pathway is critical for the best functional outcome. For example, using a pool-based environment allows the early introduction of sport-specific movement patterns, such as kicking or heading in football (Fig. 1.5).

These exercises will be introduced again in the later phases, both in the gym and on the field, creating a type of continuum in the recovery process. It is a form of stimulation

**Figure 1.5** Neuroplasticity exercises in the pool. Heading a football with partial-body submersion allows safe football-specific movement patterns while in the early phases of rehabilitation

and is thought to favour the re-education of motor skills. In fact, after the injury there may be a process of joint de-efferentation and central disorganisation. The early introduction of some complex stimuli is recommended to solve neuromuscular impairments.

The rehabilitation gym is still considered the main rehabilitation area. Aside from the classical range of motion and strength exercises, it is useful and important to introduce more neuromuscular exercises. These exercises should not only consider the affected joint, but also the whole kinetic chain and the biomechanical connection among different joints.

According to our philosophy, we progressively introduce sport-specific movements on a real sports field, to better restore players' self-confidence in a supervised environment. The on-field rehabilitation (OFR) offers three main advantages: the complete recovery of specific movement patterns, metabolic reconditioning and a real education of the athlete in prevention strategies.

#### Teamwork and communication

With regard to the sports medicine team, we think it should at least consist of a sports medicine physician, a physical therapist and a conditioning specialist. Together they follow the player from injury to return to play.

The final key point of a good strategy is to have a shared working method within the clinical team. Within our philosophy the physician should act as the case manager. He or she is in charge of controlling the process, from the beginning to the end, communicating regularly and coordinating the team around the patient, and planning a customised protocol. Having a strong and consistent communication model within the team is critical for success. Frequent clinical updates are important to constantly monitor patient's improvements and solve eventual complications. In fact, the strength of a sports medicine group has to be measured in the management of difficult cases, when both logistical considerations and clinical skills are required.

## Chapter 2

# Integrating evidence into shared decision making with patients

with STEVEN J KAMPER and CATHERINE SHERRINGTON

*Incredibly, some scientifically educated medical school graduates still see evidence as inferior to intuition and experience: those are the ones who give me chills.*

Dr Harriet Hall

### Case: introduction

Your patient is Mrs J, a 55-year-old woman with knee pain. She complains of pain, stiffness and mechanical symptoms consistent with a meniscal tear. She has had an X-ray in which the radiologist notes degenerative changes consistent with osteoarthritis.

#### Question

Should you recommend surgical or non-surgical management?

to junior clinicians and personal clinical experience weighed more heavily than quality research evidence. We acknowledge that many clinicians provided wonderful evidence-based practice before the term 'evidence-based practice' was coined.

Today, healthcare systems and consumers expect practice to be grounded in science. This mirrors the progression to today's technology-supported world from a society based on semi-mystical beliefs and paternalism. EBP, however, asks more than just acceptance of a scientific world view; it requires explicit understanding and integration of the three elements.

### WHAT IS EVIDENCE-BASED PRACTICE?

Evidence-based practice (EBP), also known as evidence-based medicine (EBM), is the dominant paradigm under which healthcare professionals across the world are now expected to practice. We use the term 'practice' to avoid the ambiguity in the word 'medicine' (which is sometimes used to refer only to the work of medical doctors). Clinicians and researchers from McMaster University in Canada in the 1980s and 90s are credited with developing the ideas behind EBP and championing the movement. The most commonly used definition comes from David Sackett<sup>1</sup> and it highlights the integration of three elements: best available evidence from well-conducted and relevant scientific research, clinical expertise, and patient values and preferences<sup>2</sup> (Fig. 2.1).

Evidence-based practice should provide better patient outcomes than so-called 'eminence-based practice' whereby the opinion of the clinician alone defines an optimal management decision. In the caricature of eminence-based practice, inappropriate and outdated methods and practices were perpetuated from senior

*'Evidence-based practice' is the integration of best research evidence with clinical expertise and patient values—David Sackett*

**Figure 2.1** Schematic illustration of how clinical skills, evidence from research and patient desire should overlap to provide the 'quality decision' for the patient \*evidence-based practice

## WHY IS THE EVIDENCE-BASED PRACTICE CONCEPT CONTROVERSIAL?

Superficially, the principles of EBP are straightforward and few argue that it represents a superior model to a paternalistic opinion-based medical model. In general, clinicians have positive attitudes towards EBP. Yet debate over the merit of EBP occupies space in numerous high-profile medical journals. In particular, there is contention when research evidence conflicts with clinical opinion that is based on observation and recall of patient outcomes.

### PRACTICE PEARL

To accept the primacy of relevant high-quality research evidence requires acceptance of the flawed nature of one's own observations and recollections.

Also, engagement with EBP requires the clinician to be continually up-to-date as new scientific evidence emerges. This represents a substantial, perpetual commitment when compared to the alternative of basing decisions only on one's clinical expertise and prior academic training.

Many critics of EBP accuse its practitioners of focusing only on research results. This is an inappropriate criticism of EBP because EBP by definition integrates the best available research evidence *with* clinical expertise to guide treatment of individual patients.

### PRACTICE PEARL

All three elements of EBP (not one alone), guide the final informed and shared decision about the treatment course.

## CHALLENGES TO EBP

Four barriers facing clinicians who embrace EBP are:

- lack of access to digestible evidence
- inadequate skills to appraise and interpret published research<sup>3, 4</sup>
- limited patient understanding of clinical issues—health literacy
- lack of time to address the above.

A lack of access to research, inadequate computer and internet services, and the inability to locate and retrieve

articles may become less problematic with time. Clinicians' self-perceived inability to locate, appraise, synthesise and integrate research into practice reflects limitations in their training. As a newcomer to the curriculum, EBP is squeezed in behind the established curriculum. Of course, it should be naturally integrated into all clinical teaching and supplemented with formal training in technical issues such as performing or interpreting meta-analysis. As with all elements of clinical practice, 'time' limits clinicians in accessing evidence, synthesising evidence to plan best practice, and in sharing all the evidence with the patient in a 10, 20 or even 30-minute consultation. We stress that 'shared decision making' means that patient scheduling must include time for the patient to truly engage, consider and discuss the options.

## IMPLEMENTING EBP

Here we outline some first steps and resources<sup>2, 5, 6</sup> for clinicians aiming to follow EBP guidelines.

### Accessing research

Continuously updated and freely available databases including the Physiotherapy Evidence Database (PEDro), PubMed and the Cochrane Library index health and medical literature. Their search interfaces are intuitive. These resources can be accessed via personal computers as well as tablet and mobile devices. Designing and carrying out searches of these databases is a particular skill in itself, but one that is easily learned using these free websites and their 'help' resources.

The PubMed database cites more than 24 million references in all areas of biomedicine and it provides free access to abstracts. Its 'clinical queries' feature can greatly assist in locating relevant articles ([www.ncbi.nlm.nih.gov/pubmed/clinical](http://www.ncbi.nlm.nih.gov/pubmed/clinical)).

The Physiotherapy Evidence Database (PEDro) indexes more than 30 000 clinical practice guidelines, systematic reviews and randomised controlled trials (RCTs) relevant to physiotherapy.<sup>6</sup> Two important features of PEDro are its specificity to physiotherapy research and study design, which means that searches are more likely to find relevant studies and the methodological quality rating of all RCTs via the PEDro scale.

The Cochrane Library houses carefully conducted systematic reviews that provide the most robust evidence related to the effectiveness of interventions and diagnostic tests. Cochrane reviews are all conducted according to rigorous standards and processes to ensure maximum reliability of results. Cochrane reviews are freely accessible from all IP addresses within the countries that pay a subscription fee, as well as in developing countries.

### Case: eminence-based practice

You ask a senior colleague for advice regarding Mrs J. He has seen lots of these cases and says that Mrs J. needs to get her meniscus sorted out with an arthroscopy, the sooner the better.

## Retrieving articles

While databases such as PEDro and PubMed provide the article abstract, this is rarely enough to appraise the reliability and applicability of a study so it is necessary to access the full text. A recent change in scientific publishing toward the 'open-access model', comes with a trend toward increasing availability of free, full-text versions of articles. This is likely to increase in the future. Currently, research articles are freely available from large general medical journals such as the *British Medical Journal* and specialty journals published by the BioMed Central (BMC) and Public Library of Science (PLOS) groups, among others. Some other individual journals make selected content or material greater than one year old freely available. An index of freely available journals can be found at [www.freemedicaljournals.com](http://www.freemedicaljournals.com). Clinicians working in universities or large hospitals will have access to the full text articles of journals for which their institution pays a subscription fee and some professional associations pay subscription fees to relevant journals so that content is available to members.

## Published appraisals

In addition to complete reports of original research studies, some journals publish short summaries, including critical appraisal of studies published elsewhere. These include the *British Journal of Sports Medicine*, *Evidence-based Medicine* and the *Journal of Physiotherapy*. The Cochrane Library also includes lay-language summaries of their systematic reviews. The advantage of these short summaries is that the quality of the study and reliability of the evidence is appraised and reported along with the findings themselves.

## Interpreting research about treatment effects

The top level of evidence for questions regarding the effectiveness of an intervention comes from a systematic review of RCTs; evidence from an individual RCT occupies the level underneath (Fig. 2.2). Systematic reviews of RCTs provide the highest level of evidence<sup>1, 2, 5</sup> because a well-designed and conducted RCT design overcomes many of the sources of bias associated with other study types; appropriate synthesis of the findings of all available RCTs relevant to a particular question gives the most accurate estimate of the size of the treatment effect. However, the strength of the evidence depends on the number and quality of the RCTs in the systematic review.

Why prioritise RCTs over case series or observational studies when it comes to determining the effect of treatment? The key issue with observational studies is that

**Figure 2.2** Hierarchy of evidence about the effects of treatment

we do not know what would have happened to patients if they received a different treatment or no treatment at all. It is also not enough to compare the response to treatment in one study with the response to another treatment (or no treatment) in another study, as there may be important unmeasured differences between the two samples.

## Risk of bias

All research studies are not created equal; some are more likely to give a reliable answer to the question than others.<sup>5, 6</sup> All RCTs indexed on the PEDro database are rated for

### Case: initial search

A search of the Cochrane Library using the words 'knee and arthritis' returns 33 records. One is a Cochrane systematic review titled 'Arthroscopic debridement for knee osteoarthritis' published in 2008. The authors conclude that debridement is no different to sham surgery (based on one RCT) and no different to arthroscopic lavage (two RCTs).

### Case: second search

You recognise that the systematic review is a bit old and not completely specific to patients with meniscal pathology, so you look further. A search of PEDro using the keywords 'arthritis and surgery' specifying the method 'clinical trial' and the body part 'lower leg or knee' returns 10 studies. One is an RCT titled 'Surgery versus physical therapy for a meniscal tear and osteoarthritis', from 2013. The authors found that there was no difference between the meniscectomy group and the physiotherapy group in terms of pain and disability at 6 months.

methodological quality. In practice, this means that trained raters have gone through every trial and scored whether it satisfies each of a list of criteria (the PEDro scale) that are reported on the PEDro website. ([www.pedro.org.au](http://www.pedro.org.au)).

The Cochrane risk of bias tool has many commonalities with the PEDro scale and is used to assess the quality of trials in many Cochrane reviews. Each item of the quality scale relates to an issue that could result in biased study results; for each criterion that is not met, the risk that the study results are biased is greater. Examples of items that might bias a study result include:

1. whether the researcher deciding whether patients were included in the study knew to which group they would be assigned (concealed allocation)
2. whether the intervention and control groups were comparable at baseline
3. whether a large proportion of the patients who began in the study remained until follow-up was complete.

## Research about other types of clinical questions

Not all clinical questions relate to the effectiveness of treatments. For example, there are also relevant clinical questions about predicting the likelihood of good or poor outcomes in a patient or about the accuracy of a diagnostic test. These types of questions are fundamentally different to those about the effect of treatment, so it makes sense that the study design is different.

Questions about prediction or risk require that investigators recruit a large group of people who are at the same stage of the disease process. These participants are then followed over time to see who does well and who does not (i.e. a prospective cohort study). The investigators need to measure all the factors that might be relevant in determining the patients' future outcome (e.g. body weight in people with osteoarthritis) and make sure not too many of the participants drop out over the course of the study. A prospective cohort study can be useful to help a clinician provide evidence-based advice to patients about what to expect regarding their recovery.

Questions about diagnosis should be addressed using a study that compares the results of a diagnostic test

### Case: appraisal

Looking at the PEDro scale score for the RCT you find that six of the 10 criteria were met. This indicates moderate quality, but there is the potential for bias due to certain factors, including the lack of blinding of outcome assessors and the fact that randomisation was not concealed. Further, a significant proportion of the patients randomised to the physical therapy intervention later crossed over and received surgery.

### Case: decision

Based on the evidence from the review and the RCT, you are doubtful of the benefits of surgery for Mrs J. You note, however, the moderate quality of the RCT and the issue of crossover and following discussion with Mrs J decide to trial a 2–3 month program of physical therapy prior to reviewing her condition.

(the index test) with the results of an accepted standard for the diagnosis (the reference standard or gold standard), at the same time. For example, a study might compare Lachman's test for anterior cruciate rupture (detailed in Chapter 35) with MRI assessment (reference standard) in the same patients. The accuracy of the reference standard is key to the quality of a diagnostic study.

A second critical design feature of diagnostic studies is that the person performing the index test does not know the results of the reference standard. If the tester knows whether or not the patient has the condition it may bias their interpretation of the index test. So in the example, the person performing the Lachman's test should not know the results of the MRI assessment.

A final important feature concerns how the patients in the study sample are assembled. Ideally, all the patients in the sample should represent those that present for care, which means that diagnosis is unknown before the test is performed. The Cochrane Library now includes systematic reviews of diagnostic test studies.

# Sports injuries: acute

with STUART WARDEN

*After feeling discomfort in my hamstring after the first round last night and then again in the semi-final tonight, I was examined by the Chief Doctor of the National Championships and diagnosed with a grade I tear.*

Usain Bolt, posted on Twitter 6 weeks before the Rio 2016 Olympic Games

Participation in sports and athletic endeavours has well-known health and wellness benefits. Unfortunately, participation is also associated with a risk of injury. Sporting injuries can occur during either competition or training and can affect any type of musculoskeletal connective tissue (Table 3.1). Injury to these tissues may be categorised as being either acute or overuse, based on the mechanism of injury and rapidity of symptom onset. The current chapter discusses acute injuries, whereas overuse injuries are described in the subsequent chapter (Chapter 4).

An acute injury refers to an injury that occurs during a single, identifiable traumatic event. They arise when the force applied to a tissue generates stresses and/or strains that are greater than the tissue can withstand. The net result is tissue failure which generates macroscopic damage and the rapid onset of symptoms, such as pain and loss of function. The severity of the symptoms depends on the tissue injured and the extent of the damage.

Forces applied to a tissue can be derived from either extrinsic (i.e. from outside the body, such as from a direct blow or collision with an external object) or intrinsic (i.e. from inside the body, such as from muscle contractile forces, or joint and tissue biomechanics) sources. Thus, acute injuries are frequently categorised as having extrinsic or intrinsic causes. Knowing the cause of acute injury has implications with regard to injury prevention as extrinsically generated forces may be modified by altering equipment, playing surface or sport rules, while intrinsically generated forces require an individual athlete's characteristics and capabilities to be considered (such as muscle strength, endurance and flexibility, motor control, joint range, biomechanics and proprioception). However, as an acute injury always results in intrinsic changes, an

individual athlete's characteristics and capabilities need to be considered in all instances of acute injury in order to facilitate return to participation and prevent re-injury.

When a force is applied to a tissue, the nature of the force being applied (such as the direction, magnitude and rate of loading) and the mechanical properties of the tissue in the direction of loading determine whether the tissue fails. The latter is determined by a combination of innate (non-modifiable) and environmental (modifiable) factors. Modifiable factors alter the safety factor between usual and injurious loads by either increasing or decreasing genetically endowed tissue strength. Modifiable factors include:

1. previous loading history and subsequent tissue adaptation
2. the presence and degree of any underlying microscopic tissue damage (overuse injury)
3. history of previous acute injury to the tissue and extent of mechanical strength recovery.

## PATHOPHYSIOLOGY AND INITIAL MANAGEMENT

An acute injury initiates a common sequence of preliminary processes, irrespective of the specific tissue injured. Haematoma formation from damaged blood vessels gives way to an acute inflammatory response involving fluid exudation and phagocytosis. Fluid exudation contributes to oedema formation (i.e. swelling) and the delivery of white blood cells to the injured site, while phagocytosis aids the removal of damaged tissue and cellular debris. Swelling occurring within a joint is referred to as an 'effusion' and usually takes place slowly over the course of 12–24 hours. More rapidly occurring joint swelling (e.g. within the first 2–3 hours after injury)

Table 3.1 Classification of sporting injuries

Site	Acute injuries	Overuse injuries
Bone	Fracture (including growth plate) Periosteal contusion	Stress injury (including stress reaction and stress fracture) Osteitis, periostitis Apophysitis, enthesopathy Osteophyte/bone spur
Hyaline cartilage	Chondral/osteochondral injury	Chondropathy (e.g. softening, fibrillation, fissuring, chondromalacia)
Fibrocartilage	Acute tear (including meniscal, labral, and intra-articular and intervertebral discs) Herniation of nucleus pulposus from intervertebral disc	Degenerative tear Herniation of nucleus pulposus from intervertebral disc Chondropathy (e.g. softening, fibrillation, fissuring, chondromalacia)
Joint	Dislocation Subluxation	Synovitis Osteoarthritis/osteoarthritis Instability
Ligament	Sprain/tear (grades I–III)	Inflammation
Muscle	Strain/tear Contusion Cramp Acute compartment syndrome	Chronic compartment syndrome Delayed onset muscle soreness Focal tissue thickening/fibrosis
Tendon	Tear (partial or complete)	Tendinopathy (includes paratenonitis, tenosynovitis, tendinosis and tendinitis)
Fascia	Tear (partial or complete)	Fasciopathy (includes fasciitis and fasciosis)
Bursa	Traumatic bursitis	Bursitis/bursosis
Nerve	Neuropraxia	Entrapment Minor nerve injury/irritation Adverse neural tension
Fat pad	Bruise/contusion	Impingement/irritation
Skin	Laceration Abrasion Puncture wound	Blister Callus

indicates the effusion contains blood (i.e. haemarthrosis) and that an intra-articular structure has been damaged.

The acute inflammatory response to injury stimulates nociceptors to activate pain pathways. Pain is the body's way of protecting the injured site from further damage and leads to muscle inhibition and functional limitation. Muscle inhibition is also influenced by swelling. Reactive muscle spasm serves as an additional protective mechanism to further reduce potentially injurious loading, but also contributes to pain.

The acute inflammatory phase has the goals of protecting the damaged tissue from further injury, preparing the injured site for repair and stimulating the recruitment and activation of reparative cells. The inflammatory phase

is generally thought to persist for 48–72 hours; however, the duration within a particular individual can vary, and can be influenced by the tissue damaged, the severity of the damage and early management. Signs that acute inflammation is persistent include ongoing pain at rest and/or night, prolonged (>30 minutes) morning pain and stiffness and ongoing swelling that changes in volume according to recent activity.

Early management of acute injuries has historically centred on the PRICE acronym, which stands for protection, rest, ice, compression and elevation. Ice, compression and elevation are universally accepted, despite a lack of strong evidence for their efficacy,<sup>1</sup> and are introduced to reduce pain, decrease blood flow and

swelling and slow cellular metabolism to reduce risk of secondary injury (e.g. cell death due to hypoxia).

Similarly, there is general consensus for some degree of protection and rest immediately after injury; however, there is increasing acknowledgement that their duration should be limited due to the known detrimental effects of prolonged immobilisation and unloading of connective tissues. Instead, early loading is being increasingly advocated and shown as an important component of the early management of acute injuries. As a result, there are calls for the PRICE acronym to be changed to POLICE whereby 'rest' is replaced by 'optimal loading' (see Chapter 17).<sup>2</sup>

Optimal loading aims to take advantage of the responsiveness of musculoskeletal tissues to mechanical stimuli. It involves introducing progressive functional loading to stimulate connective tissue synthesis and promote healing, but without causing further damage. Optimal loading is principally guided by pain, with the induction of pain during loading indicating that tissue-level forces are too great for the current level of healing and that the load should be reduced to a pain-free level.

## BONE Fracture

There is a large safety factor between the forces bone is exposed to during athletic activities and the forces required to generate a fracture. In the absence of a bone pathology that is causing generalised or localised bone fragility, large forces are required to fracture a bone. Such forces can result from direct trauma such as a blow or indirect trauma such as an awkward fall or twisting motion.

Traumatic fractures can be dichotomised as either closed (simple) or open (compound). The skin is intact over the fracture site in closed fractures, whereas in open fractures skin integrity is lost, often due to penetration from within by the fractured bone. The presence of a skin wound in open fractures that is continuous with the fracture site enables pathogens to enter and contribute to bone infection. Thus, individuals with an open fracture should be treated with prophylactic antibiotic therapy.

Within the dichotomy of open and closed fractures, fractures can be further classified according to their fracture pattern (Fig. 3.1), location in terms of both the affected bone and the location within that bone, amount and type of displacement of the fractured ends of the bone, and/or the specific name of the fracture. For instance, a Colles' fracture refers to a fracture of the distal radius with dorsal (posterior) and radial displacement of the distal fracture segment, whereas a Smith's fracture also refers to a fracture of the distal radius, but with ventral (anterior) displacement of the distal segment.

The immature skeleton presents some unique fractures because of its lower mineralisation and presence of unfused

**Figure 3.1** Types of fracture (a) Transverse (b) Oblique (c) Spiral (d) Comminuted

secondary ossification centres with interposed growth plates. The lower mineralisation of the immature skeleton makes it more flexible than the adult skeleton and, consequently, susceptible to buckling. When a sufficient bending force is applied to an immature bone the cortex on the side that the bone is bending toward is exposed

to compressive forces and buckles, while the cortex on the opposite side cracks open due to tensile forces. The resultant greenstick fracture is named according to how a green (i.e. fresh) stick buckles and cracks when bent. When the injurious force causes axial compressive loading of an immature bone as opposed to bending, the result can be the development of a torus or buckle fracture characterised by buckling and bulging of the cortex on all sides.

Growth plate fractures in children and adolescents present a particular problem and are discussed in detail in Chapter 43. The most common growth plate fracture is an avulsion fracture. Unfused secondary ossification centres represent an area of relative weakness in the young skeleton. They serve to develop bony prominences, such as tubercles and epicondyles, upon which tendons and ligaments attach. With an appropriate tensile pull from a tendon or ligament, a secondary ossification centre can be pulled away from the rest of the bone at its growth plate resulting in the development of an avulsion fracture. Avulsion fractures can also occur in the adult skeleton when extreme tensile forces at the insertion site of a tendon or ligament pull off a portion of bone.

The primary aim of fracture management is to allow the fracture to heal in the most anatomical position possible so that the mechanical function of the bone can be restored. If the fracture is displaced, it should be reduced to realign the bone fragments back to their anatomical position. A fracture that heals in an abnormal position (i.e. mal-united fracture) can lead to the long-term development of secondary complications, such as osteoarthritis.

Reduction is typically extremely painful and resisted by muscle spasm. Thus, it is usually performed under a short-acting anaesthetic, sedative or nerve block and with muscle relaxants. Once the fragments are reduced, the fracture needs to be held in place to permit fracture gap bridging. The method of stabilisation depends on the stability of the fracture. Stable fractures may be managed with a simple sling, cast or fracture brace, whereas more rigid stabilisation is required for unstable fractures that do not readily maintain their reduced position. Rigid stabilisation may consist of open reduction and internal fixation (ORIF) wherein the fracture site is opened surgically, reduced and fixed using metal plates, rods, screws, pins, and/or wires. ORIF has the advantage of allowing earlier introduction of forces across the fracture site. However, the trade-offs include:

- potential hardware loosening, failure and irritation
- opening the fracture site to the possibility for infection
- excessive stabilisation of the fracture leading to insufficient fragment micromotion and atrophic non-union
- peri-implant fracture resulting from regional osteoporosis due to stress shielding.

In addition to reducing a fracture and providing an environment that is permissive of bone regeneration, it is necessary to assess and monitor for other possible complications of fracture. Infection and mal-union have already been mentioned. Other acute complications that need consideration include acute compartment syndrome (discussed later), associated injuries (e.g. nerve, vessel), deep venous thrombosis/pulmonary embolism, and delayed or non-union.

Soft tissue injury, such as ligament or muscle damage, is often associated with a fracture and may cause more long-term problems than the fracture itself. Thus, it is important to address any concomitant soft tissue injury. Occasionally, deep venous thrombosis and pulmonary embolism may occur after a fracture, especially a lower limb fracture. This should be prevented by early movement and active muscle contraction.

Delayed or non-union of a fracture causes persistent pain and disability, and can be caused by excessive or insufficient fracture site stabilisation, presence of a complicated fracture type (e.g. open or highly comminuted fractures), insufficient or disrupted blood supply (e.g. due to abnormal regional anatomy or the presence of comorbid conditions such as diabetes) and lifestyle factors (e.g. smoking, excessive alcohol intake and poor nutrition), to name a few. Management options for delayed or non-united fractures include non-surgical treatments, such as low-intensity pulsed ultrasound and electromagnetic therapies (Chapter 16), as well as surgical treatments, such as bone graft or bone graft substitute, internal fixation and/or external fixation. In the future, biological compounds and small molecule pharmaceuticals may become available. Specific fractures that are common in athletes are discussed in Part B chapters.

## Periosteal contusion

The periosteum is a dense, fibrous tissue that is firmly attached to the outer surface of bones and is both highly vascular and innervated. At subcutaneous skeletal sites (such as the medial surface of the tibia and iliac crest), the periosteum is susceptible to acute trauma from a direct blow with an external object, such as a ball, stick, opponent or playing surface. The blow damages periosteal blood vessels resulting in the development of a subperiosteal haematoma, otherwise known as a periosteal contusion. The confined space beneath the periosteum limits the spread of the haematoma, occasionally leading to the development of a palpable lump. The raised periosteum is tensed and inflamed/irritated, stimulating its plentiful nociceptive nerve endings to cause considerable pain, especially upon palpation and on contraction of muscles attaching to the injured region.

A periosteal contusion at the iliac crest, often referred to as a 'hip pointer' injury, can be extremely painful because of involvement of the cluneal nerve which runs along the iliac crest. Management of periosteal contusions focuses initially on minimising the extent of the haematoma using conventional first aid approaches followed by a gradual return to activity. Protective equipment (such as shin guards and padding) should be considered for future prevention.

## HYALINE CARTILAGE

### Chondral and osteochondral injuries

Hyaline, or articular, cartilage lines the articular surface of bone regions forming synovial joints. It provides a smooth, lubricated surface allowing for low-friction gliding and possesses unique viscoelastic properties which facilitate the absorption and distribution of loads to the underlying subchondral bone. In fulfilling these roles, hyaline cartilage is principally exposed to compressive loads. Acute joint subluxation or dislocation (discussed below) and acute ligament sprain or rupture (discussed later) can lead to locally high compressive forces and the superimposition of shearing forces due to excessive joint translation. The net result can be development of an acute chondral (cartilage), as shown in Figure 3.2a and b, or osteochondral injury, with the latter involving both the articular cartilage and underlying (subchondral) bone (Fig. 3.2c).

Articular cartilage is radiolucent and therefore most chondral injuries are not visible on conventional radiology. As a result, these injuries have historically been underdiagnosed. With the advent of magnetic resonance imaging and direct visualisation via arthroscopy, it has become clear that chondral injuries are far more common than previously realised. Clinicians must maintain a high index of suspicion for chondral involvement if an apparently 'simple joint sprain' remains painful and swollen for longer than expected, despite the presence of normal X-rays. Common sites for chondral and osteochondral injuries are the femoral condyles, superior articular surface of the talus, capitellum of the humerus and patella.

Chondral injuries are a concern due to their poor healing and their contribution to the development of premature osteoarthritis. Articular cartilage has limited regenerative and repair capacity due to its avascular nature. As larger lesions or defects have lower probability of healing, classification systems have been developed to quantify the severity of chondral damage and guide prognosis. Chondral lesion severity is determined by the depth the injury extends towards the underlying bone and the size of cartilage affected, whereas osteochondral lesion severity is determined by the continuity of the overlying cartilage

**Figure 3.2** The three types of articular cartilage injury

and stability of the lesion. Scales generally extend from 0 (normal) to a high score of 4 (exposed bone for chondral injuries; fragment displacement for osteochondral lesions), with higher scores indicating greater damage and a worse prognosis.

Chondral and osteochondral injuries in young active individuals represent a therapeutic challenge. The goal of treatment is to restore the structural integrity and function of the affected surface so that it can withstand the significant stresses associated with athletic endeavours. The hope is to permit a return to participation while minimising cartilage degeneration and the need for early arthroplasty (joint replacement). Treatment options for chondral injuries range from palliative techniques (such as chondroplasty to smooth loose edges of damaged cartilage and arthroscopic washout to remove debris) to techniques aimed at stimulating

cartilage repair or restoration. Reparative techniques include bone marrow stimulation techniques such as abrasion arthroplasty, drilling and microfracture, whereas restorative approaches include autologous osteochondral mosaicplasty, osteochondral allograft transplantation, and chondrocyte and mesenchymal stem cell-based therapies wherein cells are implanted into the cartilage lesion and covered with a periosteal or collagen-membrane cover. Treatment choice depends upon the size of the chondral or osteochondral lesion, with great debate continuing as to the most effective approach. Ultimately, return to sport depends on a range of factors, including athlete age, duration of symptoms, level of play, repair tissue morphology, lesion size, type and location, and the number of surgeries and concomitant procedures.<sup>3</sup>

## FIBROCARTILAGE

### Acute tear

Fibrocartilage consists of a mixture of fibrous and cartilaginous tissue in varying proportions, which provide it with both toughness and elasticity. Fibrocartilage forms a range of structures in different joints with varying functions, but roles generally include enhancing joint stability, contributing to shock absorption and distribution and promoting joint lubrication. Example fibrocartilage structures include the knee menisci, glenoid and acetabular labrums, triangular fibrocartilage complex (TFCC) at the radio-carpal joint, volar plates of the digits, and articular discs within the acromioclavicular and sternoclavicular joints.

Given the predominantly mechanical roles of fibrocartilage structures in enhancing joint congruency and distributing stresses, it is not surprising that they are at risk of acute injury when excessive forces are introduced. For instance, the knee menisci are at risk when rotation is superimposed onto a flexed and loaded knee, whereas a fall onto an outstretched hand can acutely injure the TFCC at the radio-carpal joint. Joint fibrocartilage structures can be injured in isolation; however, simultaneous injury with associated joint structures (e.g. ligaments and joint capsule) is common due to their close anatomical and mechanical relationships. For instance, it is common for a knee meniscus and the anterior cruciate ligament to be simultaneously injured as they share a common mechanism of injury (i.e. rotating on a flexed and loaded knee). Similarly, during shoulder dislocation it is common for the anterior glenoid labrum to be simultaneously injured with the glenohumeral ligaments and joint capsule due to their anatomical connections and forces being introduced.

Signs and symptoms of acute fibrocartilage injury are region- and injury-specific, but generally include pain and

swelling in the affected joint combined with joint clicking, catching or locking. The latter joint events are often delayed in their presentation, occurring once the initial acute symptoms have subsided and normal use of the joint has recommenced. Joint clicking, catching or locking can contribute to reflex muscle inhibition and the sensation of the joint 'giving way' during load bearing.

Management of acute fibrocartilage injuries depends on the type, size and location of damage. Management options are dichotomised into conservative and surgical, with surgical options including repair, removal and replacement of the damaged fibrocartilaginous structure. Surgery is an option for individuals who have failed to respond to conservative management, but is also frequently used as a first-line management approach, particularly for injuries in regions that have limited healing potential. The latter regions include the relatively avascular zones within the inner two-thirds of the menisci and the central region of the TFCC.

## Herniation of nucleus pulposus from intervertebral disc

Herniation of the nucleus pulposus in athletes most commonly occurs secondary to damage accumulation within the disc in response to repetitive flexion and/or rotational loading. Thus, the vast majority of disc herniations are overuse injuries, despite the onset of symptoms often occurring relatively spontaneously and in response to an apparently trivial loading event. However, it is possible to acutely prolapse or herniate an otherwise healthy intervertebral disc with sufficient compressive and flexion force. This can occur during contact sports when the spine is axially loaded while in a flexed position, such as when driven into the ground when being tackled. The disc may protrude or herniate radially beyond the usual margins of the annulus fibrosis or herniate through the vertebral body endplate into the vertebral body to form a Schmorl's node.

## JOINT

### Dislocation/subluxation

Joint stability depends on the interaction between the passive, active and neural subsystems. Muscles and tendons combine to form the active subsystem, which is controlled by the neural subsystem, to provide dynamic joint stability. When the force applied to a joint exceeds the capabilities of the active subsystem or when the active and/or neural subsystems are compromised, loads are transferred to the passive subsystem. The passive subsystem consists of non-contractile connective tissues, which includes the bony anatomy, joint capsule, ligaments and fibrocartilage joint structures (e.g. labrum, volar plates, menisci).

Excessive load placed on the passive subsystem can cause the bones forming a joint to abnormally translate or luxate relative to one another. When the bones are forced to completely separate so that the articulating surfaces are no longer in contact it is referred to as dislocation (Fig. 3.3a). Subluxation (partial dislocation) refers to when the bones shift relative to one another, but the articulating surfaces remain partially in contact (Fig. 3.3b).

Luxation of a joint invariably results in damage to passive subsystem structures. The structures damaged and extent of damage depends on the direction and magnitude of the luxation force and the inherent stability of the joint created by the passive subsystem. The hip joint is inherently stable because the large ball shape of the femoral head is well encased in a reciprocating socket-shaped acetabulum and the bones are supported by a strong joint capsule that is reinforced by robust ligaments. Thus, considerably more force is required to luxate the hip joint compared to a less stable joint, such as the shoulder.

The shoulder lacks inherent stability because the large humeral head outsizes the small, shallow glenoid fossa and the joint possesses a thin, loose capsule that is minimally supported by ligaments. The heightened force required to luxate inherently stable joints (such as the hip, elbow, ankle and subtalar joints) means that subluxation or dislocation of these joints is more likely to be associated with damage beyond that to the joint capsule and ligaments, including fractures and damage to cartilage, vessels and nerves.

A dislocated joint is readily identifiable by gross deformity with complete loss of joint function. The individual presents with significant, acute pain and often has the afflicted limb cradled or held. Following a neurovascular screen to assess for nerve and blood vessel damage, the dislocated joint should be reduced as quickly as possible. In most cases, this can be performed by applying gradual and controlled

distraction of the joint while simultaneously moving the joint through a passive range of motion. When distraction is unable to overcome the opposing muscle spasm and the joint does not readily reduce, use of an injected muscle relaxant or general anaesthetic may be required.

After reduction, all dislocated joints should be X-rayed for the presence of an accompanying fracture and the joint should be protected to allow the joint capsule and ligaments time to heal. However, early protected mobilisation is encouraged to promote functional healing, and training of the active and neural subsystems should commence as early as possible and progress to functional activities so that these subsystems may compensate for the reduced stability afforded by the damage to the passive subsystem. Unfortunately, in some joints (such as the shoulder), active and neural subsystem training is often insufficient to prevent re-dislocation or chronic subluxation, necessitating eventual surgical reconstruction of the damaged capsule and ligaments.

## LIGAMENT

### Sprain/tear

Ligaments typically span joints to connect articulating bones, and present as either discrete extra-articular structures or thickenings of the joint capsule. Their structure consisting of tightly packed bundles of collagen arranged nearly in parallel along the longitudinal axis of the ligament is designed to resist tensile loads. Ligaments function to provide passive stability and guide what directions of motion are available at a joint. When force is applied to a joint that attempts to move the bones in a direction they are not designed to move, passive tension rises in ligaments on the side of the joint being gapped open. When the load is sufficient, and dynamic joint stabilisation afforded by the active and neural subsystems is insufficient, collagen fibres within ligaments begin to yield resulting in an acute ligament injury (commonly referred to as a 'sprain').

Ligament sprains range in severity from mild injuries involving tearing of only a few fibres to complete tears of the ligament where ligament continuity and its stabilising role is completely lost. Based on the number of fibres torn and the subsequent degree of joint instability, ligament sprains are classified into three grades (Fig. 3.4), each representing an increase in injury severity (Table 3.2).

Management of acute ligament sprains is summarised in Figure 3.5. Initial management consists of first aid techniques to minimise bleeding and swelling (Chapter 17). For grade I and II sprains, subsequent treatment aims to promote tissue healing, prevent joint stiffness, protect against further damage and strengthen muscle to provide dynamic joint stability. Return to sport usually takes place before tissue level healing is complete, with healing of collagen in a partial

**Figure 3.3** Acute joint injury (a) Dislocation (b) Subluxation

**Figure 3.4** Ligament sprains (a) Grade I (b) Grade II (c) Grade III

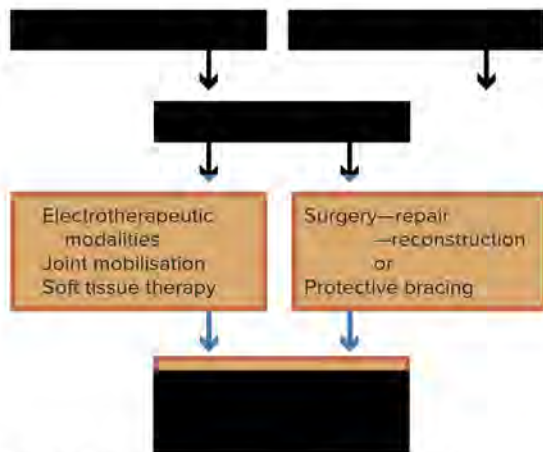

ligament tear taking several months.<sup>4,5</sup> Earlier return to sport is facilitated by the use of bracing or taping to help protect against re-injury. Rehabilitation (especially neuromuscular training) should continue in some form following return

**Table 3.2** Classification of ligament injuries

Grade	Pathology	Clinical findings
I	Disruption of some collagen fibres	<ul style="list-style-type: none"> <li>• Localised tenderness on palpation</li> <li>• Minimal inflammation (swelling)</li> <li>• Normal range and end feel on ligament stress test, but test may be painful</li> <li>• Little functional deficit</li> </ul>
II	Disruption of considerable proportion of collagen fibres	<ul style="list-style-type: none"> <li>• Significant tenderness on palpation</li> <li>• Can be considerable inflammation (swelling) involving the whole joint (effusion)</li> <li>• Increased joint play on ligament stress test (increased ligament laxity), but a definite end point is present</li> <li>• Moderate functional deficit</li> </ul>
III	Complete disruption of all collagen fibres	<ul style="list-style-type: none"> <li>• Audible 'pop' may have been heard at the time of injury</li> <li>• Often immediately painful, but may become pain-free a short time after the injurious event due to simultaneous disruption of nociceptors (pain returns thereafter due to effusion and inflammatory mediators activating alternative nociceptors)</li> <li>• Can be considerable swelling which may occur rapidly due to bleeding into the joint (haemarthrosis)</li> <li>• Significantly increased joint play on ligament stress test with no discernible end point</li> <li>• Significant functional deficit</li> </ul>

to sport as injury risk is heightened, and individuals often have ongoing objective mechanical laxity and subjective instability. For instance, as much as one-third of individuals report ongoing pain and subjective instability one year following acute ankle sprain, while up to a third report at least one re-sprain within a period of 3 years.<sup>6</sup>

The treatment of a grade III sprain may be either conservative or surgical. For example, the torn medial collateral ligament of the knee and the torn lateral

**Figure 3.5** Management of acute ligament sprains

ligament of the ankle may be treated conservatively with full or partial immobilisation. Alternatively, the two ends of a torn ligament can be reattached surgically and the joint then fully or partially immobilised for approximately 6 weeks. In certain instances (e.g. anterior cruciate ligament rupture), torn ligament tissue is not amenable to primary repair and surgical ligament reconstruction may be required (Chapter 35).

During the past few decades, there have been mounting efforts to develop tissue engineering strategies that encourage ligament regeneration (as opposed to repair) so that the final product matches that of native ligament. Strategies have included the use of growth factors, cell-based therapies, gene transfer and therapy, and the use of scaffolding materials of varying origin.<sup>7</sup> While these approaches have shown promise in preclinical studies, translation to clinical populations remains lacking and is required before clinical utility.

## MUSCLE

Muscle injuries are among the most common injuries in sports, accounting for up to half of all sport-related injuries at the elite level. They result from either intrinsic or extrinsic causes, with the former contributing to muscle strains/tears and the latter resulting in contusions.

### Strain/tear

A muscle is strained or torn when excessive tensile and/or shear forces within the muscle cause muscle fibres and their surrounding connective tissue to fail. Muscles consist of a hierarchy of active contractile elements and passive non-contractile connective tissue. The actin and myosin machinery responsible for producing active contractile forces form myofibrils which are housed in elongated, rod-shaped cells called muscle fibres. The cell membrane of the

muscle fibre (i.e. sarcolemma) attaches to a basal membrane surrounded by a connective tissue sheath called the endomysium. Groups of muscle fibres bundle together to form fascicles encased in a connective tissue sheath called the perimysium. The fascicles in turn combine to form the muscle which is surrounded by a final dense sheath of connective tissue called the epimysium.

During muscle contraction, actin and myosin form cross-bridges to generate force, which is transmitted either via the surrounding connective tissue or directly to an attached tendon and subsequently the skeleton, to produce motion. In muscle strains, excessive tensile force results in muscle fibre failure, which ruptures its cell membrane and the basal membrane to which the membrane attaches, damages the surrounding connective tissue sheaths and tears blood vessels contained within the connective tissue sheaths. Depending on the severity of the injury, the net result can be pain on active contraction and passive stretch of the muscle, a reduction in strength due to pain-inhibition, decreased range of motion due to muscle spasm and loss of function.

Muscle strains most commonly occur within the hamstring, quadriceps and gastrocnemius muscles, as these muscles are exposed to the highest amounts of total tension. Total tension is the sum of active tension generated by muscle fibre contractile forces and passive tension due to stretch on the connective tissue components. Active tension can be high in the hamstring, quadriceps and gastrocnemius muscles as these muscles often contract eccentrically and they contain a high proportion of type-II (fast-twitch) muscle fibres—both factors associated with the generation of greater active tension. Passive tension is also often high in these muscles as they are biarthrodial (cross two joints) and are often required to contract while on passive stretch over more than one joint.

To guide prognosis, muscle strains have historically been graded using a three-tiered system, with increasing grade suggesting a greater severity of injury requiring longer recovery.<sup>8</sup> A minor strain causing localised pain but no or minimal loss of strength is referred to as a grade I injury and suggests the involvement of a small number of muscle fibres. A grade II strain involves a greater number of muscle fibres and is clinically evident by greater pain, swelling and loss of strength, while a complete tear of the muscle is classified as a grade III injury. In addition to these three grades, a grade 0 injury has been described wherein an athlete presents with a clinical syndrome of muscle abnormality, but without imaging evidence of pathology.

Grading systems provide an indication of the severity or extent of muscle damage; however, the variable recovery time for individuals with similarly graded injuries suggest that other factors influence prognosis. With advances in magnetic resonance imaging and ultrasonography, it

is now possible to also classify or categorise injuries in terms of their anatomical location and the type/s of tissue involved. The role of imaging in predicting recovery time from muscle strains remains unclear.<sup>9</sup> However, there is increasing recognition of the benefits of combining clinical and radiological findings, which has resulted in the generation of a number of 'new' muscle injury grading and classification systems (Table 3.3 and Fig. 3.6).<sup>8, 10-12</sup> These systems have yet to be convincingly validated,<sup>13</sup> but may represent a new era in understanding and establishing prognosis for muscle strains.

Common to the new muscle strain grading systems is the recognition that strains involving tendinous components of the muscle have a worse prognosis. Muscle strains most commonly occur at or near the musculotendinous junction, which appears as an area of relative weakness in skeletally mature individuals. The traditional view of the muscle-tendon unit involved a relatively distinct separation between the muscle belly and the free tendon at the end via which active contractile forces are transmitted to the bone. However, advanced imaging and anatomical dissection studies have clearly shown that tendinous structures extend

deeply into the muscle belly and that some muscles also have isolated central tendinous structures within the muscle belly itself.

It is well established that muscle strains involving concomitant damage to the free tendon (e.g. proximal hamstring tendon) require a longer recovery time than strains isolated to the musculoskeletal junction. However, the presence of and damage to intramuscular and central tendons may explain why some individuals with historically labelled 'muscle belly strains' have a slower than expected recovery. The presence of intramuscular and central tendinous structures means that musculotendinous junctions occur throughout a greater length of a muscle and that 'muscle belly strains' still represent an injury occurring at one or more of these junctions. As tendinous structures have a slower healing rate than muscle tissue, a muscle strain that also involves damage to intramuscular or central tendinous structures has the potential to delay healing and return to play.<sup>13</sup> Indeed, a recent cohort study reported that strains of the biceps femoris muscle with and without central tendon disruption required contrasting median recovery times of 72 and 21 days, respectively.<sup>14</sup>

**Figure 3.6** Letter classification based on the anatomical site of muscle injury within the British Athletics Classification system described by Pollock et al.<sup>12</sup> (a) Myofascial (b) Musculotendinous (c) Intratendinous

The goal of management of an acute muscle strain is to return the athlete to activity at the prior level of performance and with minimal risk for re-injury. This requires the underlying pathology and the changes it introduces (i.e. pain, swelling, weakness, reduced range of motion), be addressed. It also requires causative risk factors be addressed, with a previous muscle injury being the single largest risk factor for a future strain.

Acute management of muscle strains focuses on minimisation of pain and oedema, restoration of neuromuscular control at slow speeds and prevention of excessive scar formation while protecting the healing fibres from excessive lengthening. Recommended early techniques include: 1) ice and compression; 2) mobilisation and motion, within pain limits and while avoiding aggressive stretching techniques; and 3) gentle massage of the affected muscle peripheral to the lesion.<sup>15</sup>

Subsequent management allows for increased exercise intensity, neuromuscular training at faster speeds and larger amplitudes and the initiation of eccentric resistance training. The final stage of recovery progresses to high-speed neuromuscular training and eccentric resistance training in a lengthened position in preparation for return to sport.<sup>16</sup>

## Contusion

Muscle contusion is the medical term for a muscle bruise, and refers to bleeding and subsequent haematoma formation within a muscle and its surrounding connective tissue sheaths. Contusions occur when a muscle is compressed against the underlying bone by a blunt, external force. The force can result from a direct blow or collision with an external object, such as an opposing player, teammate or piece of equipment. Thus, they are common in contact sports and sports involving the use of rapidly moving hard objects (e.g. sticks and balls).

The most common site for muscle contusion is the quadriceps, with contusions at this site being referred to as a 'corked thigh', 'charley horse' or 'dead leg'. Other common sites for contusion include the gastrocnemius and gluteal muscles; however, a contusion can occur in any muscle exposed to a blunt compressive force.

Muscle compression causes muscle fibre damage and rupture of microvessels. The released blood clots to form a haematoma that initiates an acute inflammatory reaction aimed at removing the haematoma and damaged tissue and initiating a repair response. The haematoma may form either within (i.e. intramuscular) or between (i.e. intermuscular) the fascial coverings of the muscle. Intramuscular contusions are more self-limiting as the rise in pressure within the confines of the fascial compartment reduces blood flow, but they are also generally more painful and more restrictive because muscle contraction results in further rises in compartment pressure and stimulation of nociceptors.

In contrast, intermuscular contusions are generally less painful as the fascial sheath is damaged which allows the haematoma to spread to relieve compartment pressure. Intermuscular haematomas are generally more evident externally as the blood is able to travel distally due to gravity and into the subcutaneous tissues resulting in a visible bruise.

Initial management of a muscle contusion involves assessing for presence of an acute compartment syndrome (discussed below), controlling bleeding to reduce secondary injury (i.e. muscle fibre hypoxia) and protecting the injured site from further injury. Techniques include compression and ice with the muscle placed in a pain-free stretched position to help stop the bleeding and reduce muscle spasm. Techniques such as heat, alcohol and

vigorous massage, which have the potential to increase blood flow and/or cause a rebleed, should be avoided in the acute and subacute stages. Subsequent management focuses on restoring muscle function via progressive stretching and strengthening. The use of protective equipment in the form of force dissipating and dispersing padding should be considered to prevent re-injury upon return to activity. However, the reduction in injury risk gained by using protective equipment will need to be weighed against any associated reduction in athlete mobility and performance.

### Myositis ossificans

Myositis ossificans is a form of heterotrophic ossification and refers to the formation of bone within a muscle. It is an infrequent complication of a contusion injury wherein bone-forming osteoblasts invade the haematoma and begin to lay down bone. The cause remains unknown; however, risk factors include severe contusions that limit joint range of motion (e.g. thigh contusions that limit knee flexion to  $<45^\circ$ ), repeat contusion injury and inappropriate initial management that causes a rebleed.

Myositis ossificans should be suspected in muscle contusions that do not resolve in the expected time. Particular signs and symptoms include initial improvements in range and pain followed by subsequent deterioration

and ongoing or reappearance of inflammatory symptoms (i.e. resting, morning and night pain). The bone grows from 2-4 weeks after injury at which time an area of calcification may be visible on X-ray (Fig. 3.7a) or ultrasound (Fig. 3.7b) and a firm lump may be felt. Once active bone formation ceases the area of calcification gets slowly reabsorbed. As myositis ossificans is self-limiting, management is typically conservative and consists of anti-inflammatory approaches and non-painful stretching and strengthening.

### Acute compartment syndrome

Muscles in the extremities are surrounded by a strong, thick connective tissue called fascia. The fascia serves as an attachment site for muscle, aids in force transmission and forms non-distensible compartments that facilitate muscle-pump mediated venous return. Injury leading to swelling or bleeding into one of the fascial compartments (usually the flexor compartment of the forearm or anterior compartment of the lower leg) can result in the development of acute compartment syndrome.

Acute compartment syndrome occurs when interstitial pressure within a compartment exceeds perfusion pressure leading to the onset of ischaemia and, ultimately, cellular anoxia and death. It is characterised by pain that is out of proportion to the inciting injury, pain on passive stretch and at rest, paraesthesia and pulselessness (although the

**Figure 3.7** Myositis ossificans (a) X-ray appearance (b) Ultrasound appearance: yellow arrow points to haematoma within gluteal muscle; blue arrows to calcification within gluteal muscle; green arrow to acoustic shadowing, characteristic of calcification. Red arrow is skin and then subcutaneous fat, and below it are layers of gluteal muscles

latter is a late finding as the interstitial pressure needs to be high enough to occlude arterial flow). Acute compartment syndrome represents a medical emergency that may require urgent fasciotomy (i.e. release of the fascia surrounding the muscle compartment) in order to prevent permanent, irreversible damage.<sup>17</sup> Hence, referral to an orthopaedic emergency specialist is recommended.

## Cramp

Muscle cramps are sudden, painful, involuntary contractions characterised by repetitive firing of motor unit action potentials. When they occur during or immediately after exercise in healthy individuals with no underlying metabolic, neurological or endocrine pathology, they are referred to as 'exercise associated muscle cramps' (EAMC).<sup>18</sup> EAMC are usually temporary (lasting <60 seconds), but are often incapacitating and tend to recur if activity at the same exercise intensity level is continued without an adequate recovery period. Thus, EAMC can significantly impair athletic performance. The most common sites for EAMC are in the calf and foot muscles, followed by the hamstring and quadriceps muscles.

EAMC were historically thought to be due to dehydration and/or electrolyte depletion, but this hypothesis has not been supported by scientific evidence. As EAMC most commonly occur towards the end of or after fatiguing exercise, or following a rapid increase in exercise intensity, fatigue appears to be a significant contributing factor. The current leading theory is that EAMC result from abnormal neuromuscular control at the spinal level in response to fatiguing exercise.<sup>18</sup> This theory ascribes EAMC to increased excitatory and decreased inhibitory afferent inputs to motor neurons during fatigue. The net result is sustained motor neuron activity and the production of a cramp-inducing discharge.

Immediate treatment of EAMC aims to reduce motor neuron activity, with the most popular and effective technique being passive stretching. Passive stretching increases the Golgi tendon organ's inhibitory activity to reduce muscle electromyographic activity within 10-20 seconds and provide symptomatic relief. Ideally, passive tension should be maintained to the affected muscle for up to 20 minutes or until fasciculation ceases.<sup>19</sup> If the EAMC were particularly intense or prolonged, icing while the muscle is on stretch may be considered to offset any potential delayed onset muscle soreness resulting from microscopic muscle fibre damage. Other potential methods of reducing motor neuron activity during EAMC include electrical stimulation of tendon afferents and antagonist contraction to induce reciprocal inhibition.

The incomplete knowledge of the aetiology of EAMC has limited the development of preventative strategies.

Fluid and electrolyte replacement has not been shown to be beneficial, consistent with the now debunked dehydration-electrolyte imbalance theory. In contrast, strategies aimed at modulating fatigability and altering neuromuscular control may be beneficial. Fatigability may be modified by improving generalised conditioning and endurance, and ensuring and maintaining adequate carbohydrate reserves. Neuromuscular control may be targeted by performing plyometric and eccentric exercises, which may elicit changes in muscle spindle and Golgi tendon organ firing to enhance efficiency and sensitivity of reflexive and descending pathways used for neuromuscular control. Regular stretching is also recommended as EAMC frequently occur when the muscle is in its shortened position, while massage and treatment of myofascial trigger points may improve muscle efficiency and reduce fatigability.

## TENDON

### Tear/rupture

Tendons connect muscle to bone and function to transmit muscle contractile forces necessary for motion. They consist of parallel collagen fibres that are more tightly packed than in ligaments, which endow tendons with the consummate ability to resist tensile loading. The tensile strength of tendon is so great that acute tear or rupture of a normal, healthy tendon is relatively rare, with forces more likely to cause an avulsion fracture or failure at the musculotendinous junction (i.e. muscle strain).

Tendons that do acutely fail usually have some form of underlying pathology (i.e. tendinosis). The pathology is usually asymptomatic, such that the tendon failure appears to occur without warning. As the presence of pathology increases with age, tendon ruptures most frequently occur in middle-aged and older athletes. The two most commonly ruptured tendons are the Achilles and supraspinatus tendons, with ruptures involving either a portion (partial rupture) or the full thickness (complete rupture) of the respective tendon (Fig. 3.8). Partial ruptures are characterised by the sudden onset of pain, localised tenderness and a loss of tendon function that is inversely related to the size of the tear. In contrast, complete ruptures are associated with total loss of tendon function and acute pain, but the pain often settles quickly due to concomitant damage of nociceptor afferents.

Diagnosis of tendon ruptures can be confirmed using imaging, with both ultrasonography and magnetic resonance imaging being useful at distinguishing between partial and complete rupture. Partial tendon ruptures may be managed conservatively using progressive rehabilitation; however, complete ruptures may be treated by surgical repair to restore tendon continuity and function, followed by rehabilitation or by rehabilitation alone.

**Figure 3.8** Tendon rupture (a) Partial (b) Complete

## FASCIA

### Tear/rupture

Fascia is a dense, regular connective tissue consisting of closely packed bundles of collagen fibres. It divides muscles into compartments and forms specific force-transmitting structures, such as the iliotibial band (ITB) and plantar fascia. Most injuries to fascia are associated with overuse, with prominent conditions being ITB syndrome (Chapter 37) and plantar fasciopathy (Chapter 43). Acute sprain or rupture of fascia is rare, but has been reported.

## BURSA

### Traumatic bursitis

Bursae are small, synovial membrane-lined sacs that are filled with an inner layer of viscous fluid. They are frequently found between bone and overlying connective tissues (such as tendon, muscle and skin) where they function to provide cushioning and facilitate movement by reducing friction. Most injuries to bursae are associated with overuse (Chapter 4), but occasionally a direct fall

onto a bursa may result in acute traumatic bursitis due to bleeding into the bursa. The management of acute haemorrhagic bursitis involves the application of ice and compression. Aspiration may be considered if the condition does not resolve, but corticosteroid injection is rarely indicated.

## NERVE

### Neuropraxia

Major acute nerve injuries are unusual in athletes. Specific nerves are susceptible to compression injury because of their subcutaneous location, including the ulnar nerve at the elbow and common peroneal nerve at the neck of the fibula. Similarly, some nerves are vulnerable to being co-injured with other tissues, such as axillary nerve injury during shoulder dislocation and radial nerve injury with humeral shaft fracture.

The most common acute nerve injury in athletes is a 'stinger' or 'burner'. A stinger or burner results from an overstretching injury to the brachial plexus that conveys the nerve supply to the arm. Overstretching can occur when the head is forcibly bent away from the shoulder while the shoulder is simultaneously depressed. This can occur when an athlete is driven into the playing surface during a high-contact sport, such as ice hockey, rugby, wrestling and various football codes.

Symptoms are a stinging or burning sensation that spreads from the shoulder to the hand, which may be associated with numbness in the sensory distribution of the involved nerves. The paraesthesia is often temporary, disappearing in minutes and usually within hours; however, injuries that are more serious can result in longer lasting symptoms involving the loss of both sensory and motor function due to blockage of nerve conduction. The later type of injury, known as 'neuropraxia', usually resolves spontaneously but slowly.

## FAT PAD

### Bruise/contusion

Fat pads consist of closely packed adipose cells surrounded by fibrous septa, which commonly divide the fat pad into separate compartments. The function of fat pads is not well established and may vary according to anatomical location. However, they appear to have roles in cushioning and facilitating joint lubrication. It is in their cushioning role that fat pads are susceptible to acute compression injury. In particular, the calcaneal fat pad under the heel and the infrapatellar fat pad located behind the patellar tendon can be acutely injured. The plantar fat pad can be injured during landing onto the heel from a height, while the infrapatellar fat pad can be injured by landing on the knees or pinching the fat pad between the femoral

condyles, proximal tibia and inferior pole of the patella during knee hyperextension. The infrapatellar fat pad is also often acutely injured when creating portals during knee arthroscopic surgery.

Fat pads are well vascularised and innervated. The blood supply contributes to haematoma formation (contusion) in response to acute injury, but also enables fat pad injuries to readily heal. The rich innervation of fat pads means that they can be a significant source of pain, with the infrapatellar fat pad being reported to be the most pain evoking structure in the knee.<sup>20</sup> The integrity and function of the calcaneal fat pad may be compromised if its organised compartments are disrupted; however, this is rare, with compression injuries sufficient to fracture the calcaneus not damaging the fibrous septa.<sup>21</sup> Management

of fat pad injuries, beyond acute care techniques, includes externally padding using heel cups or knee pads and using tape to limit radial expansion of the calcaneal fat pad or unload the infrapatellar fat pad. These injuries can take considerable time to heal.

## SKIN

Acute skin injuries are common in athletes, particularly those competing in contact sports and cycling. Open wounds may be caused by a scraping (abrasion), cutting (laceration) or piercing (puncture) force. Possible damage to underlying structures, such as tendons, muscles, blood vessels and nerves, should always be considered. The principles of treatment of all open wounds are shown in Table 3.4.

**Table 3.4 Principles of treatment of all open wounds**

Principle	Details
1. Stop any associated bleeding	Apply a pressure bandage directly to the injured part and elevate it. If the wound is open and clean, bring the wound edges together using adhesive strips or sutures. A contaminated wound should not be closed.
2. Prevent infection	Remove all dirt and contamination by simple irrigation. Extensively wash and scrub with antiseptic solution as required as soon as possible. If the wound is severely contaminated, prophylactic antibiotic therapy should be commenced (e.g. flucloxacillin, 500 mg orally four times a day). If anerobic organisms are suspected (e.g. wound inflicted by a bite), add an antibiotic such as metronidazole (400 mg orally three times a day).
3. Immobilisation (where needed)	This applies when the wound is over a constantly moving part, for example, the anterior aspect of the knee. Certain lacerations, such as pretibial lacerations, require particular care and strict immobilisation to encourage healing.
4. Check tetanus status	All contaminated wounds, especially penetrating wounds, have the potential to become infected with <i>Clostridium tetani</i> . Tetanus immunisation consists of a course of three injections over 6 months given during childhood. Further tetanus toxoid boosters should be given at 5 to 10 year intervals. In the case of a possible contaminated wound, a booster should be given if none has been administered within the previous 5 years.

# Sports injuries: overuse

with STUART WARDEN

*During training, I suffered a stress fracture. It was madness that I carried on and ran the 800 metres and 1500 metres, but because it's the Olympics, you run through the pain.*

*You never know if you'll have another chance at the Olympics, so unless you can't actually walk you carry on, because you don't want to be asking yourself, 'What if?'*

Dame Kelly Holmes, MBE, DBE, 800 and 1500 m gold medallist, Athens 2004 Olympic Games

Overuse injuries present three distinct challenges to the clinician—diagnosis, understanding of why the injury occurred and treatment. Diagnosis requires taking a comprehensive history of the onset, nature and site of the pain along with a thorough assessment of potential risk factors, for example training and technique. Careful examination may reveal which anatomical structure is affected. It is often helpful to ask patients to perform the manoeuvre that produces their pain.

The skilled clinician must seek a cause for every overuse injury. The cause may be quite evident, such as a sudden doubling of training quantity, poor footwear or an obvious biomechanical abnormality, or it may be more subtle, such as running on a cambered surface, muscle imbalance or leg length discrepancy. The causes of overuse injuries are usually divided into extrinsic factors, such as training, surfaces, shoes, equipment and environmental conditions, and intrinsic factors, such as age, gender, malalignment, leg length discrepancy, muscle imbalance, muscle weakness, lack of flexibility and body composition. Possible factors in the development of overuse injuries are shown in Table 4.1.

Treatment of overuse injuries will usually require addressing of the cause as well as specific additional elements such as activity modification, specific exercises to promote tissue repair, soft tissue therapy and pharmacologic agents where appropriate (Chapter 17).

### BONE STRESS INJURY

A bone stress injury (BSI) represents the inability of bone to withstand repetitive mechanical loading, which results in structural fatigue and localised bone pain

**Table 4.1 Overuse injuries: predisposing factors**

and tenderness. It occurs along a pathology continuum beginning with a stress reaction, which can progress to a stress fracture and ultimately a complete bone fracture.

## Pathophysiology

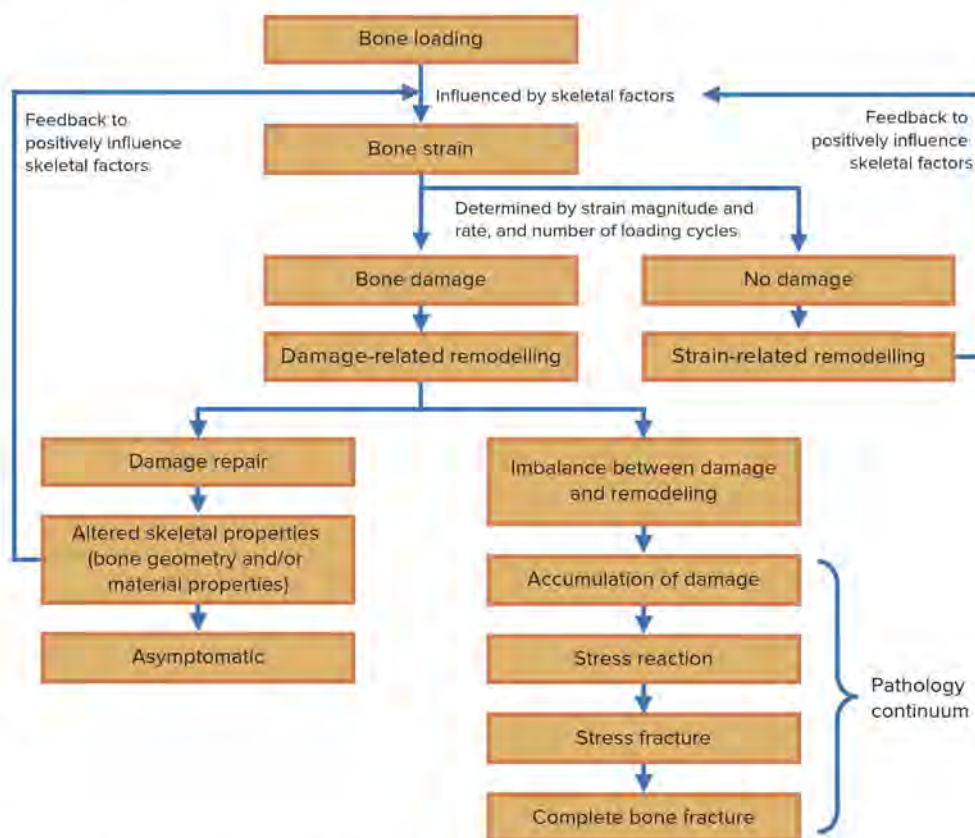

BSIs result from an imbalance between the formation and removal of load-induced damage. A theoretical model is presented in Figure 4.1. Bones deform in response to loading, with the amount of deformation (expressed in terms of strain) depending on the magnitude of load applied and the ability of bone to resist deformation. While the safety factor between exercise-induced strains and those required for complete bone fracture is large, exercise-induced strains can generate microscopic damage (termed 'microdamage').<sup>1</sup> The threshold for microdamage formation depends on the interaction between the number of bone-loading/-strain cycles, the load/strain magnitude and the speed at which load/strain is introduced (strain rate).

Microdamage serves as a stimulus for targeted remodelling.<sup>2</sup> Targeted remodelling involves activation of remodelling units consisting of advancing front-of-bone-resorbing osteoclasts which remove the damage, followed by rows of bone-forming osteoblasts which deposit layers of new bone. Targeted remodelling maintains homeostasis between damage formation and its removal to preserve bone mechanical properties and enable a bone to adapt

over time to meet changing demands. The adaptation decreases bone strain for a given load,<sup>3, 4</sup> which means greater loads can be tolerated before the threshold for microdamage formation is surpassed.

Remodelling normally removes damage approximately as fast as it occurs and a reserve exists whereby additional remodelling units can be activated in response to increased microdamage formation. Thus, changes in loading are generally well tolerated. However, remodelling is time dependent and, if insufficient time is given to adapt to a new mechanical stimulus, progressively more damage may form as a result of feedforward between remodelling and damage formation. Feedforward results from resorption preceding formation in remodelling so that an increase in the number of active remodelling units locally reduces bone mass and the energy absorbing capacity of the bone, which potentiates further damage formation.

Accumulating microdamage may combine to initiate the BSI pathology continuum, which includes stress reactions, stress fractures and ultimately complete fracture (Fig. 4.1). Stress reactions are characterised by increased bone turnover associated with periosteal and/or marrow

**Figure 4.1** A theoretical model of bone stress injury

REPRINTED WITH KIND PERMISSION FROM SPRINGER SCIENCE+BUSINESS MEDIA, *CURRENT OSTEOPOROSIS REPORTS* 2006;4(3):103–9

oedema, whereas stress fractures have the addition of a discernible fracture line.

## Epidemiology

As BSIs develop in response to repetitive mechanical loading, it is not surprising they frequently occur in athletes. In athletes, BSIs cause a considerable loss of participation time and are a significant source of frustration, particularly when they occur in the lead up to a major event or competition. Between one- and two-thirds of runners have a history of a BSI,<sup>5, 6</sup> while the one-year cumulative incidence of BSIs in cross-country and track and field athletes ranges between 5% and 21%.<sup>7, 8</sup> Also of note is the high recurrence rate of BSIs, with half of track and field athletes reporting a history of BSIs on more than one occasion and 10-13% of cross-country and track and field athletes with a history of a BSI sustaining a subsequent BSI when followed for 1-2 years.<sup>6, 7</sup>

BSIs are site specific, occurring at sites exposed to repetitive mechanical loading. Given their association with mechanical loading, BSIs predominantly occur at weight-bearing sites, with the most common sites being the tibia, the metatarsals and the fibula. The exact location depends on how the skeleton is loaded, with different activities resulting in different loading patterns within different

bones. For example, long distance runners typically use a rearfoot strike pattern to preferentially load long bones (tibia, fibula, femur), whereas sprinters use a forefoot strike pattern to introduce relatively greater loads to the bones of the feet. As a result of the differential bone loading, distance runners are at a greater risk of developing long BSIs, whereas sprinters are more prone to BSIs of the tarsals and metatarsals.<sup>7</sup>

Although BSIs predominantly occur at weight-bearing sites, they also occur in response to repetitive loading at non weight-bearing sites.<sup>9</sup> For instance, rowers repetitively load their rib cage during the drive phase of the rowing stroke and, consequently, are at heightened risk of generating BSIs in their ribs (see Chapter 9).<sup>10</sup> Similarly, throwing athletes are at risk of developing humeral diaphysis BSIs as they repetitively expose their humerus to significant loads during the throwing motion.<sup>4, 11</sup> As BSIs can occur at both weight-bearing and non weight-bearing sites, they can occur in virtually any bone (Fig. 4.2). Thus, they need to be considered in the differential diagnosis of all presenting injuries.

## Risk factors

BSIs can be viewed as occurring when the mechanical stimulus at a specific bone site repetitively exceeds the threshold for microdamage formation. As the bone

Site of stress fracture	Associated sport/activity
Coracoid process of scapula	Trapshooting
Scapula	Running with hand weights

**Figure 4.2** Stress fracture site and common associated activity

mechanical stimulus is dependent on the interaction between the applied load and the ability of the bone to resist deformation, risk factors for BSIs can be grouped into two categories:

1. factors modifying the load being applied to a bone
2. factors modifying the ability of a bone to resist load without damage accumulation (Fig. 4.3).

### Factors modifying the load applied to a bone

The load applied to a bone during athletic activities represents the summation of external and internal forces, and has magnitude, rate, frequency, duration and direction components. These components influence bone strain magnitude, rate, frequency, duration and location, respectively. Factors modifying the load applied to a bone include biomechanical, training and muscle factors, playing surface and shoes and inserts (orthoses and insoles).

#### Biomechanical factors

Faulty biomechanics can contribute to BSI risk, and can be dichotomised into those related to abnormal forces and abnormal motions. Increased forces on a normally aligned skeleton can result in abnormal bone loading, with athletes exhibiting high ground reaction force (GRF)

magnitudes and rates, and high accelerations during the early stance phase of running gait being proposed to be at heightened BSI risk. Alternatively, normal forces applied to a malaligned skeleton can also abnormally load bone. Altered movement patterns have the potential to alter the magnitude and/or rate of bone loading, and also alter the direction a bone is loaded and the subsequent distribution of strain within the bone.

The net result may be increased loading of a less accustomed bone site. Statically assessed biomechanical variables that have been implicated in BSI development include external rotation range of motion of the hip,<sup>13</sup> leg length discrepancy,<sup>14</sup> and both pes planus<sup>15</sup> and cavus.<sup>16</sup> Dynamically assessed variables implicated in BSI development include greater peak hip adduction, knee internal rotation and peak rearfoot eversion in the frontal plane during running<sup>17-19</sup> and less knee flexion in the sagittal plane.<sup>20</sup> Having the combination of abnormal forces coupled with a malaligned lower limb is thought to further amplify BSI risk.

#### Training factors

Chronic introduction of high absolute load magnitudes, rates and accelerations may reduce bone fatigue life, particularly

**Figure 4.3** Risk factors for bone stress injuries<sup>12</sup>

when the number of loading cycles is high (i.e. running long distances). However, the influence of these variables may be most prominent when an athlete attempts to progress their training. Increases in running speed increase GRFs and their rates of introduction,<sup>21</sup> while increases in the duration and/or frequency of training sessions increase the total number of bone-loading cycles. In the absence of a change in the load-bearing capacity of a bone, altered loading associated with large changes in training may contribute to microdamage accumulation and the generation of a BSI.

Evidence from military studies confirms that individuals exposed to large changes in physical activity have a heightened BSI risk. For instance, recruits with a lesser history of regular physical activity prior to the commencement of standardised basic training (i.e. those with larger changes in physical activity levels) are at a greater risk of developing a BSI.<sup>22-24</sup> While most athletes do not introduce changes in their bone-loading environment to the same extremes as many military recruits, change is a frequent and required means of inducing adaptation. Incrementing training too rapidly or frequently relative to an athlete's usual activities is thought to be central to disrupting the balance between bone microdamage formation and removal.

### Muscle factors

Training changes may independently contribute to BSI development, but the relative risk associated with the change may be compounded by muscle factors. An intimate mechanical relationship exists between muscle and bone and the general hypothesis is that muscle is generally protective of BSIs, particularly those occurring in the lower extremity. During impact loading, muscle acts as an active shock attenuator helping to reduce loads as they are transmitted proximally.

When muscles are dysfunctional (weakened, fatigued or altered in their activation patterns) their ability to attenuate loads becomes compromised leading to increased loading of the skeleton. For instance, fatigue results in a decrease in shock attenuation,<sup>25, 26</sup> increase in GRF loading rates and peak accelerations,<sup>27, 28</sup> and increase in bone strain magnitude and rate.<sup>29, 30</sup> In addition, fatigue can lead to altered kinematics, which may alter the direction a bone is loaded resulting in increased bone strain at less accustomed bone sites.<sup>31</sup> Further support for a protective role of muscle in stress fracture development comes from prospective clinical studies which demonstrated that BSI susceptibility was directly related to muscle size<sup>14, 32, 33</sup> and strength.<sup>34</sup>

### Playing surface

Playing surface has historically been considered a contributor to BSI risk, with participation on harder surfaces such as asphalt hypothesised to increase loading

compared to participating on softer surfaces such as grass, rubber and sand. However, the interaction between playing surface and injury risk is complex. Athletes alter their leg stiffness when running on surfaces of differing compliance apparently to maintain a constant vertical excursion of their centre of mass.<sup>35</sup> Leg stiffness decreases when running on stiffer surfaces to normalise to some extent GRF magnitude; however, GRF loading rates do appear to be systematically increased when running on surfaces that are less compliant.<sup>36</sup>

Ultimately, what may be important with regards to BSI risk is whether there has been a recent change in running surface that an athlete has yet to become accustomed to. Changes may include increased participation on:

1. less compliant surfaces, which may increase bone strain magnitudes and rate<sup>37</sup>
2. very compliant surfaces (such as sand), which may increase energy expenditure and influence muscle-related risk factors and kinematics<sup>38, 39</sup>
3. downhill slopes, which may decrease shock attenuation<sup>40</sup> and increase loading magnitudes and rates<sup>41</sup>
4. altered terrain, which may alter kinematics to load less accustomed skeletal sites.<sup>42</sup>

### Shoes and inserts

The role of shoes and inserts (orthoses and insoles) on bone loading and BSI risk is a topic of ongoing debate. Located at the foot-ground interface, shoes and inserts act as filters that theoretically attenuate ground impact forces. In addition, they have the potential to influence motion of the foot and ankle and the subsequent mechanics proximally in the kinetic chain. Via these two mechanisms, shoes and inserts may influence bone loading and have an effect on BSI risk.

### Factors influencing the ability of the bone to resist load without damage accumulation

The amount and rate of strain engendered when a load is applied to a bone is dependent upon the ability of the bone to resist deformation in the direction of loading. For a given applied load, less rigid bones experience greater strain and at a faster rate than more rigid bones and, thus, are more susceptible to microdamage and BSI formation. Skeletal features that influence bone rigidity include the amount of bone material present (mass) and its distribution (structure). There is strong evidence that both contribute to BSI risk<sup>14, 23, 33, 43, 44</sup> and therefore it is important to consider modifiable factors that may contribute to these skeletal characteristics. Three modifiable factors in athletes that may impact the ability of bone to resist loading and contribute to BSI risk are physical activity history, energy availability, and calcium and vitamin D status.

### Physical activity history

A longer history of physical activity appears to be protective against the development of a BSI.<sup>22-24, 45, 46</sup> An improved ability of the skeleton to resist loading likely contributes to the reduced BSI risk in individuals with a prior history of physical activity. The skeleton responds and adapts to mechanical loading in a site-specific manner to increase its rigidity in the direction of loading. It principally does this during the growing years by preferentially depositing small amounts of new bone on the outer periosteal surface at a distance from the bending axes. As the rigidity of a unit area of bone is proportional to the fourth power of its distance from a bending axis, the addition of a small amount of mass to the outer surface of a bone results in a disproportionate increase in bone strength. The net result is a decrease in the bone strain engendered in response to a given load and increase in bone fatigue life.<sup>3</sup>

### Energy availability

Gender factors contribute to BSI susceptibility, with females being at greater risk.<sup>47</sup> The cause for the higher incidence of BSIs in females appears to relate to the interrelationships between energy availability, menstrual function and bone mass—otherwise known as the female athlete triad. While athletes can have one or more components of the triad, low energy availability appears to be the central factor.<sup>48</sup> Low energy availability results from insufficient dietary intake to meet exercise energy expenditure. It can result from low dietary energy intake (whether inadvertent, intentional or psychopathological) and/or excessive exercise energy expenditure. The menstrual and skeletal changes associated with low energy availability reduce the ability of bone to resist load and/or impair its ability to repair microdamage. The net result is heightened BSI risk, particularly in elite female long distance runners where the difference between dietary energy intake and exercise energy expenditure is often small and the incidence of menstrual dysfunction is elevated.

### Calcium and vitamin D status

Calcium combines with phosphate to form hydroxyapatite crystals to endow bone with rigidity, while vitamin D contributes by promoting calcium absorption in the gut and reabsorption in the kidneys. Prospective studies provide evidence for roles of both low calcium and vitamin D in BSIs,<sup>49, 50</sup> and a large randomised controlled trial demonstrated a 20% reduction in BSI incidence in female Navy recruits with suboptimal baseline daily calcium intake when they were supplemented with daily calcium and vitamin D.<sup>51</sup> Overall, the data suggest that athletes should ensure sufficient calcium and vitamin D

intakes to meet or exceed the current recommended dietary allowances of 1000–1300 mg and 600 IU (for individuals aged 14–50 years), respectively.<sup>52</sup>

### Diagnosis

BSIs often present with a history consistent with an overuse injury—the gradual onset of activity-related pain. As BSIs occur along a pathology continuum, signs and symptoms may vary depending upon what point along the continuum the athlete presents. An astute clinician may be able to diagnose the pathology at the stress reaction stage. However, some patients may not present until the pathology has progressed to a stress fracture where there is actual cortical disruption. The earlier within the continuum an athlete presents and a diagnosis is made, the more likely the pathology may respond quickly and favourably to management. Thus, bone as the tissue of origin of an athlete's symptoms needs to be considered at all times during differential diagnosis to ensure prompt diagnosis and management.

The diagnostic features of a stress fracture are shown in Table 4.2.

### History

A thorough history is the first step to the diagnosis of a BSI. In most instances, individuals with a BSI have a consistent and predictable history that centres on pain. At the start of the pathology continuum, pain is usually described as a mild diffuse ache that occurs after a specific amount of activity and at specific times (depending on which bone is afflicted and when loaded during activity). The pain does not tend to resolve or 'warm-up' as activity is continued and only abates once activity (i.e. bone loading) is ceased.

As the initial pain often subsides soon after activity completion and is not present during rest it is often ignored at first. However, with continued training and progression of the pathology the pain may become more severe and localised and occur at an earlier stage. It may also persist for longer periods following the completion of activity and begin to be present during activities that involve lower levels of bone loading, such as walking. Eventually, the pain can result in activity restriction or the

**Table 4.2 Diagnostic features of a stress fracture**

- Localised pain and tenderness over the fracture site.
- A history of a recent change in training or taking up a new activity.
- X-ray appearance often normal or there may be a periosteal reaction (Fig. 4.4).
- Abnormal appearance on MRI (Fig. 4.5), radioisotopic bone scan (scintigraphy) (Fig. 4.7) or CT scan (Fig. 4.8).

need to cease training altogether. At this more advanced stage, any associated inflammatory response to the injury may also occasionally contribute to resting and night pain.

### Examination

On physical examination, the most obvious feature of a BSI is localised bony tenderness. Certain bones (such as the tibia, fibula and metatarsals) lend themselves well to palpation because of their well-defined anatomical boundaries and the absence of overlying muscle. In these relatively subcutaneous bones, precise and thorough palpation is required as tenderness may be localised with adjacent areas being completely pain-free. Occasionally redness, swelling and warmth from an associated inflammatory reaction may also be felt, along with periosteal thickening and callus formation in longer-standing BSIs.

Direct palpation is obviously not possible at deeper sites (such as the femur and pars interarticularis of the spine), with symptoms at these sites possibly being provoked by specific bone-loading tests, such as hopping,<sup>53</sup> the fulcrum test for the femoral shaft,<sup>54</sup> or the one-legged hyperextension test for the pars interarticularis.<sup>55</sup> However, the sensitivity and specificity of these bone-loading tests have either not been investigated or disputed.<sup>56</sup> Likewise, the application of a vibrating tuning fork or therapeutic ultrasound for the clinical diagnosis of BSIs is not supported.<sup>57</sup>

### Imaging

Imaging plays a significant role in the diagnosis. Imaging options include plain radiography, bone scan, computed tomography (CT), magnetic resonance imaging (MRI) and, more recently, ultrasound.

Plain radiographs have poor sensitivity and may not detect stress injury until the injury has developed along the bone stress continuum.<sup>58, 59</sup> Although some old textbooks suggested that stress fractures become visible on plain radiographs after 2-6 weeks, prospective studies prove that some stress fractures remain invisible on plain radiography. Radiographic changes, when present, include subtle focal periosteal bone formation (Fig. 4.4), or, later, frank cortical defects.

In countries where physicians have ready access to MRI, this is generally the first line investigation of bone stress injuries. MRI is sensitive in detecting pathophysiological changes in soft tissue, bone and marrow associated with bone related stress injuries. It can reveal abnormalities in these structures before plain radiographic changes and has comparable sensitivity to a bone scan.<sup>58</sup> Other advantages of MRI for bone imaging are its multiplanar capability (which helps the clinician precisely define the location and extent of injury), lack of exposure to ionising radiation and significantly less imaging time than a three-phase bone scan.

**Figure 4.4** X-ray showing periosteal new bone formation indicative of a stress fracture

The typical MRI appearance of a stress fracture shows periosteal and marrow oedema plus or minus the actual fracture line (Fig. 4.5). Several fat-suppression techniques such as short tau inversion recovery are used to maximise the sensitivity of MRI in bone stress injuries.<sup>60</sup>

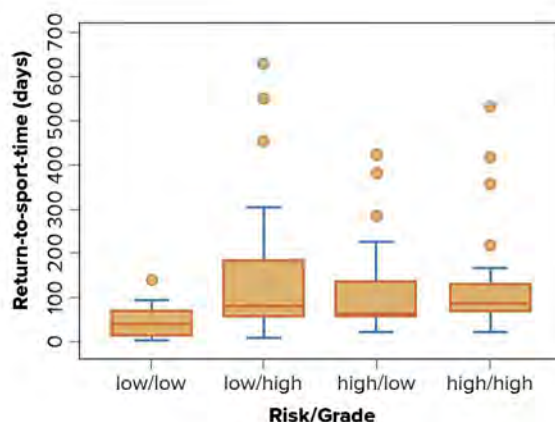

Various grading systems for stress fractures based on MRI appearances have been suggested.<sup>61</sup> The most commonly used systems<sup>62-64</sup> are shown in Table 4.3.

Attempts have been made to use the MRI appearance to predict return to play (RTP). In a prospective study involving 34 fractures among 211 college athletes, MRI grading severity, lower bone mineral density (BMD) and the fracture site (trabecular > cortical bone) were important variables associated with time to return to sport.<sup>64</sup> The mean time to full return to sport for grade 4 BSIs (31.7  $\pm$  3.7 weeks) was significantly higher compared with grade 3 (18.8  $\pm$  2.9 weeks), grade 2 (13.5  $\pm$  2.1 weeks) and grade 1 injuries (11.4  $\pm$  4.5 weeks). Among grade 3 and 4 injuries, the mean time to return to sport was significantly longer for those at sites high in trabecular versus cortical bone (38.1  $\pm$  6.4 vs 18.8  $\pm$  2.1 weeks, respectively).<sup>64</sup>

**Figure 4.5** MRI of a stress fracture showing bony oedema (white)

It should be recognised that the above values are based on the average time taken to return to sport. However, as illustrated in Figure 4.6, this fails to reflect the wide variation among individuals—particularly those with higher MRI-grade injuries or injuries located in high-risk sites (covered in the section 'Classification of bone stress injuries').<sup>65</sup> Care should therefore be taken in making definitive return-to-sport predictions based on imaging alone, except perhaps in the case of mild stress reactions in low-risk sites.

(Dots indicate outliers).

**Figure 4.6** Return-to-sport times for BSIs grouped according to a combination of their location (low risk/high risk) and MRI grade (low: grades 1 and 2; high: grades 3 and 4)<sup>66</sup>

**Table 4.3** MRI grading scales for BSIs

Grade	Fredericson et al. <sup>62</sup>	Arendt et al. <sup>63</sup>	Nattiv et al. <sup>64</sup>
1	Mild to moderate periosteal oedema on T2 Normal marrow on T2 and T1	Positive signal change on STIR	Mild marrow or periosteal oedema on T2 T1 normal*
2	Moderate to severe periosteal oedema on T2 Marrow oedema on T2 but not T1	Positive STIR plus positive T2	Moderate marrow or periosteal oedema plus positive T2 T1 normal
3	Moderate to severe periosteal oedema on T2 Marrow oedema on T2 and T1	Positive STIR plus positive T2 and T1	Severe marrow or periosteal oedema on T2 and T1
4	Moderate to severe periosteal oedema on T2 Marrow oedema on T2 and T1 Fracture line present	Fracture line present on T2 or T1	Severe marrow or periosteal oedema on T2 and T1 Fracture line present on T2 or T1

STIR: short T1 inversion recovery

\*Radiograph results are often negative at all grades; they may be normal, or a periosteal reaction may be evident

Beck and colleagues in their study included grading systems for radiography, isotope bone scan, CT scan, as well as MRI and found that only the MRI grading system had any relationship to clinical severity.<sup>67</sup>

A radioisotopic bone scan was the most important diagnostic test for athletic stress fractures in the 1990s.<sup>60</sup> The technical aspects of this modality are outlined in Chapter 15. The appearance of a BSI on a bone scan is a focal area of increased uptake (Fig. 4.7).

Note that bone scans lack specificity for stress fractures—bony abnormalities such as tumours, especially osteoid osteoma and osteomyelitis, have similar appearances. It may also be difficult to precisely localise the site of the area of increased uptake. Increased uptake can occur in non-painful sites, indicating subclinical accelerated remodelling. As with plain film, CT and MR imaging, imaging appearance returns to normal after clinical resolution because of ongoing bony remodelling.<sup>60</sup>

CT is less sensitive than a bone scan or MRI in the early detection of a BSI.<sup>58, 59</sup> However, it is more sensitive than both radiographs and MRI for the detection of cortical fracture lines. CT is thus well suited to demonstrate stress fractures of the sacrum, pars interarticularis, tarsal navicular and longitudinal stress fractures of the tibia.<sup>58</sup>

A CT scan will clearly image the fracture (Fig. 4.8) and differentiate between a stress fracture (positive bone scan, clear fracture line) and a stress reaction (positive bone scan and negative CT scan). CT can also distinguish a BSI and other causes of hot bone scans such as osteoid osteoma and osteomyelitis.

**Figure 4.7** Radioisotopic bone scan of a stress fracture  
COURTESY OF ZS KISS

**Figure 4.8** CT scan of a stress fracture showing a cortical defect (arrowed)

Ultrasound has some potential in the diagnosis of stress fractures but it is not ready for routine clinical use.<sup>59</sup>

Ultimately, athletes who display clinical signs and symptoms of a possible BSI require imaging to confirm suspicions and make a definitive diagnosis. Briefly, in most clinical settings, plain radiographs remain the first line of imaging for BSIs because of their low cost and wide availability; however, radiographs are limited by their planar nature and low spatial resolution, which contribute to extremely low sensitivity. CT also lacks sensitivity, but may be utilised in specific cases where demonstration of a fracture line may affect treatment. In contrast, bone scintigraphy has high sensitivity, but is limited by low specificity and the use of extremely high ionising radiation doses. Of the imaging modalities currently available, MRI is the modality of choice because of its superior contrast resolution, lack of exposure to ionising radiation, and its combined high sensitivity and specificity.

The different imaging appearances of the various stages of the BSI continuum are shown in Table 4.4.

### Classification of bone stress injuries

BSIs can be dichotomised into either low or high-risk groups according to their location (Table 4.5).<sup>68</sup> Low-risk BSIs predominantly occur on the compression side of a bone's bending axis, and have a favourable natural history in that recovery occurs with a low incidence of complications and without the need for aggressive intervention (such as surgery and/or prolonged modified weight-bearing). In contrast, high-risk BSIs often occur on the tension side of a bone's bending axis, and present treatment challenges demanding specific attention

**Table 4.4 Imaging findings with different phases of the BSI continuum**

Clinical features	Early bone stress	Stress reaction	Stress fracture
Local pain	Nil	Usually	Always
Local tenderness	Nil	Usually, if superficial	Usually, if superficial
X-ray appearance	Normal	Normal	May be abnormal (periosteal reaction or cortical defect in cortical bone, sclerosis in trabecular bone)
Radioisotopic bone scan appearance	Increased uptake	Increased uptake	Increased uptake
CT scan appearance	Normal	Normal	Features of stress fracture (as for X-ray)
MRI appearance	May show increased high signal	Increased high signal	Increased high signal $\pm$ cortical defect

**Table 4.5 Low-risk and high-risk BSIs**

Low risk	High risk
Posteromedial tibia	Femoral neck
Fibula/lateral malleolus	Anterior cortex of the tibia
Femoral shaft	Medial malleolus
Pelvis	Talus (lateral process)
Calcaneus	Navicular
Diaphysis of second to fourth metatarsals	Proximal diaphysis of the fifth metatarsal
	Base of second metatarsal
	Great-toe sesamoids

because they are prone to delayed or non-union and/or are at high risk for progression to complete fracture.

## Management

This section focuses on general management principles for a low-risk BSI, such as one occurring at the posteromedial border of the tibia. The management of specific high-risk BSIs is summarised in Table 4.6 and detailed management is included in chapters covering different regions of the body.

Low-risk BSIs represent relatively straightforward management problems in the sense that they readily heal without complication. A two-phase approach consisting of modified activity followed by a gradual resumption of activity forms the cornerstone of management. While the overarching goal is to return the athlete to his or her

**Table 4.6 Stress fractures that require specific treatment other than rest**

Stress fracture	Treatment
Femoral neck	Non-displaced: initial bed rest for 1 week, then gradual weight-bearing Displaced: surgical fixation
Anterior tibial cortex	Non weight-bearing on crutches for 6–8 weeks or intramedullary screw fixation
Medial malleolus	Non weight-bearing cast immobilisation for 6 weeks or surgical fixation
Talus (lateral process)	Non weight-bearing cast immobilisation for 6 weeks or surgical excision of fragment
Navicular	Non weight-bearing cast immobilisation for 6–8 weeks or surgery
Metatarsal—2 <sup>nd</sup> base	Non weight-bearing for 2 weeks; partial weight-bearing for 2 weeks
Metatarsal—5 <sup>th</sup> base	Cast immobilisation or percutaneous screw fixation
Sesamoid bone of the foot	Non weight-bearing for 4 weeks

pre-injury level of function in the shortest time possible without compromising tissue level healing, it is generally acknowledged that there is more to the successful management of athletes with a BSI. The high recurrence rate of BSIs indicates that a central goal for clinicians when managing low-risk BSIs should be to identify and modify potential risk factors for future BSIs. Using the concept that BSIs occur when the load being applied exceeds a bone's ability to resist the load without microdamage accumulation, runners with a BSI require strategies to either reduce the load being introduced or increase the load-bearing capacity of their skeleton.

## Phase 1. Initial management

### Activity modification

There is no question that temporary discontinuation of usual activity and the introduction of a variable period of modified activity is required in the initial management of low-risk BSIs in order to permit tissue-level healing and prevent pathology progression. However, the duration and extent of activity modification is highly variable and is decided upon on an individual basis using pain as the principal guiding variable. The presence of pain either during or after an activity indicates that the pathological site is being excessively loaded for the current stage of healing and that loading needs to be titrated.

In the initial stages of BSI management, the goal is for the athlete to be pain-free during and after usual activities of daily living (ADLs). Cushioned shoes and/or insoles may provide assistance with dissipating impact forces during ADLs in athletes with a rearfoot or leg BSI,<sup>67, 68</sup> whereas athletes with a BSI within the mid or forefoot may consider wearing a stiff soled shoe to reduce bending forces and symptoms.<sup>69</sup>

Walking should be minimised to that essential to perform ADLs and must use a normal gait pattern. If a normal gait pattern cannot be used or symptoms are produced either during or after walking, partial weight-bearing via the use of assistive gait devices should be considered. Alternatively, a pneumatic leg brace may be introduced to promote pain-free gait in the case of BSIs of the fibula or posteromedial border of the tibia.<sup>70</sup> If a pain-free normal gait pattern cannot be achieved, a short period in a walking boot or of non weight-bearing may be considered. However, in each scenario progression to unassisted pain-free gait should be sought as soon as possible.

Athletes need to be pain-free not only during, but also after activities. The presence of resting and/or night pain is a sign that the underlying pathology may have an inflammatory component. While resting pain does not typically require specific intervention as it is usually short term and abates with activity modification, some

athletes may consider non-steroidal anti-inflammatory drugs (NSAIDs) or other analgesics. The use of these agents should be discouraged beyond a few days because of their ability to mask pain and subsequently influence activity progression and their potential to impede tissue-level healing when taken for prolonged periods.<sup>71</sup>

### Identification and initial management of potential risk factors

The initial period following BSI diagnosis is a useful time to evaluate and begin addressing potential contributing factors as it is often the time when an athlete gives most attention. A detailed activity history is important. Consider not only usual and recent changes in activity frequency, duration and intensity, but also unusual or new participation in physical activities beyond running. BSI risk reflects the sum of all bone loading and loading from non-running activities may be enough to push an athlete beyond their injury threshold. Note should also be taken of any recent changes in running surfaces, shoes/ inserts or technique. By combining knowledge of recent running progressions with knowledge of lifelong physical activity history, it may be possible to provide a runner returning from a BSI with advice with regards to future running program design. For instance, novice runners with a minimal physical activity history may need to progress their training program at a slower rate so as to not overload the skeleton and disrupt the homeostasis between microdamage formation and removal.

History taking in an injured athlete should also assess factors influencing the ability of their skeleton to resist loading. It is essential to obtain a history of the patient's general health, medications and personal habits to ensure that there are no factors that may influence bone health. A past history of BSIs (and other bone injuries) and current body mass index of less than 19 are strong risk factors for BSIs that require assessment and thorough exploration.<sup>6, 8</sup>

A full dietary history should be taken with particular attention paid towards the possible presence of deficits in energy intake and/or eating disorders, and calcium and vitamin D intake. A maternal family history of osteoporosis or low bone mineral density should be explored and a detailed menstrual history should be taken in female runners including their age of menarche and subsequent menstrual status. Identification of any issues of concern warrants appropriate referral when indicated, remembering that consultation for a BSI may be the first time that an athlete's issues associated with their relative energy deficiency are identified.

In addition to history taking, initial assessment and management of potential factors influencing bone loading can be explored. To guide the interventions and formulate

an initial biomechanical impression of the athlete, it is important to gather as much circumstantial evidence as possible. Such evidence may come from recent videos of the athlete running, assessment of their shoe wear pattern, their history of overuse injuries and whether there is a unilateral predominance, static posture and alignment, and hip, knee and foot mechanics during non-painful activities such as walking or single-leg squats.

Depending on the individual athlete and the preliminary examination findings, initial biomechanical interventions can be introduced to maintain what the athlete already has or address suspected deficits. Activities can include muscle strength, endurance and control training and interventions for muscle length and joint mobility. Key areas to consider include control, endurance and strength at the hip, knee and ankle, core stability, and strength of the intrinsic and extrinsic muscles of the foot. The activities may need to be modified in order to be pain-free, and are often performed in non or partial weight-bearing.

### Maintenance of physical conditioning

Maintaining conditioning during recovery is important for as seamless a return to activity as the athlete's pathology permits. Conditioning activities should be introduced early and can include cycling, swimming, deep-water running and anti-gravity treadmill training. The latter two methods may be most specific in running athletes as they more closely reproduce the neuromuscular recruitment patterns involved in running. Anti-gravity treadmill training is not introduced until a runner is pain-free during both walking and ADLs. In the interim, deep-water running can be introduced as long as the athlete is pain-free both during and after sessions.

### Accelerating tissue healing

It would be beneficial to provide an athlete with a means of accelerating healing of their BSI. While there are no proven methods of accelerating BSI healing, a number of candidate methods have been proposed. Low intensity ( $<1.0 \text{ W/cm}^2$ ) pulsed ultrasound (LIPUS) therapy currently has the greatest support given its observed beneficial effects on complete bone fractures.<sup>72</sup> LIPUS has been effective in stimulating union in 98% and 94% of BSIs displaying delayed and non-union, respectively.<sup>73</sup> However, the benefits of LIPUS on uncomplicated BSIs currently remain unclear. Extracorporeal shock wave therapy and electromagnetic and capacitive coupled electric fields have also been considered as modalities for promoting BSI repair, but studies of their effects have principally been limited to recalcitrant BSIs. At this stage, the use of electrotherapeutic agents to accelerate BSI healing cannot be recommended.

A number of pharmaceutical agents may facilitate BSI healing but currently none are accepted as standard treatment. They include bisphosphonates<sup>74</sup> and the anabolic therapies parathyroid hormone and anti-sclerostin antibody therapy. Parathyroid hormone, when administered intermittently, promotes osteoblastogenesis and osteoblast survival. Anti-sclerostin antibody therapy inhibits osteocyte-secretion of sclerostin to facilitate Wnt signalling and subsequently promote osteoblast proliferation and function. Both agents stimulate bone formation and accelerate fracture healing in preclinical models. Whether the same fracture healing benefits carry over to humans and to BSIs currently remains unknown.<sup>75</sup>

## Phase 2. Return to running

### Beginning and progressing initial running

A graduated running program can be used in low-risk BSIs to introduce controlled loading and facilitate a return to activity in a timely, yet safe manner. While loading is central to the development of low-risk BSIs, recovery is best met by a balance between rest from aggravating activities and performance of appropriate loading. Appropriate loading can be defined as loading that does not provoke BSI symptoms either during or after completion of an activity. Once an athlete with a low-risk BSI becomes pain-free during unassisted walking, they can start reintroducing running-related loads. While there is no established protocol for returning to running during recovery from a low-risk BSI, a prescriptive program to facilitate the return of a recreational athlete to 30 minutes of running is provided in Table 4.7. The program consists of a pre-entry stage and three running stages.

Once the athlete is completely pain-free for five consecutive days during usual activities, they leave the pre-entry stage (stage 0) and commence deliberate progressive loading. Stage 1 introduces loading in 30-minute sessions separated by rest days. Sessions in this stage consist of increasing durations of jogging (defined as running at 50% of normal pace) and decreasing durations of walking. The pace of running is progressed in stage 2 until the athlete can run for 30 minutes at their usual pace, with stage 3 consisting of running on two consecutive days followed by a rest day. The last stage incorporates individualised running until there is complete return to desired running activities.

Progress through each stage of the graduated running program is determined by BSI provocation. If an athlete is able to complete a session with no BSI symptoms and they do not experience latent symptoms, they can progress to the next level during the ensuing session. However, if BSI symptoms are experienced during or after a session, the athlete must stop the session and at the next session return to the last level they were able to successfully complete.

**Table 4.7 Graduated running program to return a runner to 30 minutes of pain-free running<sup>12</sup>**

Stage 0 Pre-entry to graduated running program	
Pain during walking in normal ADLs	
Stage 1 Initial loading and jogging (50% normal pace) with increasing duration	
Level	A Walk 30 minutes
	B Rest
	C Walk 9 minutes and jog 1 minute (x3)
	D Rest
	E Walk 8 minutes and jog 2 minutes (x3)
	F Rest
	G Walk 7 minutes and jog 3 minutes (x3)
	H Rest
	I Walk 6 minutes and jog 4 minutes (x3)
	J Rest
	K Walk 4 minutes and jog 6 minutes (x3)
	L Rest
	M Walk 2 minutes and jog 8 minutes (x3)
	N Rest
Stage 2 Running with increasing intensity	
Level	A Jog 30 minutes
	B Rest
	C Run 30 minutes at 60% normal pace
	D Rest
	E Run 30 minutes at 60% normal pace
	F Rest
	G Run 30 minutes at 70% normal pace
	H Rest
	I Run 30 minutes at 80% normal pace
	J Rest
	K Run 30 minutes at 90% normal pace
	L Rest
	M Run 30 minutes at full pace
	N Rest
Stage 3 Running on consecutive days	
Level	A Run 30 minutes at full pace
	B Run 30 minutes at full pace
	C Rest
	D Run 30 minutes at full pace
	E Run 30 minutes at full pace
	F Rest
	G Run 30 minutes at full pace
Stage 4 Return to running	

Using a graduated loading program that is strictly guided by pain, the athlete and clinician can facilitate recovery while being relatively confident that there is no pathology progression. This requires the full understanding of the athlete regarding the appropriate progression through the program and adherence to the set pain levels. Patients with lower grade BSIs may be able to progress more quickly through a graduated loading program and the total duration of their program may be reduced from that outlined. Program duration should be based on the expected time course for recovery and, thus, all patients should perform individualised programs.

### Anti-gravity treadmill training

When available, an anti-gravity treadmill may initially be used in the place of overground running as anti-gravity treadmill training may allow an athlete to run at higher intensities earlier during recovery, but with lower bone loading. Thereby, anti-gravity treadmill training can be used to maintain fitness while protecting the BSI site. Anti-gravity treadmills consist of a treadmill with an air-filled pressure-controlled chamber that surrounds the lower half of the body from the waist down. Pressure in the chamber is modulated to unweight the runner in 1% increments so that they are running with between 100% and 20% body weight.

Runners with a low-risk BSI can start anti-gravity treadmill training once they are pain-free during walking and ADLs for at least a week. A typical starting point is to jog every other day three times for five minutes with between 50% and 70% body weight and one-minute recovery between repetitions. This is performed for an initial week to acclimatise to anti-gravity treadmill training while symptoms are monitored for provocation. How to progress from this initial stage is currently somewhat of an art rather than a science; however, a proposed progression is, over the next 2 weeks, to increase the duration of each run to a total of 20–30 minutes, the body weight percentage by 5–10% and the running speed.<sup>76</sup> The progression continues thereafter as long as there are no BSI symptoms until the athlete is running at their usual speed and duration with 90% body weight. Once this is achieved, ground running is introduced and relatively quickly progressed over a couple of weeks to normal durations and intensities.

### Running gait retraining

Despite a slow, progressive return to a running program, the persistence of faulty mechanics may hinder the healing process or contribute to elevated risk for a repeat injury. Therefore, it is important to identify and address any underlying mechanics when treating a runner with a BSI. Using the hypothesis that bone loading is directly

related to GRF and acceleration parameters, interventions that reduce GRFs and shock during running gait may represent a means of decreasing BSI risk. By reducing the magnitude and rate of bone loading, the number of loading cycles until microdamage accumulation and fatigue failure may be increased. A number of gait retraining techniques are currently being investigated to reduce bone loading during running, including:

- the use of accelerometer-based biofeedback to encourage reductions in loading magnitude and rate<sup>77, 78</sup>
- increasing stride rate to reduce stride length and, subsequently, vertical excursion and velocity of the centre of mass, and GRFs and tibial accelerations<sup>79-81</sup>
- modifying initial contact to encourage a more forefoot, rather than heel or rearfoot, strike pattern.<sup>82, 83</sup>

These gait retraining techniques should not be taken lightly. Athletes have typically been running with their particular gait pattern for many years and the ability of an athlete's musculoskeletal system to adapt to the nuances of their particular gait should not be underestimated. However, a history of repeat BSIs and the accumulating loss of running time is a sign that gait retraining should be considered. In doing so, it must be remembered that, when inducing a change in gait, there is always the potential of altering injury risk at an alternative site. Thus, transitioning to a new running gait should be performed slowly and may be benefited by a preconditioning program.

### Running program design

Incrementing a training program too rapidly or frequently relative to an athlete's usual activities can contribute to the generation of a BSI by upsetting the balance between bone microdamage formation and its removal. Unfortunately, there is no accepted algorithm for how much an individual can modify their training program before excessively heightening their BSI risk. The historical rule of thumb has been to change a training program by no more than 10% per week to reduce injury risk. However, this 'rule' is not generalisable on an individual basis, with different runners being able to tolerate more or less change before development of an injury.<sup>84</sup>

In order to provide an athlete returning from a BSI with appropriate advice regarding the design and advancement of their running program, it is important that they recall as much as they can of their pre-injury training regime. This should include information on changes in any feature that may have altered the load being introduced to the skeleton, including training intensity, duration, frequency, type, surface, technique, shoes and so on. In addition, recovering athletes should be encouraged to maintain a training diary containing these

data, to not only track their training progress, but also to provide reliable data regarding their training program for future reference.

In addition to the obvious limiting of the magnitude and number of training variables changed at any one given time, the use of cyclic training methods should be encouraged. Cyclic training may involve the introduction of rest periods into a training program, or the replacement of overground training sessions with lower bone-loading activities such as deep-water running or anti-gravity treadmill training. This may involve a monthly regime of 3 weeks of training and 1 week of rest or low-load activities.

### Healing of bone stress injuries

Healing is assessed clinically by the absence of local tenderness and functionally by the ability to perform the precipitating activity without pain. It is not useful to attempt to monitor healing with X-ray or radioisotopic bone scan.<sup>85</sup> CT scan appearances of healing stress fractures can be deceptive as in some cases the fracture is still visible well after clinical healing has occurred.<sup>86</sup> Figure 4.9 shows the relationship between imaging appearance and the various stages of bone stress.

### Osteitis and periostitis

Osteitis (impaction trauma or primary inflammation of bone) and periostitis (abnormal histological appearance of periosteal collagen) are also considered overuse injuries. The condition known as osteitis pubis occurs in the pubic bones of the pelvis and is characterised by deep-seated pain and tenderness of the symphysis pubis with generalised increased uptake on the radioisotopic bone

**Figure 4.9** MRI, bone scan and CT scan return to their normal appearance well after clinical union occurs

scan. The exact pathogenesis of this injury remains in debate (Chapter 32).

Periostitis occurs commonly, mainly at the medial border of the tibia, a condition often known as 'shin splints'. In this condition, tenderness along the medial border of the tibia at the interface between the muscles and their bony attachments corresponds with an area of increased uptake on the bone scan.

The treatment of periostitis consists of local symptomatic therapy as well as unloading the muscle contraction on the periosteum. In the shin, strain may be reduced by altering the biomechanics through controlling excessive pronation. Soft tissue therapy and stretching may also be effective.

### Apophysitis

Bony injury may occur at the attachment of the strong, large tendons to the growth areas. This condition is called 'apophysitis' and the most common examples are Osgood-Schlatter disease at the attachment of the patellar tendon to the tibial tuberosity and Sever's disease at the attachment of the Achilles tendon to the calcaneus. A full description of apophysitis is given in Chapter 44.

### ARTICULAR CARTILAGE

Overuse injury can affect the articular cartilage lining of joints, particularly in osteoarthritis. Changes range from microscopic inflammatory changes to softening, fibrillation, fissuring and, ultimately, to gross visible changes. In younger people, this pathology can arise at the patella (patellofemoral syndrome), but it is important to note that the pain of patellofemoral syndrome can occur in the presence of normal joint surfaces. This very common condition is discussed in Chapter 36.

### JOINT

Inflammatory changes in joints associated with overuse are classified as synovitis or capsulitis. Examples of these problems are the sinus tarsi syndrome of the subtalar joint and synovitis of the hip joint.

Impingement syndromes occur when a bony abnormality, either congenital or acquired, causes two bony surfaces to impinge on each other (e.g. femoro-acetabular impingement at hip, posterior impingement at ankle) or impinge on a structure passing between them (e.g. supraspinatus tendon in shoulder) causing damage to that structure. Treatment requires either removal of the structural abnormality or modification of biomechanics to relieve the impingement.

### LIGAMENT

Overuse injuries of ligaments are uncommon, but may occur as a result of excessive load.

Injury to the medial ulnar collateral ligament of the elbow in baseball pitchers is the most common ligamentous overuse injury.<sup>87</sup>

### MUSCLE

Muscle may respond to overuse in a number of ways, including myofascial pain, chronic compartment syndromes and exercise-induced muscle soreness.

#### Myofascial pain: trigger points or just sore spots of unknown origin?

The clinical phenomenon of localised palpatory muscle pain is one that is well known to sports medicine practitioners. The concept of myofascial pain caused by trigger points is a popular explanatory model with several putative pathophysiological mechanisms having been proposed to explain these findings.

#### The trigger point model

The myofascial trigger point theory was pioneered by Travell and Simons over 30 years ago.<sup>88</sup> The theory postulated by Travell and Simons has, until recent times, had widespread acceptance. Trigger points are classified as either active or latent, with only active trigger points being symptomatic. Active trigger points are thought to be tender to palpation, generate a local twitch response on stimulation and create a predictable pattern of referred pain on compression.

The term myofascial pain syndrome is commonly used to describe the clinical signs thought to represent active trigger points. As per Travell's original description, this is characterised by:

1. localised areas of deep muscle tenderness or hyperirritability, referred to as 'trigger points'—palpable taut bands within the muscle associated with muscle inhibition, intolerance to stretch, as well as autonomic symptoms such as vasoconstriction or dilation
2. a predictable, discrete reference zone of deep aching pain which is worsened by palpation of the trigger point. This may be located in the immediate region of or remote from, the trigger point.

Dommerholt expanded on Travell's theory, postulating a role for excessive release of acetylcholine from dysfunctional neuromuscular endplates, causing taut bands and subsequent muscle ischaemia. This muscle ischaemia was thought to precipitate an energy crisis in the muscle, causing the release of pro-inflammatory molecules, thereby activating nociceptive neurons.<sup>89</sup> Newer theories currently subject to research include the principle of neurogenic inflammation leading to sensitisation of innervated muscle,<sup>90</sup> secondary allodynia

secondary to irritation of deeper structures such as ligament or bone (central sensitisation),<sup>91</sup> descending inhibitory pain modulation,<sup>92</sup> and diffuse noxious inhibitory control.<sup>93</sup>

Despite the abundance of hypothesised theories regarding the pathophysiology of myofascial trigger points, their existence is not widely accepted in the medical literature. Furthermore, much of the research to date is limited by significant methodological flaws.<sup>90</sup> Consequently, despite many years of research endeavour, the diagnosis, treatment and pathophysiological mechanisms underlying localised palpatory muscle pain remains an area of vigorous debate.<sup>90, 94</sup> Despite this, the lack of definitive anatomical or biochemical evidence has not prevented the concept of trigger points from achieving popularity among sports and musculoskeletal medicine clinicians.

While many alternative hypotheses of myofascial trigger points have been proposed since Travell's original description, none have been widely accepted. Consequently, there are no generally accepted diagnostic criteria for myofascial trigger points.<sup>95</sup> Meakins articulated a key component of this controversy by coining the term 'sore spots of unknown origin'.<sup>92</sup> This reflects the unreliability of identifying taut bands in skeletal muscle<sup>96-99</sup> while acknowledging the acceptable reliability of localising muscle tenderness based on patient feedback, presumably through the removal of the subjective phenomenon of palpatory pareidolia.<sup>100</sup>

A diagnosis of trigger points causing pain must only be made following the appropriate exclusion of alternative diagnoses. Failure to respond to appropriate treatment should necessitate a review of the diagnosis.

### Pain from trigger points

The onset of pain from trigger points may follow either an acute or subacute pattern. Some patients may be able to recall the onset of pain, often noting a precipitating event, while others will report a gradual onset of pain over time. Where a precipitating event is recalled, the initial amplitude of pain is often only minor, with a subsequent progressive increase over time.

In contrast, the onset of pain due to acute mechanical tissue trauma, as with a ruptured ankle ligament, displays a very rapid onset to near maximal severity (though exceptions such as meniscal tears do exist). Subacute onset trigger point pain may be more difficult to identify on history, as patients often present following many months of pain. In this situation, identification of aetiological or exacerbating factors, such as inappropriate loads or sustained postures, is useful.

Fluctuations in pain, over the course of a day or longer periods, are typical of trigger points and suggestive that

acute tissue trauma is not involved. Fluctuations usually follow particular events, such as lying on a particular side in bed or computer-based work. This is quite distinct from the diurnal variation as seen in inflammatory conditions. While the pain of trigger points has a different temporal pattern to that of tissue trauma, it is important to note that trigger points are often secondary to and therefore frequently coexist with acute tissue trauma.

The spatial distribution of pain also differs between that of trigger points and localised tissue trauma. Travell describes predictable referred pain patterns attributed to myofascial trigger points,<sup>97</sup> derived from the injection of hypertonic saline into muscle. As referred pain tends to be poorly localised, patients often indicate the location of referred pain with a wave of the hand. Direct stimulation of tissue nociceptors in contrast, as may occur with a ligament rupture, typically results in more precisely located pain, able to be indicated with a pointed finger.

### Clinical features

Recent years have seen attempts to utilise medical imaging techniques in the detection of myofascial trigger points. Unique features of localised elliptical hypoechogenicity corresponding to palpable findings have been demonstrated with sonoelastography,<sup>98-100</sup> while magnetic resonance elastography has demonstrated the ability to identify increased tissue stiffness in muscle.<sup>101, 102</sup> A lack of control groups in this research, however, limits the ability to draw firm conclusions regarding the role of myofascial trigger points in these findings.

While Travell describes palpable taut bands in muscle as a diagnostic feature of trigger points,<sup>97</sup> several controlled studies have found this finding to be unreliable and therefore not recommended.<sup>103-106</sup>

In contrast, the identification of localised muscle tenderness based on patient feedback has shown acceptable inter-examiner reliability,<sup>96</sup> presumably by removing the subjective phenomenon of palpatory pareidolia. Thus, on the basis of existing research, the clinical identification of trigger points should be based primarily on localisation of maximally tender points within muscle. Consideration also may be given to the reproduction of any referred pain patterns.

### Treatment

Evidence for the effectiveness of trigger point treatments is inconclusive.<sup>107</sup> Despite widespread anecdotal reports of effectiveness, systematic reviews and blinded randomised placebo-controlled studies show no clinical worthwhile effect of these treatments over sham, standard care or exercise therapy.<sup>108-110</sup> The apparent contradiction between the anecdotal experience of many clinicians and research findings may be explained by the phenomenon

of the localised twitch response, an involuntary localised transient contraction within the muscle being treated. Many experienced practitioners elicit multiple twitch responses when treating a muscle. In contrast, much of the research conducted on trigger point therapy has not placed any emphasis on the localised twitch response, failing to account for its presence or absence in findings of efficacy.

A variety of methods of treating trigger points have been described in the literature, with the most effective method unclear. These include spray and stretch, digital ischaemic pressuring, dry needling, wet needling, proprioceptive neuromuscular facilitation and muscular 'stripping'. Published research on these methods is frequently sparse, confounded by methodological limitations or both.

The most rigorously researched of the above methods are dry needling, wet needling and digital ischaemic pressure. Wet needling is generally considered to be at least equal to alternative methods. In many jurisdictions, however, injection therapy is limited to appropriately qualified medical practitioners. The application of dry needling has been shown to be a reasonable alternative. Subsequent digital ischaemic pressure applied immediately following needling therapy may further improve efficacy.

Dry needling and other techniques used in the treatment of trigger points are discussed in Chapter 17.

### Chronic compartment syndrome

Chronic compartment syndrome (CCS) refers to the intermittent and reversible pathologic elevation of compartment pressures following exertion.<sup>111</sup> The condition usually affects the lower leg but may also occur in the forearm in the sports of tennis, rock climbing and weightlifting.<sup>112</sup>

The muscles of the lower leg are divided into a number of compartments by fascial sheaths, which are relatively inelastic thickenings of collagenous tissue. Exercise raises the intracompartmental pressure and may cause local muscle swelling and accumulation of fluid in the interstitial spaces. The tight fascia prevents expansion. This impairs the blood supply and causes pain with exertion. Compression of neurological structures may also contribute to the clinical presentation. Muscle hypertrophy may also precipitate CCS.

The main symptom of CCS is pain that commences during activity and ceases with rest. This differs from other overuse injuries such as tendinopathies, where pain may be present with initial exercise, then diminish as the affected area warms up, only to return following cessation of activity. The role of imaging in the diagnosis of CCS is unclear.<sup>113</sup>

The gold standard for diagnosis of CCS has always been measurement of compartment pressures at rest and during

pain-provoking exercise. Compartment pressure testing is described in Chapter 15. In recent years, various authors have expressed reservations regarding the reliability and validity of these tests.<sup>114-116</sup>

Surgical treatment—fasciotomy (release of the fascia) or fasciectomy (removal of the fascia)—has always been the mainstay of treatment of compartment syndromes. Results of surgery are often disappointing with a high incidence of recurrence of exercise-related leg pain. The role of surgery is now being questioned.<sup>117</sup>

A biomechanical basis of the exercise-related leg pain has been suggested by Franklyn-Miller,<sup>118</sup> and changes in running gait has shown promising initial results in the management of these patients.<sup>119</sup>

### Exercise-induced muscle soreness

Exercise-induced muscle soreness is a common complaint during or immediately following vigorous unaccustomed exercise. Muscle soreness that develops 24–48 hours after unaccustomed high-intensity activity is known as delayed onset muscle soreness (DOMS). DOMS appears to be more severe after activities that involve eccentric muscle contractions; that is, when muscle contracts whilst simultaneously lengthening. Activities that involve both high muscle forces and eccentric muscle contractions, such as skiing and downhill running, are a common cause of DOMS in untrained individuals.

The exact cause of acute exercise-induced muscle soreness and DOMS is unclear. Although debate in the literature about the mechanism of muscle soreness is ongoing, the general consensus is that the soreness is caused by microtrauma of muscle cells and connective tissue. Microtrauma is followed by a local inflammatory process within the extracellular space which sensitises nerve endings via mechanical, chemical or thermal stimulation.<sup>120-122</sup>

### Signs and symptoms

Exercise-induced muscle soreness is often accompanied by muscle stiffness, ache and mild cramping. Symptoms can persist for several hours post exercise before resolving.<sup>121</sup> DOMS is characterised by tenderness on palpation and a sense of stiffness with physical activity. Soreness can peak around 48 hours after exercise. Resolution of symptoms can take up to 10 days.<sup>120</sup> Soreness can vary from mild discomfort to incapacitating pain; this is largely dependent on the intensity and volume of training, as well as the actual inducing event.

Importantly, DOMS can be associated with muscle strength deficits, which may affect physical performance. Strength deficits associated with DOMS are typically greatest between 24 and 48 hours after activity.<sup>123, 124</sup> A reduction in muscle power and reduced joint range

of motion may also affect an athlete's performance. Local muscle swelling and intracellular proteins in the blood are also common signs.<sup>120, 123-125</sup> Exercise-induced muscle soreness and DOMS are often associated with elevated levels of creatine kinase in the blood. However, given the self-limiting nature of acute muscle soreness and DOMS, blood tests are rarely warranted and the clinical interpretation of such tests is unclear.<sup>125</sup>

## Management

Management strategies in the treatment of DOMS focus on encouraging healing and recovery of the inflamed and damaged muscle tissue. Intense exercise during the symptomatic period can potentially cause more micro-trauma and muscle injury, particularly as strength, power and coordination of movement are compromised. Therefore, during the symptomatic period, training and competition performance should be modified accordingly.

Common modalities used to treat exercise-induced muscle soreness and DOMS include massage, cryotherapy, stretching and active recovery. The management of DOMS is described in Chapter 13.

## Prevention of exercise-induced muscle soreness and delayed onset muscle soreness

Prevention of exercise-induced muscle soreness should be centred on a properly planned training program, which adequately addresses strength, power, endurance and quality of movement. Adequate periods of training and conditioning are needed before individuals participate in strenuous activity to ensure the exercise-induced muscle soreness is minimised and more serious injuries are prevented. DOMS occurs less in those who train regularly, although even trained individuals may become sore after an unaccustomed exercise bout. There is little evidence to support the use of static stretching to prevent acute muscle soreness and DOMS.<sup>121</sup> Variable results have been shown with preventative approaches such as the use of vitamins C and E and protein supplements.<sup>126</sup> Understanding an athlete's current training volume including exercise intensity, duration, rate of progression and recovery will provide a context for understanding and preventing future episodes of muscle soreness.

## TENDON

### Tendon overuse injury (tendinopathy)

with JILL COOK, CRAIG PURDAM

Tendon overuse injuries provide a major proportion of the sports clinician's workload. The clinical presentation is straightforward in many cases—the patient presents with tendon pain during or after activity (Table 4.8)

and loading tests demonstrate increased pain with increased load.

In the 1980s, the underlying pathology was often referred to as 'tendinitis'—this was associated with a belief that cellular inflammation contributed to the pathological process. Histopathological studies in the 1990s indicated that inflammatory cells were absent in patients who underwent surgery for tendon pain. Recently, low levels of inflammatory cells and markers have been demonstrated, but it is unlikely that inflammation is a key driver of tendon pathology and a resident cell-driven process remains the best-supported pathoaetiology.

The pathological findings at surgery are consistent with 'tendinosis'. The boxed item illustrates tendon pathology—'tendinosis'—at the anatomical level (Fig. 4.10) and at two microscopic levels (Figs. 4.11 and 4.12). The pathology is also summarised in Table 4.9.

## A contemporary model of a continuum of tendon pathology

Tendon authorities Jill Cook and Craig Purdam have proposed that tendon pathology should be considered as a continuum.<sup>127</sup> They contend that the dichotomy of 'normal' and 'degenerative tendinosis' is too simplistic. Importantly, their three-part classification has implications for treatment, and so it is summarised here and illustrated (Fig. 4.13).

### Stage 1. Reactive tendinopathy

This refers to the non-inflammatory response of tendon cells and matrix proteins to an acute tensile or compressive overload. Tendon cells become activated and may proliferate in this stage—they become more prominent—consistent with the appearance of cells that

**Table 4.8 Clinical presentation of patients with overuse tendon pain (tendinosis)**

- Pain after exercise or, more frequently, the following morning upon rising.
- It can be pain-free at rest and initially becomes more painful with use.
- Athletes can 'run through' the pain or the pain disappears when they warm up, only to return after exercise when they cool down.
- Athletes are able to continue to train fully in the early stages of the condition; this may interfere with the healing process.
- Examination reveals local tenderness and/or thickening.
- Frank swelling and crepitus may be present, although crepitus is more usually a sign of associated tenosynovitis (it is not 'inflammatory fluid').

## Tendinosis: what is it?

This box illustrates the pathology found at end-stage tendinopathy—when symptoms have been present for at least 3 months. The illustration (Fig. 4.10) is based on pathological specimens (Figs 4.11 and 4.12) obtained at surgery for chronic sports-related tendon pain.

**Figure 4.10** The contrasting features of normal tendon (left side) and tendinosis (right side). Characteristic features at this macroscopic level are the collagen fibres of different sizes in disarray, abnormal cell numbers (decreased and increased), abnormally prominent blood vessels and an increase in matrix proteins

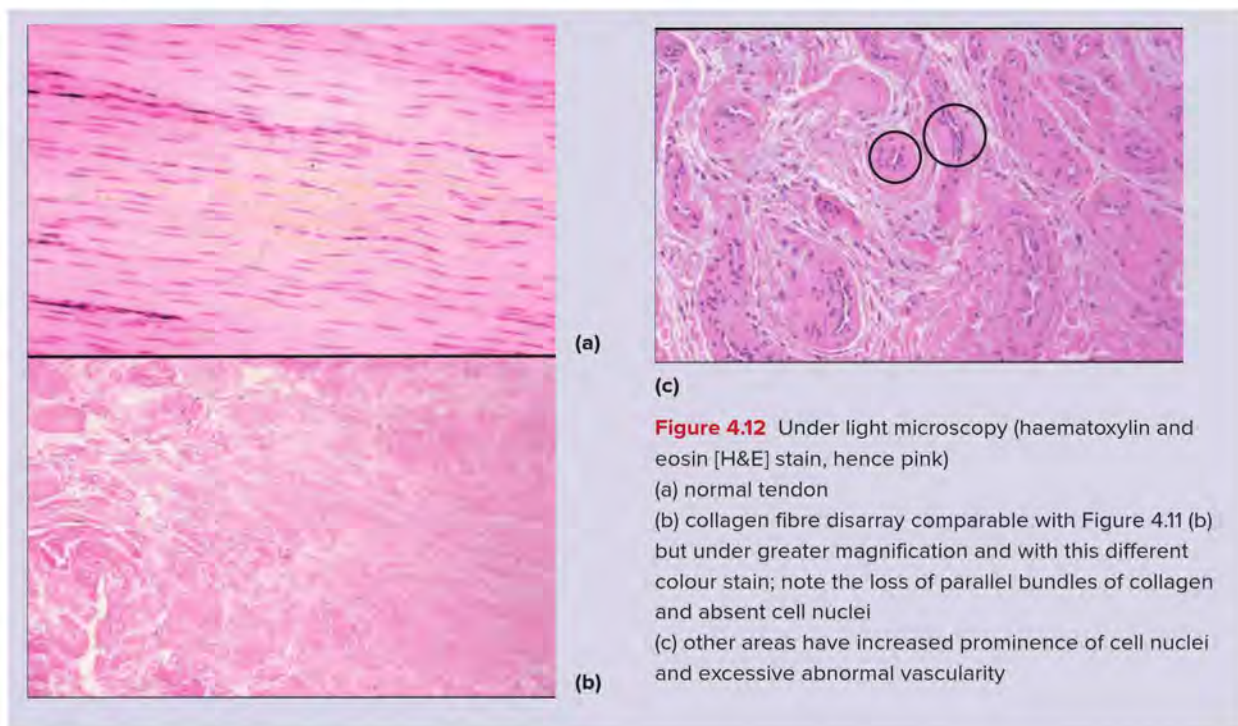

(a)

(b)

**Figure 4.11** Under polarised light microscopy: (a) normal tendon has tightly bundled parallel collagen fibrils with a characteristic golden reflectivity; (b) a specimen from a patient with chronic patellar tendinopathy showing collagen fibril separation and frank discontinuity within some fibrils

*continued*

**Table 4.9 Five elements of normal tendon compared with the characteristic elements of end-stage tendon overuse injury**

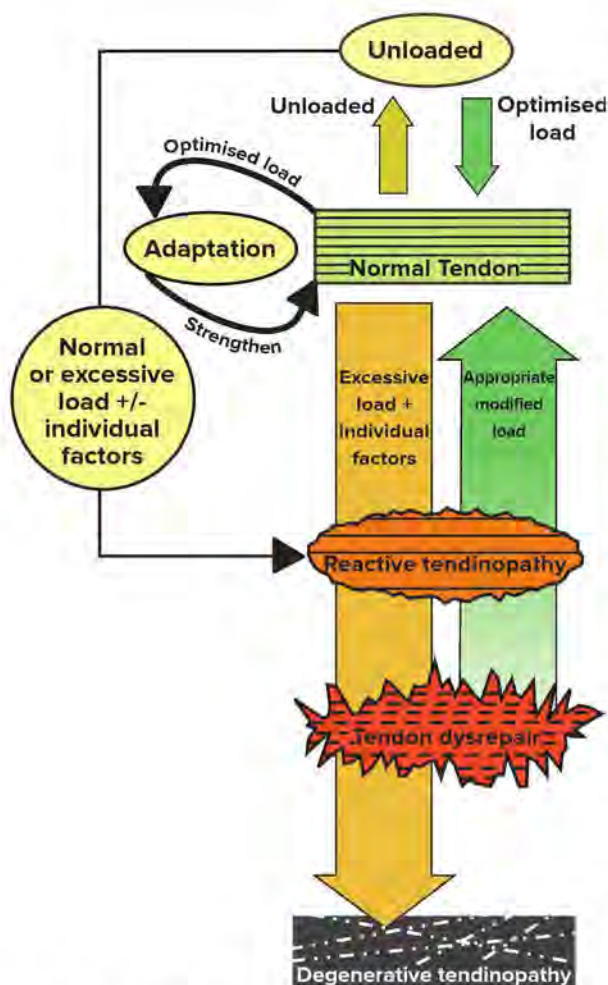

Tendon element	Normal tendon	Changes that occur in response to excessive tendon loading
Cells—tenocytes	Tendon cells are spindle-shaped and nuclei cluster in longitudinal chains on microscopy	Tissue has proliferation of cells with abnormally rounded nuclei (Fig. 4.12c) and areas with fewer than normal cell numbers (Fig. 4.12b)
Ground substance or 'matrix' proteins	The ground substance in the matrix is minimal and is not visible when stained for light microscopic viewing	Increased amount of ground substance/matrix proteins which stain and are visible under light microscopy
Collagen	Linear and tightly bundled and has a characteristic crimp under polarised light	Disrupted—both longitudinally and in its bundles (Fig. 4.12b)
Nerves	Minimal intratendinous nerves, some innervation of connective tissue in and around the tendon	Abnormal ingrowth of nerves (mostly sympathetic) and a preponderance of neuropeptides
Vessels	Minimal vascularity when examined histologically or by using ultrasound	Prominent vessels histologically or using ultrasound (Fig. 4.12c)

are producing repair proteins, especially proteoglycans. This results in a short-term thickening of a portion of the tendon that reduces stress. This differs from the normal tendon adaptation to tensile load that generally occurs through tendon stiffening with little change in thickness. This is seen clinically in the acutely overloaded tendon and is more common in the younger

person. It also arises when there is trauma to a tendon, such as a direct blow.

At this stage, both ultrasound and MRI show mild fusiform swelling—greater tendon diameter with little disruption of the collagen fascicles. The change in imaging appearance is mainly derived from the increase in bound water within the matrix proteins (proteoglycans).

**Figure 4.13** The Cook–Purdum model to help clinicians understand the relationship between loading/unloading and the several stages of tendon pathology

REDRAWN FOR CLINICAL SPORTS MEDICINE. REPRODUCED WITH PERMISSION FROM BRITISH JOURNAL OF SPORTS MEDICINE<sup>27</sup>

### Stage 2. Tendon dysrepair

This describes a worsening tendon pathology with greater matrix breakdown. Tendon cells are more prominent and take on a rounded appearance (chondrocytic). Protein production increases—both matrix proteoglycans and collagen. As a result of these changes, collagen separates and the matrix becomes somewhat disorganised. The disruption of the matrix may allow for some ingrowth of vessels and nerves.

This is seen clinically in overloaded tendons in the young, but it may appear across a spectrum of ages and loading environments. The transition from the previous stage may be difficult to detect clinically, but imaging

will reveal more focal changes of hypoechogenicity on ultrasound. There may be a mild increase in vascularity on colour or Doppler ultrasound. MRI reveals a swollen tendon with increased signal.

### Stage 3. Degenerative tendinopathy

This is the stage that is present in patients who undergo surgery for chronic tendon pain—it is the 'end stage' of tendon overuse injury. The matrix and cell changes described in stages 1 and 2 may progress so that areas of apoptosis (absent cell nuclei due to cell death) are evident. Large areas of matrix are disordered and filled with cells, vessels, matrix breakdown products and disordered type I, II and III collagen. The structure of the tendon is heterogeneous—degenerative pathology is interspersed between other stages of pathology and normal tendon.

This pathology exists in the older person, or the younger person or elite athlete with long-term tendon overload. Typically, it is seen in a middle-aged, recreational athlete with focal tendon swelling and pain (e.g. mid-Achilles region). The tendon may have focal nodular areas with or without general thickening. This is the type of tendon that may rupture if the degenerative pathology is extensive.

In this stage, compromised matrix and vascular changes are obvious on ultrasound scans as hypoechogenic regions with few reflections from collagen fascicles. Larger vessels are usually prominent on Doppler ultrasound. MRI shows increased tendon size and intratendinous signal. The changes are more focal than spread throughout the tendon.

### Reactive on degenerative tendon

Degenerative tendinopathy exists in a tendon that has normal tissue. When these tendons are overloaded, the degenerative part of the tendon is unlikely to take load because of a lack of matrix structure, so the load is borne by the normal part of the tendon. Overload can induce a reactive change in this normal tendon, resulting in a reactive on degenerative tendon.

### Other terms associated with overuse tendon injuries

Although the most-used clinical label for tendon overuse injuries is 'tendinopathy' as above and is used in specific chapters of this book (i.e. Achilles tendinopathy), the terms 'paratenonitis', 'partial tear' and 'tendinitis' need definition.

#### Paratenonitis

This term includes peritendinitis, tenosynovitis (single layer of areolar tissue covering the tendon) and tenovaginitis (double-layered tendon sheath). This

occurs in situations where the tendon rubs over a bony prominence and/or where repeated movement directly irritates the paratenon. Uncommonly, it can coexist with partial tears and tendinosis.

#### Partial tears

The term 'partial tear of a tendon' should be reserved for a macroscopically evident subcutaneous partial tear of a tendon, an uncommon acute, not overuse, injury, at least in the Achilles and patellar tendon (see Chapter 3). The distinction on imaging between tendon degeneration and partial tear is difficult because there are no definite signs that allow a clear distinction and diagnosis is reliant on radiologist expertise.

### Principles of rehabilitating lower limb tendinopathy

#### Before starting

Ensure that the diagnosis is correct and the pain is from the tendon. Tendon pain will respond best to the loading program described.

#### Decide the start and end of the program

Start at the functional level and capacity of the person. This can be determined from a comprehensive examination of function and its relationship to pain. The program should end at the functional level required for the person to return to their desired activity level. This can be determined from their history; both the sport that the person has been involved in as well as the sport or activity and level they want to return to. The sport and the level will determine how much endurance is required for the tendon, associated muscle and kinetic chain.

A schematic of tendon rehabilitation, improving tendon capacity with progressive loads, is shown in Figure 4.14.<sup>128</sup>

#### Stages of rehabilitation

##### Stage 1. Isometric exercise

Isometrics are a great way to relieve tendon pain, hence a good spot to start as most clinical presentations are for tendon pain. Isometric exercises result in pain relief in

**Figure 4.14** Schematic of tendon rehabilitation, improving tendon capacity with progressive loads. Introduction and progression of endurance and compressive loads are critical within each stage. The start and end points of rehabilitation will vary between individuals

WITH PERMISSION FROM BRITISH JOURNAL OF SPORTS MEDICINE<sup>128</sup>

7–10 days in a reactive on degenerative tendon, but can take up to 6–8 weeks in a purely reactive tendon.

Isometrics have been shown to immediately relieve patellar tendon pain more than isotonic exercise and the pain relief was sustained for 45 minutes.<sup>129</sup> Rio et al. also showed in this study that isometric exercise normalised cortical inhibition that was excessive in patellar tendinopathy, whereas isotonic exercise had no effect on cortical inhibition.<sup>129</sup>

Clinically, isometrics are therefore used to manage pain in the reactive or reactive on degenerative phase of tendon pathology. The research protocol in young, jumping men was four repetitions of 45 second holds at 70% of maximal voluntary contraction and this level of loading is appropriate for the painful athletic tendon.<sup>129</sup> This level of loading may be too much for the older person with clinical tendinopathy, and varying both the load and time held is necessary. Using body weight loads for longer holds is a simple place to start and adding weights often requires equipment. As isometrics may need to be done more than once a day, doing them at home is the best option. Hiring gym equipment such as a seated calf raise for a few months can help adherence to regular isometric exercise.

### Stage 2. Isotonic exercise

Once the pain has settled and/or is stable at a low level, isotonic exercises can be started. These are slow and heavy concentric/eccentric exercises directed at improving strength in the muscle tendon unit. These are best performed with a slightly longer eccentric component (e.g. three-second concentric, four-second eccentric) for brain plasticity. These should be performed for every muscle in the kinetic chain that has a functional deficit—most likely the anti-gravity muscles such as the calf (gastrocnemius and soleus), quadriceps and gluteal muscles. Hamstrings are clearly addressed as a priority in hamstring tendinopathy.

Isotonic exercises should be continued until there is good strength in the affected musculotendinous unit and the agonists in kinetic chain function. This can take up to 12 weeks in a profoundly unloaded limb. An endurance set is added if the person requires higher levels of endurance for their activity. Endurance can also be added with weight-bearing exercise, such as stair climbing for either Achilles or patellar tendinopathy.

#### PRACTICE PEARL

Performing a bout of isometrics before isotonic exercises increases maximum voluntary contraction, most likely due to cortical pain inhibition.<sup>129</sup>

### Stage 3. Energy storage exercise

Once the muscles are stronger, the tendon can be loaded with energy storage exercises. To store energy in a tendon you need to do faster eccentric exercises, initially with a slower release (concentric phase), but building to stage 4 with quick energy storage and faster release. As these exercises place high loads on the tendon they are best completed only 2–3 times a week. These faster exercises need to be controlled in terms of numbers and/or time, started at a low level and gradually increased.

#### PRACTICE PEARL

It is essential to continue isotonic exercises at least two days a week throughout the entire rehabilitation program, as well as after the athlete has returned to full training and competition. Continued isometric loading before isotonic exercises may also be helpful throughout the whole program.

### Stage 4. Sport-specific energy storage and release exercise

Once the tendon can tolerate high-energy storage loads, then functional activity-specific exercises can be introduced in a clinical setting. These will replace stage 3 exercises and can only be completed 2–3 times a week. Once the tendon is tolerant to training numbers of high-level functional activities then the person can return to a controlled training environment and from there to a graduated return to competition.

## Enthesopathy

Enthesopathies occur at the bone-tendon junction, such as the Achilles tendon insertion onto the calcaneus. Enthesopathies are similar to tendinopathies in that they are primarily degenerative in nature. Treatment principles are the same.

## BURSA

The body contains many bursae situated usually between bony surfaces and overlying tendons. Their role is to facilitate movement of the tendon over the bony surface. All bursae are susceptible to injury. Typically, injuries to bursae are overuse injuries resulting from excessive shearing and/or compressive forces.<sup>130, 131</sup>

Overuse injuries in bursae are quite common, particularly at the subacromial bursa,<sup>132</sup> the greater trochanteric bursa,<sup>133</sup> the bursa deep to the iliotibial band at the knee,<sup>131, 133</sup> and the retrocalcaneal bursa separating the Achilles tendon from the calcaneus.<sup>134</sup> Overuse

pathologies affecting bursae commonly couple with other local pathologies such as tendinopathies and impingement syndromes.<sup>135, 136</sup> Symptoms include localised pain and swelling and typically increase with activity. Conservative approaches to treatment are often trialled first.

Treatment involves removal of irritating loads, reduction of inflammation and a progressive return to pain-free activity. Specific treatments including ice, electrical stimulation, iontophoresis and gentle stretching. Once initial inflammation subsides, a stretching and strengthening program for the surrounding tissues and muscles can commence. NSAIDs are widely prescribed for these conditions and corticosteroid injections, often guided by ultrasound, are considered where conservative approaches have failed.

## NERVE

Nerve entrapment syndromes occur in athletes as a result of swelling in the surrounding soft tissues or anatomical abnormalities. These may affect the suprascapular nerve, the posterior interosseous, ulnar and median nerves in the forearm, the obturator nerve in the groin, the posterior tibial nerve at the tarsal tunnel on the medial aspect of the ankle and, most commonly, the interdigital nerves, especially between the third and fourth toes, a condition known as Morton's neuroma. This condition is not a true neuroma but rather a nerve compression. These nerve entrapments occasionally require surgical decompression.

Chronic mild irritation of a nerve may result in damage manifested by an increase in neural mechanosensitivity. These may be the primary cause of the patient's symptoms or may contribute to symptoms. This concept is discussed more fully in Chapters 5 and 6.

## SKIN

The skin's integrity is constantly challenged by athletic activity, weather conditions and pathogenic organisms.

### Blisters

The skin of many athletes is subjected to friction-related forces and compounded by perspiration.<sup>137, 138</sup> Exposure to shearing and compressive forces can lead to mechanical separation of the epidermal cell layers. Hydrostatic pressure causes further separation and allows plasma-like fluid or sweat into the space to form a blister.<sup>137</sup> The repair process starts 24 hours post incident and blisters generally heal in approximately five days.<sup>137</sup> Blisters may occur at any site of friction with an external source, such as shoes or sporting equipment.

Blisters are common in marathon runners, rowers, race walkers, triathletes, hikers and in military populations. Foot blisters are painful and can have an impact on sporting performance. Sock type, race, previous hiking

or military experience and certain orthopaedic foot conditions predict the development of foot blisters in the military population.<sup>138</sup>

Foot blisters can be prevented by wearing-in new shoes, wearing socks and smearing petroleum jelly over the sock at sites of friction. Strategies to prevent blisters also serve to prevent callus. Symptomatic callus can be pared down with a scalpel blade, taking care not to lacerate the normal skin.

At the first sign of a blister, the aggravating source should be removed and either adhesive tape applied over the blistered area or blister pads should be applied. Blister pads prevent blisters by acting as a barrier between skin and shoe.

Treatment of blisters involves prevention of infection by the use of antiseptics and protection with sticking plaster. Fluid-filled blisters may be punctured and drained.

### Skin infections

Almost any cutaneous infection can afflict athletes. However, their activities place these individuals at higher risk to develop and subsequently transmit their skin ailment to competitors. Athletes acquire infections as a result of their interaction with other athletes and with the environment in which they compete. An athlete's skin is often macerated from sweating which promotes common infections in sports including bacterial, fungal and viral infections, but parasites can also afflict the athlete.<sup>139</sup>

### Dermatitis

An athlete's skin suffers repeated exposure to trauma, heat, moisture and numerous allergens and chemicals. These factors combine with other unique and less well-defined genetically predisposing factors in the athlete's skin to cause both allergic contact dermatitis (ACD) and irritant contact dermatitis (ICD). As with other cases of contact dermatitis, these eruptions in athletes present as a spectrum of acute to subacute to chronic dermatitis. Recognising the unique environmental irritants and allergens encountered by athletes is paramount to facilitate appropriate therapy and prevention.<sup>140</sup>

### Skin cancers

Skin cancers are not true overuse injuries, but perhaps can be described as 'overexposure.' Nevertheless, athletes are particularly vulnerable as many sports involve prolonged exposure to sun during training and games.

The incidence of melanoma and non-melanoma skin cancers is increasing worldwide. Ultraviolet light exposure is the most important risk factor for cutaneous melanoma and non-melanoma skin cancers. Non-melanoma skin cancer includes basal cell carcinoma and squamous cell carcinoma. Constitutive skin colour and genetic factors,

as well as immunological factors, play a role in the development of skin cancer. Ultraviolet light also causes sunburn and photoaging damage to the skin. Studies conducted within athletic populations have found that certain sports are associated with increased risk for skin cancers.<sup>141</sup>

Athletes should take care to avoid excessive exposure to ultraviolet light and in particular should avoid sunburn.

### BUT IT'S NOT THAT SIMPLE

Although it is important to have a good understanding of the conditions outlined in this chapter and Chapter 3, three important additional components are necessary for successful management of patients with sporting injuries.

#### Pain: where is it coming from?

The pain your patient feels at a particular site may not necessarily be emanating from that site. It is essential to understand pain, which is the topic of Chapters 5 and 6.

#### Masquerades

There are many medical conditions whose presentation may mimic a sporting injury. While many of these conditions are relatively rare, it is nevertheless important to keep them at the back of your mind. If the clinical pattern does not seem to fit the obvious diagnosis, then think of the conditions that may masquerade as sporting injuries. These are described in Chapter 7.

#### The kinetic chain

Every athletic activity involves movements of joints and limbs in coordinated ways to perform a task. These activities include running, jumping, throwing, stopping

or kicking. The tasks may include throwing a ball, hitting a ball, kicking a ball, jumping over an object, or propelling the body through air or water. Individual body segments and joints, collectively called links, must be moved in certain specific sequences to allow efficient accomplishment of the tasks.

The sequencing of the links is called the kinetic chain of an athletic activity.<sup>142</sup> Each kinetic chain has its own sequence but the basic organisation includes proximal to distal sequencing, a proximal base of support or stability, and successive activation of each segment of the link and each successive link. The net result is generation of force and energy in each link, summation of the developed force and energy through each of the links, and efficient transfer of the force and energy to the terminal link.

Injuries or adaptations in some areas of the kinetic chain can cause problems not only locally but distantly, as distal links must compensate for the lack of force and energy delivered through the more proximal links. This phenomenon, called catch-up, is both inefficient in the kinetic chain and dangerous to the distal link because it may cause more load or stress than the link can safely handle. These changes may result in anatomical or biomechanical situations that increase injury risk, perpetuate injury patterns or decrease performance. For example, a tennis player with stiffness of the lumbar spine may overload the rotator cuff muscles while serving to generate sufficient power and, thus, develop a tear of the rotator cuff muscles.

These deficits in the kinetic chain must be identified and corrected as part of the treatment and rehabilitation process. We will be constantly returning to the theme of the kinetic chain throughout the following chapters.

# Pain: why and how does it hurt?

...then, [Mr Hammerhead Shark] his shirt covered in blood, spun around and hit his knee on the table, at which point he swore and yelled 'My knee! My knee!', the whole time unfussed about the hammer stuck in his neck.

Even the simplest biological organisms can protect themselves from threatening stimuli—by altering their path of movement away from the source of the threat.<sup>1</sup> As evolution has honed us into more and more sophisticated creatures, we have also honed this fundamental capacity to protect ourselves from threat. Indeed, perhaps our most sophisticated protective strategy is pain. In this chapter, some of the ‘fearful and wonderful complexity’ of pain is conveyed, by:

- ## WHAT IS PAIN?

Pain alerts us to tissue damage or the threat thereof. Pain makes us seek care. Pain stops us competing, keeps us seeking a cure, compels us to prioritise pain relief above almost everything else. That's the rub—pain changes our behaviour. In fact, if the brain concludes that there is

something more important than protecting a body part then it makes the executive decision to *not* produce pain. Therein lies the key to really understanding pain; it is as simple and as difficult as this—if *the brain* concludes that a body part is in danger and needs protecting and you, the organism, ought to know about it, then *the brain* will make that body part hurt.<sup>2</sup>

55

ascribe pain to the brain is flawed, because a brain, on its own, almost certainly would not and probably could not, produce pain. This position has been criticised, with merit and additional pieces have been authored that critique it.<sup>3</sup> The caveat, then, is this: to attribute it all to the brain is simplistic and denies the role of physiological mechanisms that extend beyond the brain. However, as much as we know now, networks of brain cells (neuronal and non-neuronal) are the most obvious 'last step' and the emergence of consciousness (and therefore pain) is likely to be most closely related to their activation.

With that rather perplexing caveat out of the way, let's consider what is *good* about this concept of pain. This concept of pain integrates a vast body of basic, applied and clinical research. It differs greatly from conventional theories, which have changed little since the 17th century when René Descartes was ridiculed for suggesting that we were not made from four bodily humours.<sup>4</sup>

#### PRACTICE PEARL

The critical concept is that pain is not a measure of tissue damage, but an indicator of the brain's conviction about the need to protect certain tissue.

To better understand pain as the protective output of the brain, not as a marker of tissue damage, let us consider several contrasts between the two models (Table 5.1).

### WHAT IS NOCICEPTION? CLUE— NOCICEPTION IS NOT PAIN!

At the risk of sounding a bit repetitive, let us start by saying that nociception is not pain. Nociception refers to the

detection, transmission and processing of noxious stimuli. A noxious stimulus is one that is actually or potentially damaging. The neurons that detect noxious stimuli and transmit a nociceptive message to the spinal cord are called nociceptors ('danger receptors').

Nociceptors are high threshold neurons, which means that they respond to stimuli that are approaching or surpassing that which is damaging to the tissue in which the neuron resides. Nociceptors are mostly thin neurons and many are not myelinated. They fall into three nerve fibre types: Aβeta (β)(fast, myelinated neurons), Aδelta (slow, myelinated neurons), C (very slow, unmyelinated neurons; see <sup>5</sup> for full review).

Nociceptors are located in almost all the tissues of the body, with the notable exception of the brain. This network of neurons, can be considered a very thorough surveillance system. Of course, the surveillance function of the peripheral nervous system is much more comprehensive than nociceptors alone—it is just that nociceptors are always surveying the anatomical landscape for dangerous events. All such events fall into one or more of three categories: thermal, chemical or mechanical. Thus, nociceptors have specialised receptors in their cell walls that are cold-sensitive, hot-sensitive, chemosensitive or mechanosensitive.

Humans have low-threshold neurons that are solely interested in one modality or another, such as thermosensitive Aβ fibres, which inform brainstem areas of even tiny fluctuations in tissue temperature—fluctuations that are well within a safe operating range. In contrast, nociceptors are most often bimodal or multimodal. That is, they are responsive to thermal and mechanical input, or to thermal, mechanical and chemical input. These nociceptors, which are situated in the tissues of

**Table 5.1 Contrasts between (a) pain as a protective output of the brain and (b) pain as a marker of tissue damage**

A Pain as a protective output of the brain	B Pain as a marker of tissue damage
Pain is in consciousness.	Damage is in the body.
One cannot be in pain and not know about it.	One can be severely damaged and not know about it.
No brain, no pain.	No body, no damage.
Pain is affected by what else is at stake.	Damage is not affected by what else is at stake.
Pain is affected by who is in the area.	Damage is not affected by who is in the area.
Pain is affected by beliefs.	Damage is not (well, not directly).
Pain can occur in a body part that does not exist.	Damage cannot occur in a body part that does not exist.
Pain can occur in a body part that is not damaged.	Damage can occur in a body part that is not painful.
Pain can occur without activation of nociceptors (see next section).	Damage cannot (excepting local anaesthetic or pre-injury nociceptor death).

the body, are called primary nociceptors (see <sup>6, 7</sup> for review).

Primary nociceptors are also different to other peripheral neurons in that they project to neurons in the dorsal horn of the spinal cord, not directly to thalamic or cortical structures. The neurons with which primary nociceptors synapse in the spinal cord are called secondary or spinal nociceptors and the synapse is open to modulatory input from other peripheral inputs and from descending neurons (see below). That the nociceptive system is polymodal and has a 'relay station' in the spinal cord raises two very important issues.

That primary nociceptors are multimodal and only project as far as the spinal cord clearly shows that the nociceptive system, per se, is not able to transmit information specific to each modality. That is, the nociceptive system does not tell the brain that something is 'dangerously hot', or 'dangerously cold' or 'dangerously squashed'. Rather, the nociceptive system has the apparently simple task of telling the brain that something is 'dangerous'. It is the non-nociceptive inputs (including non-somatosensory cues<sup>8</sup>) that provide critical information about the nature of the danger.

The polymodal characteristic also means that if a stimulus is both dangerously hot and dangerously squashing, it evokes quicker firing of primary nociceptors, which effectively tells the spinal nociceptor that something is 'doubly dangerous'. To consider a clinical example, if a primary nociceptor is activated by chemicals released by an inflammatory event and the tissues are then poked and prodded, the addition of a mechanical input to the chemical input will increase firing of nociceptors to a greater extent than either would alone.

That primary nociceptive input is open to modulation at the spinal 'relay station' (better conceptualised as a spinal 'processing station') means that other peripheral input can decrease noxious input. Peripheral input at the spinal relay station is from interneurons that are activated by wide diameter peripheral neurons (A $\beta$  fibres) from the same or adjacent area. This is why one can, for example, 'rub it better', or, in a more sophisticated way, put TENS on it. In fact, TENS was born from Melzack and Wall's famous gate control theory of 1965.<sup>9</sup> Moreover, the spinal relay station can be modulated by descending input from supraspinal structures and it is this descending input that arguably represents a more important and potent modulatory influence.<sup>10</sup>

### Sensitisation of primary nociceptors ('peripheral sensitisation')

Primary nociceptors become sensitised in the presence of chemical irritants, that is, they are subsequently activated at a lower threshold than is ordinarily required. The most common chemical irritants are generated by the tissues

themselves when they are injured. These injured tissues are often referred to as 'inflammatory soup' because there are many chemicals involved and the exact ingredients of any particular soup will vary, depending upon the particular situation/injury/context/chemical stimuli and, critically, person.

Figure 5.1 depicts typical inflammation-mediated sensitisation of primary nociceptors. This 'peripheral sensitisation' is exactly that—nociceptors become responsive

**Figure 5.1** A simplified illustration of the connection between nerve terminals and vasculature. The green (normal) and red (sensitised) bars depict nociceptor responses to test stimuli (yellow bars). When there is peripheral sensitisation (red bars), even tiny stimuli evoke responses

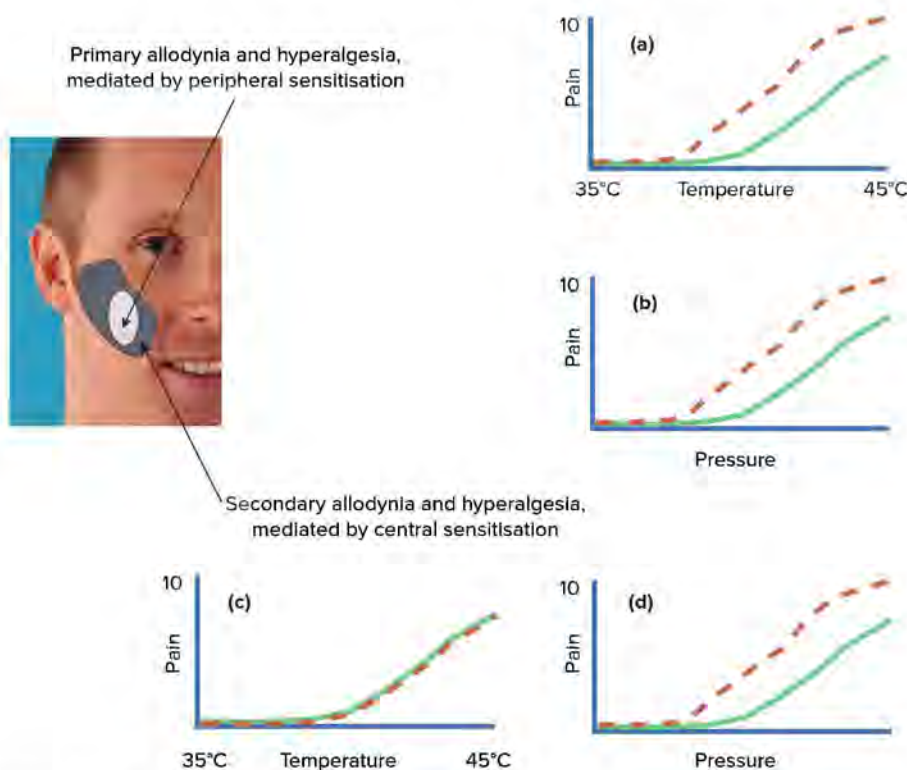

to stimuli that are not normally evocative. One obvious example is that of sunburn: sunburnt skin hurts when you get into a shower of 40°C because nociceptors are sensitised sufficiently to be activated by a thermal stimulus 4–5°C cooler than that which would normally be required. That peripherally sensitised tissues are heat-sensitive is a very important phenomenon for the reasoning clinician because sensitisation of the spinal nociceptor does not result in heat sensitivity (Fig. 5.2). Therefore, if one has concluded that there is a peripheral problem and one can heat the culprit tissues to 42°C, one can confirm the conclusion or question it, by determining whether the tissues are more sensitive in the presence of thermal stimuli that *normally* do not activate nociceptors (Fig. 5.2).

Another aspect of sunburn, the reddening of the skin, is an important aspect of peripheral sensitisation. Reddening of the skin is a sign of neurogenic inflammation (Figs 5.1, 5.2). When nociceptors are activated, an impulse is transmitted along every branch of the nociceptor.

If an impulse transmits 'in the wrong direction' and arrives at another terminal branch, then it causes the release of chemicals that in themselves are inflammatory and cause vasodilation.<sup>5</sup> This mechanism is responsible for the flare one gets around a skin wound or scratch. It is an important mechanism if the nociceptor is being activated proximally, for example, in the dorsal root ganglion or in the spinal cord, because it means that the tissues become inflamed as a consequence of action potentials being propagated elsewhere—in this situation, the tissues are not generating the inflammation.

### Sensitisation of spinal nociceptors ('central sensitisation')

When spinal nociceptors are active for some time, they too become sensitised. Many biological processes that can contribute to 'central sensitisation' have been uncovered, and while in-depth discussion is beyond the scope of this chapter, there are several resources that discuss central

**Figure 5.2** Peripheral and central sensitisation.

Presuming an injury within the lightly shaded zone, the presence of inflammation in the area and activation of primary nociceptors will lead to peripheral sensitisation. This will manifest as primary allodynia and hyperalgesia, as represented by a shift in the thermal pain threshold so that pain is evoked at lower temperatures than normal (a) and a similar shift in the mechanical pain threshold so that pain is evoked at lower pressures than normal (b). If central sensitisation ensues, the surrounding area, here represented by the dark shaded zone, will not be heat sensitive (c) but will be mechanically sensitive (d).

### A note on the evolution of meaning of central sensitisation

There has been a shift in the common understanding of central sensitisation, from that presented above, to that presented below. That is, many people with persistent pain have reduced pain thresholds across half or all of their body. The most obvious biological substrate for this sensitivity is the central nervous system. As a result, the term central sensitisation has been commandeered to explain this phenomenon.<sup>13</sup> This is understandable but may

also be problematic because it takes us away from likely candidate adaptations or problems, to a very generic and exclusion-based approach. One can describe 'new central sensitisation' as 'reduced pain thresholds not explainable by peripheral sensitisation'. In this chapter, the former definition of the term is used because it describes a series of biological adaptations that are well understood at a molecular level.

A

sensitisation in more detail and are listed at the end of the chapter. Central sensitisation manifests as mechanical sensitivity beyond the area of injury and peripheral sensitisation (Fig. 5.2). In short, central sensitisation means that the spinal cord 'upregulates' nociceptive input at the spinal cord (see<sup>10-12</sup> for reviews). This has implications for the biopsychosocial model of pain that is illustrated in Chapter 29.

### THE BRAIN DECIDES

As illustrated earlier, pain emerges from the brain and reflects the brain's evaluation of threat to body tissue and the subsequent need for action. As mentioned in the earlier caveat, it is true to say that this perspective is 'neurocentric'<sup>3</sup> insofar as pain does not emerge from a nervous system, sitting in isolation from the rest of our biology. The truth is, of course, that pain emerges into consciousness from the entire person. This acknowledgement, however, is perhaps more philosophical than a sport and exercise medicine textbook permits. To iterate, we can avoid this difficulty by conceding that although it is not just a brain that evaluates this input and creates an experience, to conceptualise it this way is faithful to much of our understanding and is far more applicable than a more precise but philosophically challenging conceptualisation.

Spinal nociceptors are important informants about danger to body tissue, but, ultimately, nociception is neither sufficient nor necessary for pain (see Table 5.1). Modern conceptual models of pain highlight this critical role of the brain. One framework that makes this clear is that of cortical representations (see<sup>7</sup> for a clinician-friendly review). According to this framework, an individual will experience, for example, ankle pain when a network of brain cells, distributed across the brain, is activated. That network of brain cells, then, is considered the neural representation of that individual's ankle pain. As it is a unique and distributed network, one might call it a *neurotag*.<sup>7</sup> Each of the brain cells that constitute this ankle pain neurotag also contribute to other neurotags and activation or otherwise, of this ankle pain neurotag is

open to modulation at every synapse of every constituent brain cell. This brings an enormous complexity to the neurobiology of pain, although pain is simply one expression of the neurobiology of consciousness, which no one fully understands (see above). For a more in-depth review of this neurotag-based concept as it applies to performance, sports medicine and rehabilitation (see Wallwork et al).<sup>14, 15</sup>

This conceptual framework means that anything that is represented by that individual's brain *and* which provides credible evidence about the danger to which the ankle is currently exposed, should modulate activity of the 'ankle pain neurotag'. In more clinical terms, anything that provides credible information about the likely danger level should modulate ankle pain. Credible information may relate to likely consequences of damage—ankle damage is more dangerous to a top-level dancer than it is to an archer, a fact that will upregulate the ankle pain neurotag in the dancer. However, a top-level dancer might have the long-held belief that his/her body is indestructible, which would downregulate the ankle pain neurotag; a top-level archer may not have this belief. As you can see, it is a very complex system.

Credible information might relate to other sensory cues—damaging one's ankle on the bend in the final of the 200 m in front of a screaming crowd may very well lead to those same cues upregulating the ankle pain neurotag when those sensory cues occur again. Clearly, this neural complexity has important implications for rehabilitation; the neuroscience of pain and protection suggests that rehabilitation of this individual with ankle pain is not complete until the athlete has been exposed to every credible 'byte' of information that implies danger to the ankle.<sup>14, 15</sup>

Hopefully the reader can now appreciate why Descartes' idea, that we have pain receptors in the tissues and pain signals are transmitted to the brain,<sup>4</sup> is as inadequate as it is popular. While its simplicity may be seductive, the ever-increasing body of evidence suggests it simply does not hold up. If, as a clinician or patient, one is to accept the true complexity of pain as evidenced by a huge

amount of experimental and clinical literature (see<sup>16</sup> for review) and to conceptualise pain by the representation framework, then one must also accept that activity in spinal nociceptors is one of many contributors to pain. The truly modern day clinician should be open to non-tissue contributions (i.e. differential modulation exerted by other systems, for example, immune upregulation, central sensitisation and central downregulation) and be alert to evidence of their influence.

Charles Darwin suggested that young scientists should write down the results that do not support their current beliefs because they are the results that are most forgettable.<sup>17</sup> As clinicians we should do the same (see also<sup>18</sup>). With regard to pain, this might mean taking note of:

- when the same mechanical input flares a condition one day and not the next
- when pain is worse in competition than it is in training
- when strength, endurance, control and flexibility are exemplary but the athlete still 'tweaks' a hamstring running at 90% effort
- when a 20-second manual therapy technique increases hip range of motion by 25°.

Sure, one might squeeze some such findings into a Descartian framework, but they arguably fit more easily in a modern knowledge-based framework and Ockham's razor<sup>\*</sup> compels us to look there first.

## THE BRAIN CORRECTS THE SPINAL CORD

There are several hundred projections from the brain to the spinal nociceptor. Projections originate throughout the brain and have both facilitatory and inhibitory effects. Structures within the brainstem, for example, the periaqueductal grey (PAG) are important relay stations between the brain and the spinal nociceptor.<sup>19</sup> Such a powerful modulatory capacity evokes, not surprisingly, powerful modulation.

Many experiments have investigated the circumstances under which the brain modulates the spinal nociceptors. We can easily summarise them here using the same language as above: if the *entire package* of credible evidence of danger is different from that suggested by spinal nociceptor input, the brain will 'correct' the spinal cord by either inhibiting spinal nociceptors or facilitating them.

Those familiar with principles of motor control will recognise the same principles also in the pain system. In motor control, this idea of re-afference and sensory-motor feedback loops is well established—a motor command generates an efferent copy that is then compared to sensory

feedback of the movement (from vision and proprioceptors) and any discrepancy between the predicted and actual outcome is used to correct the motor command.<sup>20</sup>

Going back to our example of ankle pain, we can describe it thus: activation of the brain's ankle pain neurotag also triggers its efferent copy, the latter of which is compared to spinal nociceptive input, triggering correcting descending modulation to adjust ascending 'danger' input (Fig. 5.3). This kind of feedback loop is common in human physiology.

### PRACTICE PEARL

*In short, if the brain concludes that the need to protect tissues is greater than spinal nociceptor activity would suggest, it will facilitate the spinal nociceptor. If the brain concludes the need to protect is less than spinal nociceptor activity would suggest, it will inhibit it.*

The effects of such correction will be different if the spinal cord itself is sensitised. That is, if non-tissue factors are increasing the brain's evaluation of danger to a particular tissue, such that the brain upregulates the spinal cord, it has the capacity to maintain or indeed instigate, central sensitisation. There is potential here for a vicious cycle of increasing nociception → increased perceived danger → increased descending facilitation → increased nociception. Thus, it is all the more important for the clinician to evaluate *every* factor that is contributing to the perception of threat to tissues because *any* credible evidence of danger has the potential to upregulate the spinal nociceptor (see<sup>18, 21</sup> for reviews).

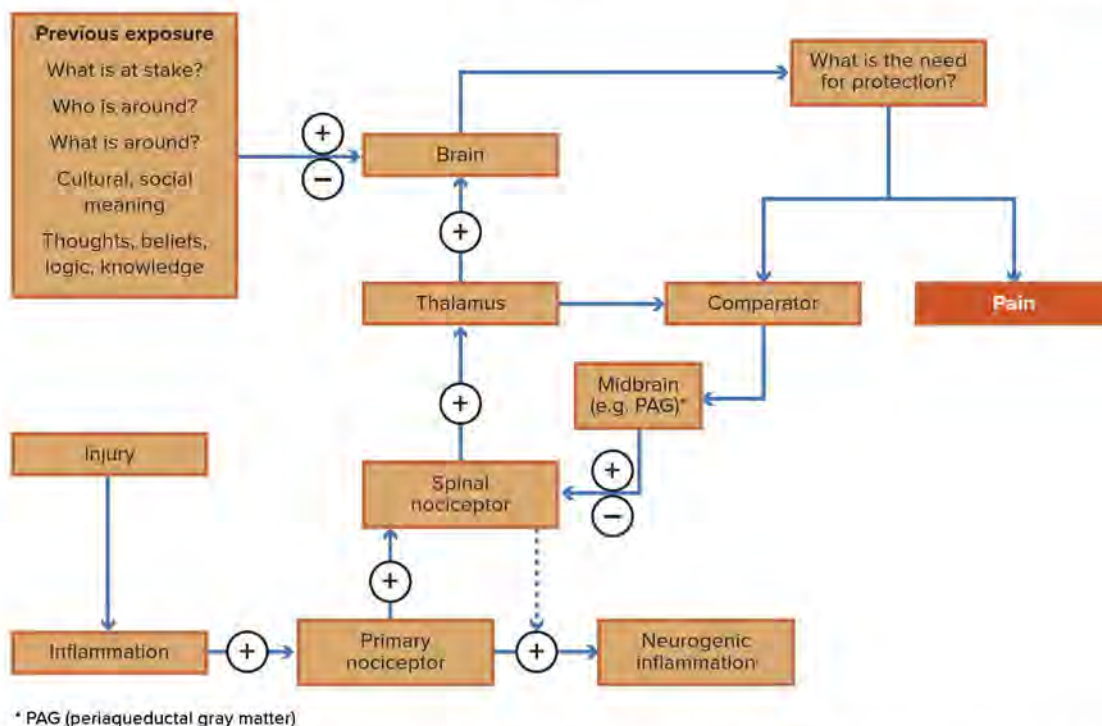

## THE BRAIN IS DIFFERENT IN THOSE WITH PERSISTENT PAIN

In much the same way that spinal nociceptors adapt to become more sensitive, so too do the brain cells that underpin pain<sup>22-25</sup> (Wand et al.<sup>26</sup> have reviewed the cortical changes in people with back pain). That is, the more the pain neurotag is active, the better it gets at being active. This manifests in more and more advanced hyperalgesia and allodynia, extended across modalities and exhibiting 'over-generalisation'.

Over-generalisation refers to that phenomenon in which pain begins to be evoked by more innocuous stimuli, in different contexts and under different circumstances.<sup>27-29</sup> Spreading pain, unpredictable pain, and pain that is less

\*Ockham's razor is attributed to William of Ockham (14th century), although it was thought to be 'invented' well before his time. Its earliest and most enduring iteration is 'Entities must not be multiplied beyond necessity' or far more commonly now 'The simplest answer is probably the correct one'.

**Figure 5.3** Feedback loops within the nociceptive system and the endpoint of pain: injury excites primary nociceptors. Injury-induced inflammation activates and sensitises primary nociceptors (peripheral sensitisation).

Activation of nociceptors causes neurogenic inflammation in nearby areas and excites spinal nociceptors. Spinal nociceptors project to thalamic nuclei, which then project to the brain. A complex evaluative process occurs within the brain, whereby every byte of information that provides credible evidence about the actual danger faced by the tissues in question is able to upregulate or downregulate the pain neurotag. This process permits the brain to determine 'What is the need for protection?' The final 'decision' leads to activation of the pain neurotag and pain emerges into consciousness. Simultaneously, as though a bifurcation of a single neural output, the determined need for protection is sent to a 'comparator', where it is used as a reference for the spinal nociceptor input. This comparator then modulates midbrain structures and thence in turn the spinal nociceptor to 'correct' its activation level. Thus, descending modulation can be facilitatory or inhibitory. The broken line from spinal nociceptor towards neurogenic inflammation refers to the possibility of tissue inflammation evoked by descending facilitation. That is, excessive facilitation of the spinal nociceptor in the absence of primary nociceptor activity is thought to activate the primary nociceptor antidromically, which induces neurogenic inflammation in the periphery.

and less related to tissue state and activity are cardinal signs of cortical dysfunction.

The full mechanisms and manifestations of cortical sensitivity are not as well understood as the changes in the spinal nociceptor are understood, but they are, at least theoretically, likely to be of far more widespread impact for the clinician and patient. Suffice it to state here that the complexity of pain and the adaptability of the nervous system mean that the modern clinician needs to think well beyond the tissues when dealing with anyone in pain. Indeed, common changes in the sensitivity of the nociception/pain system can be mediated at various levels of the neuraxis (Table 5.2).

### TREATING SOMEONE IN PAIN: A COMPLEX SYSTEM REQUIRES A COMPREHENSIVE APPROACH

This chapter is not designed to provide a comprehensive guide to treating the patient in pain. Instead, it provides an account of pain that can underpin the assessment and management of people in pain, whatever the 'clinical toolbox' of the clinician. One implication of what we now know about pain is that there are certainly 'many ways to skin a cat' insofar as there are many ways to decrease credible evidence of danger and increase credible evidence of safety (see Moseley and Butler<sup>21</sup> for a step-by-step approach to doing this).

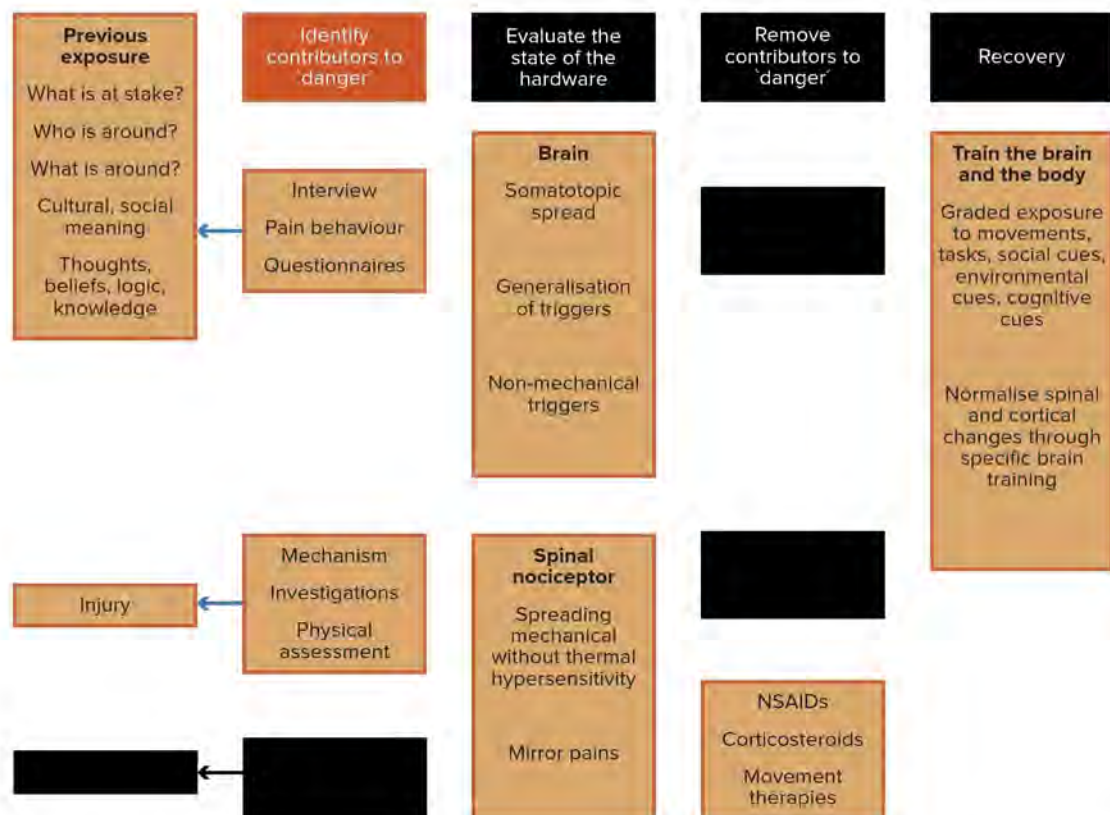

**Table 5.2 Clinical patterns of increased sensitivity to peripheral stimuli and possible underlying mechanisms**

Clinical manifestation	Possible underlying cause
Mechanical allodynia: mechanical stimuli that do not normally evoke pain now do	Peripheral sensitisation, central sensitisation, cortical modulation
Thermal allodynia: heat pain threshold is decreased	Peripheral sensitisation, cortical modulation
Hyperalgesia: normally painful stimuli are now more painful	Peripheral sensitisation, central sensitisation, cortical modulation
Primary hyperalgesia	Hyperalgesia attributed to peripheral sensitisation
Secondary hyperalgesia	Hyperalgesia attributed to central sensitisation (or simply not attributable to peripheral sensitisation)

The best practice approach to rehabilitation integrates the complexity of the individual, and targets aspects of normal and altered physiology associated with pain (Fig. 5.4). The model is most established for the

management of people in chronic pain<sup>2</sup> but can also be applied to the sporting and performance context.<sup>14, 15</sup> This is extremely relevant to sport and exercise medicine because (i) active people often present with these

**Figure 5.4** Major contributions to pain and their clinical implications.

The left column lists the major contributions to the brain's evaluation of danger to tissues, which determines pain and descending modulation. The second column suggests mechanisms with which to assess the major contributions, thereby identifying key triggers. The middle column suggests signs of spinal and cortical sensitisation, so as to determine the state of the nociceptive system. The fourth column suggests approaches to minimise the impact of the triggers that have been identified. (Note that this extends beyond physical approaches to include cognitive and educational approaches.) The final column recommends avenues to recovery. (Note the emphasis on training both the body and the brain, via specific techniques and graded exposure to physical and non-physical triggers.)

symptoms and (ii) the skillset and credibility of those working in this field is well suited to motivating people in pain to embrace a multifactorial approach to management. Because the biological mechanisms that underpin pain are the same for acute and chronic pain, albeit with increasing

sensitivity as pain persists, the model outlined is applicable across patient groups. In Chapter 6, Dr Ebonie Rio outlines approaches to several clinical scenarios to show how the principles outlined here can underpin work in the clinic.

# Pain: the clinical aspects

with EBONIE RIO

*Understanding pain biology changes the way people think about pain, reduces its threat value and improves their management of it.*

David Butler & Lorimer Moseley, *Explain Pain*

Chapter 5 provided the complex foundational elements of pain science. In this chapter, we share how clinicians can apply this knowledge to better manage patients.<sup>1</sup> Being a clinician would be straightforward if the location of pain always revealed the precise area of pathology and pain had a tissue basis. But this is commonly not the case!

It is useful to consider the contributions to a patient's pain. For example, is there peripheral sensitisation? Is there central sensitisation? Is there referral? Are there cortical contributions? Are there changes in cortical representations? No matter what the answer to these questions, pain is a sign that the brain is urging protection. Identifying the relative importance of different contributions allows you to target your treatment accordingly.

Let's consider a patient with longstanding back pain. Historically, clinicians developed a list of differential diagnoses to classify injury or disease. In this case the options include muscle strain, disc injury or facet joint injury. Working from such a list of differential diagnoses relies on several assumptions. First, that knowledge of the affected structure is important to the assessment and diagnosis. Second, that it is possible to accurately confirm the diagnosis (i.e. that a gold standard exists). Third, that making a tissue diagnosis will inform treatment. Contrary to these 1980s opinions, none of those assumptions appear correct today.

A complementary approach is to consider an overarching classification (e.g. 'the patient had an episode of back pain') that focuses on *the pain experience and contributing factors* as a distinct clinical entity. With this

foundation, the clinician can add information about the state of specific anatomical structures and determine the best treatment approach (which may change over time).

This broader perspective of painful events, which encourages assessment by body region and type of threat, is based on the neuroscience that body movements are represented on motor homunculi and body surfaces are represented on sensory homunculi (Fig. 6.1). While the chapters of this book are arranged to permit region-specific assessment and treatment of what we consider predominantly nociceptive-driven (or input-dominated) presentations, this chapter aims to help clinicians to know when to consider centrally dominated pain in their assessment and management. So, what is meant by 'input-dominated pain' and 'centrally dominated pain'?

## INPUT-DOMINATED PAIN

Let's begin with the most common type of pain that brings the patient to a clinician in this field—pain from a musculoskeletal injury. This is 'input-dominated pain' and it is distinguished from 'centrally dominated pain' (discussed in the next section). When learning about concepts like this, it is helpful to artificially distinguish ends of a spectrum. Of course input-dominated and centrally dominated pains occur together, but let's put them in very distinct boxes to start with. In this context, 'input dominated' is a term used to get the clinician to appreciate the nociceptive contribution. The input is the sensory information from the periphery that has stimulated a nociceptor (a receptor capable of transducing and encoding noxious stimuli).

**Figure 6.1** Motor and sensory homunculi

### Pain and musculoskeletal tissues

Pain is what makes a person go to see a clinician. Acute incidents or injuries are generally associated with nociceptive sensory inputs from tissues. Many patients will report that their pain has affected their function in sporting, occupational or everyday activities. The clinician should evaluate the status of musculoskeletal structures as per a normal clinical encounter (see Chapter 14) and consider the following:

1. joints, including ligaments
2. bones
3. muscles and fascia
4. tendons
5. neural structures (see below).

In acute states, pain associated with nociceptive contributions is thought by clinicians to be fairly closely linked with injury and the repair process. As explained in Chapter 5, the relationship between tissue status (damage), afferent impulses (i.e. impulses perceived as noxious), and pain is not predictable or linear. Afferent impulses may overemphasise the danger associated with an injury at first (e.g. severe pain of an ankle sprain), but this can quickly diminish. The patient can be pain-free at 2 weeks post-injury, but not fully healed for 6 weeks. It is important to avoid thinking of pain presentations purely in terms of the length of time of symptoms. An example of this is pain associated with the patellar tendon (see Chapter 36), where pain is intimately linked with patellar tendon load, implying a nociceptive contribution

even though pain can persist for years. In this example, the pain experience is of course modulated (as all pain is an output), yet there appears evidence of a nociceptive contribution.

Table 6.1 demonstrates examples of nociceptive pain descriptors and clinical examples.

#### PRACTICE PEARL

It is essential that the clinician eliminates sinister causes such as cancer (see Chapter 7).

### Less well characterised input-dominated pain—referred pain

Referred pain is an example of nociceptive input-dominated pain. It can be thought of as an error in the brain's processes that determine where, exactly, it should hurt. That is, the location of the dangerous event is 'misread' by the brain. An example of referred pain is pain in the neck or left arm when it is the heart that is the structure under threat. Another common example is leg pain when nociceptive input arises from a structure in the back or the ascending projections normally associated with that structure. An extreme case of referred pain is 'phantom pain' where pain appears to be localised in a limb that is no longer part of the body (e.g. after amputation). This is also a good example of the discrepancy between apparent input and the experience of pain.

**Table 6.1 Clinical examples of terminology and tissue-based examples of pain with nociceptive contributions<sup>2</sup>**

Nociceptive pain descriptors	Tissue-based examples
Patients describe an incident that fits with anatomical location	Ankle sprain may injure ligaments, fascia, muscles, tendon, bone and neural structures via mechanical, ischaemic and/or inflammatory processes
Patient reports clear aggravating and easing factors as well as consistent and clear pain reproduction on movement (or testing) of target tissues	Testing of the involved ligaments reproduces pain
Pain usually eases as the injury settles	Initially someone may present with a limp and this reduces over time, perhaps with appropriate treatment that may include activity modification, ice, compression and optimal loading (graduated exercise progression)

### Four case scenarios where referred pain is a common culprit!

- A patient presents with a long history of intermittent, dull, occipital headaches. The patient is thoroughly investigated for eye problems and the presence of intracranial pathology. All tests are normal.
- A patient presents with a history of an ache in the right shoulder that is difficult to localise and is associated with pain on the medial aspect of the upper arm. There is some neck stiffness and tightness in the trapezius muscle.
- A 35-year-old executive complains of episodes of sharp, left-sided chest pain related to activity. The patient has already undergone extensive cardiac investigations that were all normal.

- A young athlete presents with a history of recurrent episodes of buttock and hamstring pain. There is no history of an acute tear and the patient describes the pain as deep-seated and dull with occasional sharp cramping in the hamstring. Examination of the hamstring shows some mild tenderness but full stretch and strength.

These clinical presentations are common in sport and exercise medicine practice. All of the patients are likely to be experiencing referred pain and treatment needs to take this into account.

It is important to keep in mind that there is always a reason for pain (response to perceived threat). Because pain is the end point of a complex danger-relevant processing system, it means that when the tissue that hurts seems normal, we may need to look elsewhere rather than presume the patient is not in pain.

Consider that the brain is wrongly locating a dangerous event—that there is a noxious contributor in an area that does not hurt (and the pain is felt at a remote distance to the noxious contributor). There are common patterns and mechanisms of referred pain. Two of these are 'radicular referred pain' and 'somatic referred pain'. Being familiar with these will stand the young clinician in very good stead. You will make many diagnoses and help many patients who your colleagues will consider 'difficult' or even 'crazy'. (We don't condone terms like 'crazy' about patients, but patients have reported to us that they were told this or they felt crazy, so the term is used here to emphasise the burden that undiagnosed referred pain can have.)

### Radicular pain

The concept of radicular pain is increasingly taught to undergraduate health professionals, and it is pain associated with nerve root compression or irritation. It has the characteristic quality of sharp, shooting pain in a relatively narrow band, known as a dermatome. Dermatomes are mapped out and can be used to determine the segmental level of the nerve root compromise. Dermatomes themselves are variable both between and within individuals—they move in line with shifting receptor fields of spinal neurons.<sup>3, 4</sup> (Fig. 6.2). Nonetheless, current convention tells us that if the radicular pain is associated with compression of the nerve root, it will usually be accompanied by neurological abnormalities, e.g. paraesthesia corresponding to a reasonably typical dermatomal distribution or muscle weakness corresponding to a reasonably typical myotome.

Irritation of the dorsal root ganglion can evoke a similar distribution of pain, although the shooting pain may be delayed for several seconds and will sometimes

**Figure 6.2** Radicular pain runs in well-characterised narrow bands according to which nerve root is affected. The left panel shows the dermatomal distribution of the neck region. The image also explains mechanisms that can underpin radicular pain—convergence of multiple incoming nociceptors. Note that radicular pain within the peripheral supply of a single spinal segment can occur via convergence of multiple branches of single nociceptors (A). Radicular pain can also occur via nociceptors within the dorsal root ganglion of that peripheral nerve (B). Pain can occur within the adjacent spinal nerve root territory via convergence within the dorsal horn, where projections from levels above (C6) or below (C8) can terminate alongside those from the spinal segment concerned (C)

reverberate (see Butler and Moseley 2013<sup>5</sup> for more on this). That nerve root irritation and dorsal root ganglion irritation evoke pain in the area normally supplied by the affected nerve is intuitively sensible. The spinal neurons that convey the danger message have no method by which to differentiate where along the primary nociceptor the activity was generated, which leaves the brain allocating the danger to the target tissues.

### Somatic pain

The other type of referred pain—the one that is largely ignored in traditional medical (i.e. MBBS, MD) teaching—is often called somatic referred pain. The mechanisms that underpin somatic referred pain are not as structurally simple as radicular referred pain. This is because the ‘disrupted transmission’ occurs within the central nervous system. This might happen at the dorsal horn in the spinal cord, in the thalamus or in the brain itself (Fig. 6.3). For example, visceral and musculoskeletal afferents converge in the case of left arm pain evoked by cardiac

problems. Similarly, immune mechanisms form functional connections with contralateral spinal nociceptors and as such might evoke ‘mirror pains’ at the identical site on the opposite limb.

It can be helpful for the young clinician to conceptualise somatic referred pain as the brain attempting to localise the pain in response to ambiguous input (Fig. 6.3). As a result, the patient explains that the boundaries of pain seem indistinct, and that the pain can move. There is a large amount of variability between how individuals tell their story of this type of pain.

Two structures that are widely held by clinicians to be common contributors to somatic referred pain are (i) joints and (ii) myofascial trigger points (although the evidence concerning popular treatments for the latter is somewhat fragile). The growing ambiguity or *imprecision*, that seems to accompany somatic referred pain increases as the usual intracortical inhibitory mechanisms break down in persistent pain. The longer pain persists, the more ‘bodily real estate’ it tends to consume. Indeed, the attribution of danger to a particular area of *space*, in addition to *body*,<sup>6–8</sup> is consistent with this loss of inhibition in brain areas dedicated to spatial localisation of body parts.<sup>10</sup>

### Neuropathic pain

Neuropathic pain can be difficult to categorise and is defined as pain arising as a direct consequence of a lesion or disease affecting the somatosensory system.<sup>10</sup> In contrast to pain that arises from activating nociceptive afferents (discussed above as pain with nociceptive contribution), pain can arise by activity generated without adequate stimulation of sensory nerve endings and is probably best described as a characteristic rather than a diagnosis. However, neuropathic pain can occur concurrently with nociceptive contributions to pain, that is, initial trauma can damage peripheral musculoskeletal tissue as well as neural tissue. This provides a mixed clinical picture that makes it more challenging for the clinician to unravel the contributor(s) to pain.

There is no gold standard or even clinical test for neuropathic pain. It represents clusters of features that may or may not have a history of injury or illness preceding the symptoms. Clinically, many find it useful to grade according to the level of certainty with which it can be determined in a patient<sup>10</sup> (definite, probably, possible). This is based on the premise of pain distribution being consistent with dermatomes (that is, corresponding to peripheral innervation patterns or representations). Causes of neuropathic pain include diabetes, malignant disease, trauma and ischaemia. People presenting with pain (often to a musculoskeletal clinician) may have diabetes or an undiagnosed malignancy, so the clinician must remain alert to this possibility when a patient presenting with what would be expected to be

A

**Figure 6.3** Somatic pain is an important type of input-dominated pain. As in the illustration of the person on the left side of the figure, pain can be referred in non-radicular patterns such as within a limb or 'quadrant'. Nociceptive signals converge in higher centres, e.g. thalamus, insula, and primary (S1) and secondary (S2) somatosensory areas.

input-dominated pain (e.g. local tissue trauma) reports ongoing pain with neuropathic features.

The clinical features of neuropathic pain may include burning or shooting pain, hypersensitivity, expansion of receptive fields, deep aching, motor deficits, abnormal neurological examination and spontaneous pain.<sup>2, 11, 12</sup> A patient with neuropathic pain may experience both sensory loss (cold, warmth and pinprick) and the presence of certain hyperphenomena such as tingling or prickling sensations. However, clinical neurological testing may not be sensitive enough to detect the afferent (sensory) changes. There is no gold standard to identify neuropathic pain, nor consensus over whether neuropathic pain questionnaires should be used in clinical practice. Of the available questionnaires, PainDETECT and LANSS<sup>13</sup> have the best clinical applicability as well as acceptable sensitivity and specificity.

### CENTRALLY DOMINATED PAIN

These classifications merely aim to assist clinicians to form a treatment path. This is because people who have reduced thresholds to the way they perceive stimuli that is contributing to their pain (perhaps even a main driver) require individual approaches. The term 'centrally

dominated pain' refers to clusters of clinical features and includes sensory findings (both positive and negative findings). It is often thought of as pain that persists beyond usual time frames (however, this is difficult to quantify and could mean treatment was inappropriately directed) or as pain that is experienced without stimuli.

This is where it gets tricky as reduced sensory thresholds are also observed even in acute situations such as an ankle sprain. Thus, centrally dominated pain refers to the pain of a subgroup of people who have not responded to many traditional treatments. Unfortunately many people experience persistent pain and there are no tests that can identify people early that are at risk of persistent pain. The language strategies provided at the end of this chapter aim to help clinicians reduce their negative impact (and perhaps even have a positive impact) on their patient interactions. (Note that neuropathic pain has elements of both input-dominated and centrally dominated pain but it is included below.) Many conditions may have elements of neuropathic pain.

### Central sensitisation

The expert sport and exercise clinician recognises that the relationship between pain and tissue damage becomes

more tenuous as pain persists.<sup>14</sup> As pain persists, the central nervous system (CNS) switches to a state of spinal hypersensitivity, which generates allodynia (e.g. the experience of pain from non-noxious stimuli such as light touch) and the descending control pathways shift to excitation rather than inhibition.

Central sensitisation results from a complex cascade of physiological events involving all levels of the CNS and many areas of the brain<sup>15</sup> (see Chapter 5 for more detail). Often the patient has a reduced pain threshold that is not explained by peripheral sensitisation. (Note that the clinical finding of lowered pain threshold can be explained by one of two mechanisms—central or peripheral sensitisation. This amplified neural signalling and potential for evoked pain via non-nociceptive channels elicits pain hypersensitivity and may represent a shift in the main contributor to pain. Neural impulses may be spontaneous.

These features can be difficult to clinically assess and have been mainly reported using equipment such as qualitative sensory testing, which is expensive and time consuming. Light touch testing (e.g. with von Frey filaments) and two-point discrimination testing require practice to obtain reasonable reliability and repeatability and also rely on the assumption that there are established normative data—which there are not! This may sound very negative, but it is important for clinicians to put everything together in the clinical picture. The clinician should be alert to the possibility of central sensitisation when pain persists beyond the 'normal healing' time frames for an injury. At the same time, please listen to the voice saying that you also need to watch for 'red flags' (masquerades—see Chapter 7) at that point too. Unfortunately, no simple clinical tests provide confirmation that the pain presentation is centrally dominated. The clinician needs to take a reading from a cluster of signs and symptoms.

Another clue that pain may be centrally dominated is that it may respond poorly to treatments such as manual therapy, because CNS changes may have altered neural function (e.g. a light touch may evoke pain).

After an injury (e.g. ankle sprain), a period of increased sensitivity is an adaptation that reduces the risk of secondary injury and provides an opportunity for tissue to heal;<sup>14</sup> however, persistent hypervigilance can substantially impair quality of life. The concept of threat and pain is summarised in the previous chapter and also detailed in the book *Explain Pain*<sup>1, 5</sup> (Fig. 6.4). Remember that the relationship between perceived threat and pain is true of all pain presentations, not just chronic pain states.

Table 6.2 assists clinicians to interpret information obtained in their subjective assessment and to guide pain classification. It includes common assessment techniques

**Figure 6.4** *Explain Pain* is a book by Dr David Butler and Professor Lorimer Moseley, but the term 'explain pain' has increasingly been used to refer to an approach to treating centrally dominated pain. We recommend it as part of the essential library for the *Clinical Sports Medicine* community  
DAVID BUTLER AND G LORIMER MOSELEY, *EXPLAIN PAIN*, 2003, NOIGROUP PUBLICATIONS

and tools that may be used to assess sensory processing and pain.

It can be difficult to classify patients but some consideration of the primary contributors to their clinical presentation may assist with efficacious treatment selection. Figure 6.5 aims to assist clinicians with their clinical reasoning process. Of note, clinicians may be persistent in trying to identify a tissue-based diagnosis with ongoing pain. Conversely and of no benefit to patients, many are told the pain is all in their head! There are a number of patterns that can assist with using Figure 6.5. Here is a list of clinical symptoms and signs to assist with identifying centrally dominated pain presentations (refer to *Explain Pain* for greater detail):<sup>1, 5</sup>

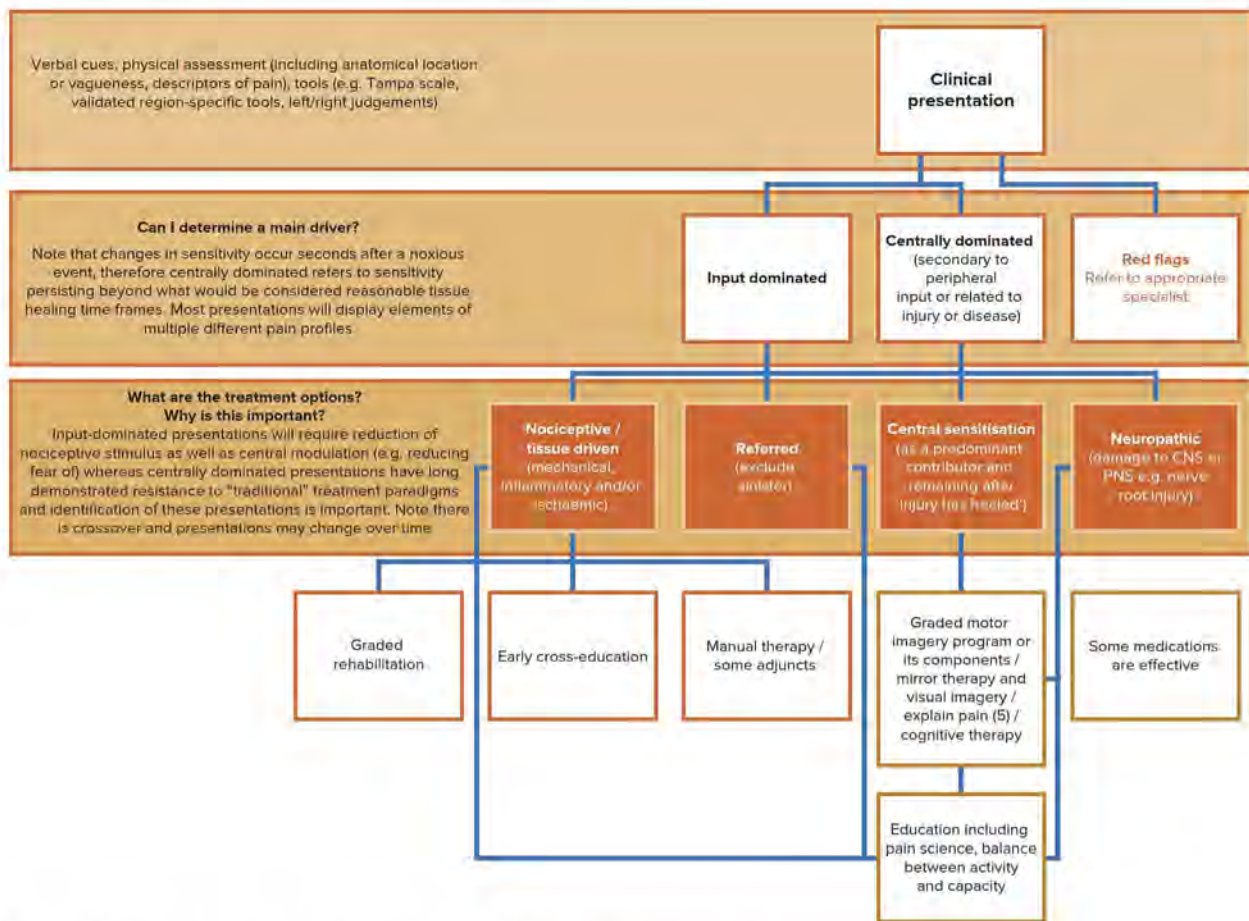

- loss of two-point discrimination<sup>17</sup>
- language of pain—'everything hurts'
- cold sensitivity
- tenderness to palpation away from injury site (secondary hyperalgesia)
- multiple diagnoses including myofascial syndrome, fibromyalgia
- red flags (see Chapter 7), including history of traumatic events, anxiety/depressive states
- cyclical or seasonal presentation (without links to changes in load or mechanical stimulus).

Table 6.3 includes common assessment techniques and tools that may be used to assess sensory processing and pain.

**Table 6.2** Questions that clinicians can use to guide their approach to patients with pain. Note there generally exists a crossover among contributors to pain<sup>2, 11, 14, 16</sup>

Question	Examples of responses	Clinical reasoning
Onset: was there an initial incident/injury and when was it?	Some people report a clear onset of pain, others do not Some individuals do not report pain even from a clear episode of severe trauma	Is the tissue a predominant driver of the pain? (No recollection of pain makes this less likely but not impossible) Overuse presentations (of input-dominated pain) may not have a sudden onset In the case of persistent pain, the incident may be a long time ago (may or may not be due to centrally dominated pain)
Where is the pain? Does it move around or spread?	Localised pain Within dermatomal distribution Pain that does not fit a dermatomal or myotomal distribution	May reflect nociceptive including compression of neural tissue May be referred (e.g. from the spine or viscera) Potential centrally dominated or neuropathic pain
Can you describe the symptoms?	Burning, electric shock-like, shooting, crushing, paraesthesia, and pins and needles Specific clusters of symptoms such as sweating, swelling, glossy skin, together with burning pain may reflect increased sympathetic activity	May reflect neuropathic pain (input dominated) These features are characteristic of complex regional pain syndrome. This is an example of centrally dominated pain
Does anything provoke the pain? (Examples given include visual and mechanical stimuli.)	No	If the patient has pain without a physical stimulus, consider centrally dominated pain such as neuropathic pain, rheumatological causes, sensitisation, inflammation or a sinister cause (see Chapter 7) Even being at rest may irritate some nociceptive pain (including neural irritation, for example, if your ulnar nerve has pressure when your elbow rests on something) People may report that pain swaps sides, or limbs or 'pain has a mind of its own' Pain may be unpredictable, non-mechanical and non-anatomical in response to movement Possible to have movement-related memory pain that is reinforced by cognitive emotional factors Some patients with centrally dominated pain experience pain with visual stimuli
Does the patient report hyperexcitability of response to stimuli?	Yes Pain with light touch (mechanical) Cold allodynia (thermal) Chemical stimuli Wind-up-like pain (abnormal temporal summation, that is, the perceived increase in pain intensity over time when the stimulus is repeated above a critical rate) or aftersensations (persistence of pain after termination of a painful stimulus)	Possibly centrally dominated or neuropathic pain. Chemical and cold allodynia can be difficult to assess in the clinic. Patients can report hypersensitivity to cold Described following repetitive noxious or non-noxious stimuli (like light touch can evoke pain)

**Figure 6.5** Flowchart to assist with clinical presentation and treatment path

## MOTOR ADAPTATION TO PAIN

It is important for the clinician to appreciate that there are movement changes with pain—technically, ‘motor adaptations.’ Understanding what may underpin abnormal movement can allow appropriate rehabilitation (see Chapter 18).

Clinicians will recall examples of what pain scientists call the *pain-spasm-pain model*—pain increases muscle activity which in turn causes pain.<sup>21</sup> Consider secondary muscle spasm associated with some forms of back pain. In contrast, the *pain-adaptation model* postulates that pain actually reduces activation of agonist muscles and increases activation of antagonist muscles<sup>22</sup> to limit movement and avoid provoking pain and further damaging tissues. An example of this would be inhibition of the quadriceps to limit patellar movement in cases of patellofemoral pain.

Both of these types of motor change may reduce movement variability and that abnormal pattern may in turn increase the likelihood of recurrence of

pain.<sup>14, 20, 23, 24</sup> Importantly, a so-called ‘protective movement-related pain memory’ may even hamper some attempts at rehabilitation for some patients.<sup>1, 25</sup>

Limiting movement can be effective in reducing pain in the short term and as long as there is a perceived threat, motor outputs may serve to protect the part. These changes in motor learning occur at multiple levels of the motor neuroaxis (e.g. motor unit, spinal cord, brain), so the patient may need to relearn appropriate motor patterns (i.e. reprogram motor outputs) after a period of sustained protection. The expert clinician builds this in to the progressive rehabilitation and exercise prescription (see Chapter 18).

## Treatment options for patients with pain

CNS modulation occurs with all sensory input—memories, thoughts, fears and expectations will influence and shape the output. There are many ways to treat people with centrally dominated pain and many aspects of the

Table 6.3 Tools for sensory processing and pain reporting

Clinical manifestation	Definition	Clinical examples	Tools
Allodynia	Stimuli that do not normally evoke pain (non-noxious stimuli) are now capable of evoking pain	Jumping can be painful for someone with patellar tendinopathy. Walking may be painful for someone who has sprained their lateral ankle	Observation Physical assessment, including palpation Note that allodynia is a normal and protective response to injury, but can also be part of persistent pain states
Hyperalgesia (primary and secondary)	Stimuli that are normally painful now evoke more pain Lowering of pain threshold response to noxious stimuli	Primary hyperalgesia—peripheral sensitisation  Secondary hyperalgesia—attributed to central sensitisation	Pressure pain algometer to detect mechanical hyperalgesia Qualitative sensory testing can examine the presence of thermal and mechanical hyperalgesia by checking thresholds and detection
Pain during function	Patient reports pain during activity Using a functional test enables re-testing of the task		Visual analogue scale Numerical rating scale (e.g. 0–10) Multidimensional descriptors such as McGill Pain questionnaire <sup>18</sup> Specific questionnaires for diagnosis, e.g. VISA-P for patellar tendinopathy <sup>19</sup>
Disrupted motor imagery performance	Accuracy and time to recognise left and right body images	This test has three steps: 1. Initial spontaneous judgment 2. Mentally match image to mimic posture shown (requires intact working body schema/cortical representation) 3. Confirm or deny initial judgment. This is impaired in some conditions such as Complex Regional Pain Syndrome and phantom limb pain <sup>20</sup>	Android and iPhone apps can test this—for example Recognise

### Be alert to the onset of centrally dominated pain

As an injury progresses from acute to chronic, the nature of the pain may change in some patients with centrally dominated pain becoming more likely as pain persists.

Let's take the example of an ankle sprain. In the acute setting with pain, swelling and disability, the major contributions to the pain are nociceptive input dominated.

In this example, the clinician has the benefit of the patient reporting that he or she had rolled the ankle, the presence of swelling in the area and perhaps their limping gait, to guide clinical assessment. The combination of subjective information and physical signs points to a tissue-based diagnosis, which helps the clinician formulate a management plan based on the philosophy that this is input dominated/nociceptive. Appropriate language that avoids fear mongering, and education to guide exercise and analgesic behaviours will be beneficial (or at least do no harm as the body heals).

If the person continues to limp after several months, is afraid to use the ankle, describes pain without activity or pain

with clothes against his or her ankle and perhaps there are skin changes, the clinician may start to think that the presentation has changed from input dominated to centrally dominated. In the former, the ligaments would be expected to be 'healed' after this period of time. However, there is no cut off for a transition to a centrally dominant picture (e.g. not greater than 3 months, as many texts will indicate).

The important point to make here is that manual techniques aimed at the ankle joint could easily make pain worse. The treatment path may need to be very creative and use techniques such as graded motor imagery to begin moving the virtual ankle before the physical ankle is re-introduced to rehabilitation. This is never easy, and the clinician must always remember the possibility of a missed diagnosis (such as a fracture) or a sinister cause, yet not continue to hunt for a tissue-based diagnosis when some contributors to pain cannot be scanned (such as beliefs and feelings).

treatment are different to that used for nociceptive pain (Fig. 6.5).

### Education

Most patients with pain will benefit from accurate education about perceived threat and pain. The clinician must avoid potentially harmful language such as 'bone on bone' changes in osteoarthritis or 'massive disc rupture/herniation' in back pain.

Identification of centrally dominated pain is important because evidence suggests the best way to help patients lies in skilled practitioners and appropriate resources. In the future, strategies need to be improved that target all aspects of CNS changes, including cortical reorganisation.<sup>14,20</sup> It is possible to achieve a positive outcome; ion channels can change in minutes (see<sup>26</sup> for review) and movement-specific motor maps can shift over days and even minutes.<sup>27,28</sup> This suggests that patients may benefit from rapid neurological changes which equate to symptom relief (usually less pain) as the nervous system is restored to a less sensitive state.

### Manual therapy

Touch can have anti-nociceptive effects<sup>29</sup> and can also benefit patients in conjunction with exercise in some conditions such as shoulder disorders.<sup>30</sup> In mechanical neck pain, with or without headache, the Cochrane review concluded that manual therapy should only be done in conjunction with exercise and that mobilisation or manipulation alone was less effective.<sup>31</sup> Inaccurate

statements from clinicians such as 'putting your spine back in place' should be avoided. Acupuncture has been shown to have short-term effects on pain.<sup>32</sup>

The remaining chapters of the book will direct the reader to appropriate and evidence-based techniques. Given the potential for anti-nociceptive effects, it stands to reason this may be an appropriate part of management for someone that has nociceptive contributions to pain, but less so for someone demonstrating sensitivity (e.g. when light touch is painful).

### Medications

Medications may modify pain. Examples include medications that block inflammatory drivers, blunt neural sensitisation or promote neural plasticity. This topic is covered in Chapter 17.

### Exercise/progressive loading

Following the initial period of unloading after an acute injury (or after prolonged changes to movement as a protective strategy), it is critical for patients to move and reload tissue in a gradual manner that promotes progressive tissue adaptation. Rest reduces capacity<sup>33</sup> in musculoskeletal tissues. (See Mechanotherapy in Chapter 17).

In nociceptive presentations, the clinician may focus more on local tissue reloading whereas, when pain is more centrally dominant, the exercise program may need to drop to below that which provokes them and take a backseat to techniques such as graded motor imagery (GMI) and 'explain pain'. This is described in

**Table 6.4** Language that may be unhelpful and how to rephrase it (adapted from *Explain Pain*—see text for more detail)<sup>5</sup>

Unhelpful language that may amplify pain experience or interfere with progress	Potential rephrasing that may be clinically appropriate	Considerations/rationale
'It's bone on bone in there.'	'Your MRI shows age- and load-appropriate changes.'	Asymptomatic pathology is common <sup>36, 37</sup> and focus on pathology (that may or may not be relevant for the patient's presentation) can be negative
'Your scan shows degeneration.'	'Your scan shows adaptations to age and load.'	Conversely, targeted education that demonstrates adaptation can improve outcomes <sup>38</sup>
'You have no core strength.'	'Your trunk muscles could be stronger.'	The body has remarkable ability to heal/adapt and, in many cases, to function better than prior to a medical incident. Treatment should facilitate this
'Your pelvis is out.'	'I am a complete idiot.'	OK—you can see Lorimer Moseley's influence here. But we are making a serious point and humour is a powerful communication tool, whether in textbooks or with patients

the GMI handbook where the GMI program is part of rehabilitation. When symptoms worsen, the techniques used are more focused on motor/functional empathy and implicit motor imagery such as left/right judgments, and as symptoms improve, the techniques are directed more towards mirror therapy and actual exposure to load. The start point can be established between the clinician and the patient by listening to their current activity and how well they tolerate it. Ultimately, clinicians should be assisting patients and athletes to restore function.

### Graded motor imagery/explain pain/cognitive therapy/sensory discrimination training

Some people will not benefit from manual therapy or exercise as touch or movement may trigger their pain. In this instance, pain science education is essential. The goal of this approach is to help patients understand the concepts of threat and related body responses. Fundamental concepts include extinction of pain/signal and desensitisation with the aim of reducing the patient's feelings of helplessness.<sup>14</sup>

Some patients may benefit from the use of mirror therapy, visual distortion (e.g. minimising lens), graded motor imagery (GMI), and strategies that stimulate sensory and motor

representations with context.<sup>14</sup> These methods are very well described in the book *Explain Pain* (see Fig. 6.6).<sup>5</sup>

### Language

Language is a powerful tool and has potential for both negative and positive impacts.<sup>5, 34, 35</sup> Skilful communication can better engage a patient in his or her own care decisions and this can improve outcomes. Table 6.4 provides some examples of language that may be considered unhelpful and how they can be rephrased.

### SUMMARY

In many cases in sport and exercise medicine, physical assessment is aimed at establishing a structural diagnosis to guide an effective treatment plan in the hope that someone will fully recover. The expert clinician appreciates pain as a protective output, maintains a level of vigilance for when it is necessary to take a broader approach, assesses the various contributors to the patient's pain and considers secondary factors that may act to modulate it at the peripheral and/or central levels (see Fig. 6.3). This approach, which incorporates advances in pain science, will mean fewer patients are given inappropriate treatment that is missing an important element of their condition.

**Figure 6.6** 'Explain pain' education, and the specific details of teaching graded motor imagery, is outside the scope of this book. We recommend that clinicians carefully consider this element when addressing painful conditions, DAVID BUTLER AND G LORIMER MOSELEY, *EXPLAIN PAIN*, 2003, NOIGROUP PUBLICATIONS

# Beware: conditions that masquerade as sports injuries

with NICK CARTER and MARK HUTCHINSON

*Belgian decathlete Thomas Van der Plaetsen had testicular cancer diagnosed because abnormal levels of the HCG hormone were detected on a routine doping test in 2014. After treatment, 2016 saw him win the European Championships and compete at the Rio 2016 Olympic Games.*

Not every patient who presents to the sport and exercise medicine clinician has a sports-related condition. Sport and exercise medicine has its share of conditions that must not be missed—'red flag' conditions that may appear at first to be rather benign. For example, a patient diagnosed with a minor 'calf strain' may have a deep venous thrombosis or a young basketball player with proximal anterior tibial pain who has been labelled as having Osgood-Schlatter disease may have an osteosarcoma or giant cell tumour of the proximal tibia. In this chapter we:

- outline a clinical approach that should maximise your chances of recognising a condition that is 'masquerading' as a sports-related condition
- describe some of these conditions to illustrate how they can present.

### HOW TO RECOGNISE A CONDITION MASQUERADING AS A SPORTS INJURY

Three key factors will assist the clinician to avoid missing an atypical or masquerading condition. The first is keeping an open mind to the possibility. Too often, we become more rigid regarding our initial diagnosis rather than being open to consider other possibilities. Sometimes a fresh perspective from a colleague can be helpful in this regard.

The second and perhaps most important key is obtaining a detailed and complete history and physical examination. If you do not ask the question or consider a broader differential diagnosis, it is impossible to pick up the subtle clues pointing to a less likely but masquerading condition. Indeed, if the concept of a masquerading condition is not triggered from the history and examination, it is unlikely that appropriate investigations to make the diagnosis will be ordered. For example, if a patient presents with tibial

pain and it is, in fact, due to hypercalcaemia secondary to lung cancer, a bone scan of the tibia looking for stress fracture will usually not help with the diagnosis, but a history of weight loss, occasional haemoptysis and associated abdominal pain may. In a basketball player with shoulder pain, the history of associated arm tightness and the physical finding of prominent superficial veins are important clues to axillary vein thrombosis; a grey-scale ultrasound scan looking for rotator cuff tendinopathy will not provide the diagnosis.

#### PRACTICE PEARL

In sports medicine, it may seem simple to jump to the obvious conclusion regarding a specific diagnosis but if more in-depth questions or a thorough physical exam are not completed, it is difficult to be alert to a less common or 'non-obvious' diagnosis.

A third important key that points to masquerading conditions is when the clinical progression does not fit the pattern expected of the more common diagnosis or condition. When this occurs, consider alternative less common conditions. For example, the lingering contusion that should have resolved long ago could represent an underlying blood dyscrasia or tumour of the soft tissue or bone.

#### PRACTICE PEARL

You must ask yourself, 'Could this be a rare condition or unusual manifestation?' When the question is asked, then other options are entertained and the appropriate diagnosis can be conceived.

Ultimately, successful diagnosis of masquerading conditions requires keeping an open mind, performing a complete history and exam, and recognition of discrepancies between the patient's clinical features and clinical progress compared to what should be expected by the more typical diagnosis.

### Conditions masquerading as sports injuries

Table 7.1 lists some of the conditions that may masquerade as sport and exercise medicine conditions. These are outlined below.

#### Bone and soft tissue tumours

Primary malignant tumours of bone and soft tissues are rare but when they occur it is most likely to be in the younger age group (second to third decade). Osteosarcoma can present at the distal or proximal end of long bones, more commonly in the lower limb, producing joint pain. Patients often recognise that pain is aggravated by activity and hence present to the sports medicine clinic. The pathological diagnosis of osteosarcoma is dependent on the detection of tumour-producing bone and so an X-ray may reveal a moth-eaten appearance with new bone formation in the soft tissues and lifting of the periosteum (Fig. 7.1). In young patients, the differential diagnosis includes osteomyelitis. It is recommended that any child or adolescent with bone pain be X-rayed.

Another presentation of tumour is when a patient presents with a mild injury that won't get better or with

an atypical finding on radiographs taken when a fracture occurs. If fractures occur with relatively low energy or when they do not have an appropriate mechanism of injury masqueraders should be considered. They may also present as progressive pain rather than pain that improves with rest and treatment.

Malignant tumours (e.g. of the breast, lung and prostate) may metastasise to bone. Patients may not recognise that a previously treated malignancy could be related to limb pain. Breast carcinoma may also present as a frozen shoulder. An accurate history is, therefore, central to making an accurate diagnosis. Red flag signs for malignancy or infection include prominent night pain, often being woken at night with pain, fever, loss of appetite, weight loss and malaise. Patients exhibiting these symptoms should be examined and investigated thoroughly to determine the cause. In the sports population, patients with metastatic disease are more likely older and have more complex medical histories.

Giant cell tumours, aneurismal bone cysts and unicameral bone cysts are benign or less aggressive bone tumours that can present in a similar fashion with pain and failure to resolve in a time frame expected of a simple contusion or traumatic injury. Osteoid osteoma is a benign bone tumour that often presents as exercise-related bone pain and tenderness and is frequently misdiagnosed as a stress fracture. It can occasionally be seen on plain radiographs (Fig. 7.2a). The bone scan appearance is similar to that of a stress fracture, although the isotope uptake is more intense and widespread. This condition is characterised clinically by the presence of night pain and by the abolition of symptoms with the use of aspirin. The tumour has a characteristic appearance on CT scan (Fig. 7.2b) with a central nidus.

Ultimately, like malignant tumours of bone, the examiner should be vigilant regarding atypical complaints and failure to progress along normal healing timelines expected of simple contusions, stress fractures or frank fractures. Care should be taken to thoroughly interpret all radiographs for other potential causes of bone weakening that led to a fracture in the first place.

As for atypical bone pathologies, when soft tissue lesions present with an unusual history or do not progress as expected, the clinician should readily consider a broader differential diagnosis.

Synovial cell sarcoma frequently involves the larger lower joints such as the knee and ankle. Patients present with pain, often at night or with activity, maybe with instability and swelling. As a masquerader, these present as chronic swelling and pain that does not resolve with standard treatment. Like synovial sarcoma, synovial chondromatosis and pigmented villonodular synovitis are benign tumours of the synovium<sup>1</sup> found mainly in

**Figure 7.1** X-ray of an osteosarcoma in the distal femur

Regional pain syndromes	<ul style="list-style-type: none"> <li>• Complex regional pain syndrome</li> <li>• Fibromyalgia/myofascial pain syndrome</li> </ul>

(a)

(b)

**Figure 7.2** Osteoid osteoma (a) Radiograph showing sclerotic focus in distal fourth metatarsal (b) Transverse image from a CT scan demonstrating an osteoid osteoma. Note the lytic lesion in the anterior cortex of the femoral neck (arrow), with radiofrequency probe in position for ablation

the knee, which present with mechanical symptoms, persistent swelling, and failure to respond to basic rest, ice and anti-inflammatory regimens.

Direct trauma to muscle tissue can lead to a contusion, haematoma or myositis ossificans. Myositis generally presents with the classic history of direct trauma and swelling. Heat or ultrasound can exacerbate the process. Imaging studies show calcification within the muscle that should not be in continuity with the bone itself. Biopsies should be performed with caution, as there are case reports in the literature of the active edge of myositis ossificans being misread as osteosarcoma. Even less typically, trauma may result in haemorrhage into an indolent, underlying rhabdomyosarcoma. The clinician should consider alternative diagnoses in patients with hematomata that is slow to resolve or when the history of trauma does not fit with the clinical signs.

The most common of benign soft tissue tumours are ganglion cysts. These cysts are lined by connective tissue, contain mucinous fluid and are found mainly around the wrist, hand, knee and foot. They may be attached to a joint capsule or tendon sheath and may have a connection to the synovial cavity. They are usually asymptomatic but can occasionally cause pain and cosmetic deformity (Chapter 26).<sup>2</sup> However, ganglion cysts may also represent an important clue regarding other underlying, masquerading disease processes such as osteoarthritis or chronic tendinopathy.

### Rheumatological conditions

Inflammatory musculoskeletal disorders in patients presenting to the sports medicine clinic frequently masquerade as a traumatic or mechanical condition. Low back pain of ankylosing spondylitis, psoriatic enthesopathy<sup>3</sup> presenting as patellar tendinopathy or flitting arthritis in early rheumatoid arthritis are common examples.

Effective management of athletes presenting with musculoskeletal complaints requires a structured history, physical examination and definitive diagnosis to distinguish soft tissue problems from joint problems and an inflammatory syndrome from a non-inflammatory syndrome. Clues to a systemic inflammatory aetiology may include constitutional symptoms, morning stiffness, elevated acute-phase reactants and progressive symptoms despite modification of physical activity. The mechanism of injury or lack thereof, is also a clue to any underlying disease. In these circumstances, more complete work-up is reasonable, including radiographs, MR imaging and laboratory testing for autoantibodies.<sup>4</sup>

When patients present with an acutely swollen knee without a history of precipitant trauma or patellar tendinopathy without overload, the clinician may be alerted to the possibility that these could be inflammatory in origin. Prominent morning joint or back stiffness, night pain or extra-articular manifestations of rheumatological conditions (e.g. skin rashes, nail abnormalities—Fig. 7.3), bowel disturbance, eye involvement (conjunctivitis, iritis) or urethral discharge may all provide clues.

**Figure 7.3** Typical appearance of nails in a patient with psoriatic arthropathy

Inflammation of entheses (e.g. in lateral elbow pain, patellar tendinopathy—Fig. 7.4, insertional Achilles tendinopathy and plantar fasciopathy) is almost universal among those with HLA (human leukocyte antigens) B27-related, seronegative (for rheumatoid factor) arthropathies. Enthesopathy is usually associated with other joint or extra-articular involvement, although a subgroup exists with enthesitis as the sole presentation.<sup>2</sup>

### Muscle disorders

Dermatomyositis and polymyositis are inflammatory connective tissue disorders characterised by proximal limb girdle weakness, often without pain. Dermatomyositis, unlike polymyositis, is also associated with a photosensitive skin rash in light-exposed areas (hands and face). In the older adult, dermatomyositis may be associated with malignancy in approximately 50% of

**Figure 7.4** Enthesopathy (such as at the distal patellar tendon shown here) should alert the clinician to consider an underlying spondyloarthropathy

cases. The primary malignancy may be easily detectable or occult. In the younger adult, weakness may be profound (e.g. unable to rise from the floor) but in the early stages may manifest only as underperformance in training or competition.

Dermatomyositis and polymyositis may also be associated with other connective tissue disorders such as systemic lupus erythematosus or systemic sclerosis, and muscle abnormality is characterised by elevated creatine kinase levels and electromyographic (EMG) and muscle biopsy changes.

Endurance athletes may complain of myalgia and fatigue that is out of proportion with their training schedule. The differential diagnosis to explain these symptoms is broad. Mitochondrial myopathies, though uncommon, may present with cramping and muscle pain.<sup>5</sup> Consider myoglobinuria in these patients. Referral to a specialist neurologist for investigations and diagnosis will be necessary.<sup>6</sup>

Regional limb girdle dystrophies such as limb girdle dystrophy and facio-scapulo-humeral dystrophy may also present with proximal limb girdle weakness in young adults. They are also associated with characteristic EMG changes. Ultimately, when an athlete complains of muscle fatigue, aches and pains that fail to respond in a normal time frame expected with the patterns of training, a broader differential diagnosis needs to be considered

### Endocrine disorders

Occasionally, the source of the masquerading symptoms in athletes is underlying endocrine disorders and pathologies. Disorders of thyroid function may present with a variety of rheumatological conditions.<sup>7</sup> Proximal muscle weakness with elevated creatine kinase and fibromyalgia may develop with hypothyroidism. Hyperthyroidism is associated with thyroid acropachy (soft tissue swelling and periosteal bone changes), adhesive capsulitis and painless proximal muscle weakness.<sup>4</sup> Hyperparathyroidism may be associated with the deposition of calcium pyrophosphate in joints. Patients may develop acute pseudogout or a polyarticular inflammatory arthritis resembling rheumatoid arthritis. X-rays of the wrists or knees may demonstrate chondrocalcinosis of the menisci or triangular fibrocartilage complex (Fig. 7.5).

Adhesive capsulitis or septic arthritis may be the presenting complaint in patients with diabetes mellitus and those with other endocrine disorders such as acromegaly may develop premature osteoarthritis or carpal tunnel syndrome. Patients with hypercalcaemia secondary to malignancy (e.g. of the lung) or other conditions such as hyperparathyroidism can present with bone pain as well as constipation, confusion and renal calculi. A proximal

**Figure 7.5** Chondrocalcinosis of the triangular fibrocartilage (arrow) in calcium pyrophosphate dehydrate deposition disease

myopathy may develop in patients with primary Cushing's syndrome or after corticosteroid use. When symptoms of myalgia, joint stiffness and swelling do not resolve, a more in-depth laboratory work-up hunting for masqueraders is appropriate and indicated.

### Vascular disorders

Patients with venous thrombosis or arterial abnormalities (Fig. 7.6) may present with limb pain and swelling aggravated by exercise. Calf, femoral or axillary veins

**Figure 7.6** Angiogram showing common iliac artery stenosis (arrow)

are common sites for thrombosis. While a precipitant cause may be apparent (e.g. recent surgery or air travel), consider also the thrombophilias such as the antiphospholipid syndrome or deficiencies of protein C, protein S, antithrombin III or factor V Leiden. When athletes with no other risk factors for thrombosis develop a blood clot, more extensive work-up is necessary to look for the masquerading underlying cause, which in turn will guide treatment.

The claudicant pain of peripheral vascular disease is most likely to be first noticed with exercise and so patients may present to the sports medicine practitioner. Remember also that arteriopathy can occur in patients with diabetes. Various specific vascular entrapments are also found, such as popliteal artery entrapment, which presents as exercise-related calf pain and thoracic outlet syndrome.

### Genetic disorders

Various genetic disorders have been associated with an increased risk of injury and in some cases catastrophic injuries in athletes. Ehlers Danlos with its increased ligamentous laxity has been associated with increased risk of ligament injuries. Osteogenesis imperfect has been associated with an increased fracture risk. Down's syndrome is associated with odontoid hypoplasia with inherent increased risk of cervical spine injuries. Marfan syndrome has been associated with sudden cardiac death. Marfan syndrome is an autosomal dominant disorder of fibrillin characterised by musculoskeletal, cardiac and ocular abnormalities.<sup>8</sup> Musculoskeletal problems are common due to joint hypermobility, ligament laxity, scoliosis or spondylolysis. In patients with the Marfanoid habitus, referral for echocardiography and ophthalmological opinion should be considered as sudden cardiac death or lens dislocation may result.

Haemochromatosis is an autosomal recessive disorder of iron handling, which results in iron overload. Patients may present with a calcium pyrophosphate arthropathy with characteristic involvement of the second and third metacarpophalangeal joints and hook-shaped osteophytes seen on X-ray of these joints. While ferritin levels are raised in patients with haemochromatosis, it is important to remember that ferritin may also be elevated in athletes taking iron supplements or in response to any acute inflammatory illness.<sup>9</sup> Fasting transferrin levels and detection of the HFE gene are central to the diagnosis of inherited haemochromatosis. Once again, considering a broad differential diagnosis based on clinical presentation and history may help make these genetic diagnoses, which in turn will allow the clinician to better counsel the athlete regarding risks of participation in certain sports.

### Granulomatous diseases

Granulomatous diseases such as tuberculosis and sarcoidosis have been called 'the great mimickers' or great 'masqueraders' secondary to their ability to present in many varied and atypical fashions. They can look like tumours, inflammation, infection or traumatic injuries. Tuberculosis is a granulomatous mycobacterial infection. Musculoskeletal involvement includes chronic septic arthritis and Pott's spine fracture.

Patients with acute sarcoidosis can present with fevers, lower limb (commonly) rash and ankle swelling. The rash of erythema nodosum (Fig. 7.7) may be mistaken for cellulitis and antibiotics have frequently been prescribed in error. The diagnosis is easily made by chest X-ray, which shows changes of bilateral hilar lymphadenopathy. The clinician should remember that the differential diagnosis of bilateral hilar lymphadenopathy includes tuberculosis and lymphoma. Chronic sarcoidosis is a systemic disorder involving the lungs, central nervous system, skin, eyes and musculoskeletal system. Patients can present with chronic arthropathy together with bone cysts or with bone pain due to hypercalcaemia.

### Infection

Bone and joint infections, while uncommon, may have disastrous consequences if the diagnosis is missed. Bone pain in children, worse at night or with activity, should alert the clinician to the possibility of osteomyelitis. Bone infection near a joint may result in a reactive joint effusion.

Septic arthritis is rare in the normal joint. In arthritic or diabetic joints or joints that recently underwent arthroscopy, sepsis is much more common. Rapid joint destruction may follow if left untreated.

Even though *Staphylococcus aureus* is the causative organism in more than 50% of cases of acute septic joints, it is imperative that joint aspiration for Gram stain, and

culture and blood cultures are taken before commencement of antibiotic treatment. Once-only or repeated joint lavage may be considered in patients receiving intravenous antibiotic treatment. The immunocompromised patient may present with a chronic septic arthritis. In this situation, tuberculosis or fungal infections should be considered. In suspected cases of septic arthritis, the patient should be admitted to hospital.<sup>10</sup>

Another cause of arthritis is Lyme disease, a common arthropod-borne infection in some countries including the US. Hallmarks of Lyme disease are erythema migrans (EM), disruption of electrical conduction of cardiac muscle, the development of neurological abnormalities and episodes of arthritis. Intermittent episodes of arthritis develop several weeks or months after infection and, despite adequate antibiotic therapy, symptoms persist in 10% of patients with arthritis. The severity of arthritis can range from mild to moderate inflammation of the joints and tendons months after infection, to a chronic, debilitating osteoarthropathy complete with destruction of cartilage and erosion of bone in a subset of these individuals within a few years. In severe cases, the highly inflammatory aspects of Lyme arthritis can lead to cartilage and bone erosion with permanent joint dysfunction. The diagnosis of Lyme disease is clinical and serological tests should be used to confirm the clinical diagnosis.<sup>11</sup>

### Pain syndromes

Complex regional pain syndrome type I is a post-traumatic phenomenon characterised by localised pain out of proportion to the injury, vasomotor disturbances, oedema and delayed recovery from injury. The vasomotor disturbances of an extremity manifest as vasodilatation (warmth, redness) or vasoconstriction (coolness, cyanosis, mottling).<sup>12</sup> Early mobilisation, use of motor imagery and avoidance of surgery are important keys to successful management (see also Chapter 6).

Myofascial pain syndromes develop secondary to either acute or overuse trauma. They present as regional pain associated with the presence of one or more active trigger points (Chapter 4).

Fibromyalgia is a chronic pain syndrome characterised by widespread pain, chronic fatigue, decreased pain threshold, sleep disturbance, psychological distress and characteristic tender points. It is often associated with other symptoms including irritable bowel syndrome, dyspareunia, headache, irritable bladder, and subjective joint swelling and pain. Fibromyalgia is diagnosed on the examination finding of 11 of 18 specific tender point sites in a patient with widespread pain. Chronic fatigue syndrome has many similarities to fibromyalgia<sup>10</sup> and may be the same disease process. It may present as excessive post-exercise muscle soreness but is always

**Figure 7.7** Erythema nodosum in acute sarcoidosis. PHOTO COURTESY OF DR RAHEEM B KHERANI

associated with excessive fatigue. There is evidence that exercise improves global wellbeing in women with this condition.<sup>13</sup>

## SUMMARY

In summary, it is important for the clinician to be on constant alert for potential masqueraders when dealing with athletic injuries. Clearly, common things are common;

most of the time the clinician will be correct with the first and most likely diagnosis. However, when the history or physical examination is not classic and an athlete fails to improve and heal in the expected time frame of the more common diagnosis, a broader differential diagnosis including masquerading causes should be considered. Stay open minded to the potential if not likelihood of important masquerading pathologies.

# Introduction to clinical biomechanics

with CHRISTIAN BARTON, NATALIE COLLINS and KAY CROSSLEY

*Mo Farah has nine key elements to his running technique that have allowed him to become Britain's greatest ever runner.*

www.telegraph.co.uk, 16 September 2013

The term 'biomechanics' can be used in a variety of ways. In this book, biomechanics refers to the description, analysis and assessment of human movement during sporting activities.<sup>1</sup> Broadly, biomechanics can be broken into three categories, including 'kinematics' (movement we can see), 'kinetics' (forces driving the movement) and 'neuromotor' (muscle function controlling forces and movement). This chapter will focus primarily on the actual movement occurring in the body segments (kinematics). Our approach can be referred to as 'subjective biomechanical analysis'. We aim to describe movement such as running or squatting as it appears to visual observation. This reflects how clinicians assess and treat, and it can be done with the assistance of video analysis and without expensive laboratory equipment.

The aims of this chapter are to:

- outline the basics of 'ideal' lower limb biomechanics
- explain the ideal biomechanics with running
- describe lower limb biomechanical assessment in the clinical setting
- outline how to clinically assess footwear
- review the best available evidence associating biomechanical factors with injuries, as well as sharing clinical opinions as to which technical factors in sports contribute to specific injuries
- discuss how to manage biomechanical abnormalities detected in the assessment
- explain normal and abnormal upper limb biomechanics.

We address lower limb and upper limb biomechanics separately for the learner's convenience, but the experienced clinician will consider the close relationship between the upper and lower limbs during a variety of functional tasks.

Ultimately, biomechanical evaluation should be completed based on task specificity to ensure the clinician is confident in the accuracy of information obtained.

## 'IDEAL' LOWER LIMB BIOMECHANICS—THE BASICS

Here we discuss ideal structural characteristics, including available joint range of motion and stance position. Note that each individual has his or her own mechanical make-up due to structural characteristics (anatomy), and may never achieve the 'ideal' position or biomechanical function. Table 8.1 and Figure 8.1 provide reference for ideal joint range of motion and planes of movement respectively.

### Lower limb joint motion

The *hip joint* is formed between the femoral head and acetabulum. The ball-and-socket structure of this joint permits motion in all three planes.

The *knee joint* is formed between the tibial plateau and femoral condyles. Primarily a hinge joint, the knee allows flexion and extension in the sagittal plane. The knee also permits some rotation in the transverse plane. This secondary motion is particularly important to allow the knee to lock into an extended position for stance stability, and to unlock when moving into flexion for shock absorption.

The *ankle joint* (between the shank and rearfoot) consists primarily of two articulations, the *talocrural joint* and the *subtalar joint* (STJ). The talocrural joint is formed between the talus and the mortise of the tibia and fibula malleoli. Its axis of motion is predominantly in the frontal plane which allows dorsiflexion and plantarflexion motion in the sagittal plane (Fig. 8.2a and b).<sup>2</sup>

**Table 8.1 A guide to lower limb joint ranges of motion when in neutral positions**

Joint	Plane	Assessment position	Available range
Hip	Sagittal	Supine	Flexion = 120°
		Prone	Extension = 20°
	Frontal	Supine	Abduction = 40°; adduction = 25°
	Transverse	Supine/prone±hip flexion/extension	Internal rotation = 45°; external rotation = 45°
Knee	Sagittal	Supine	Flexion = 135°; extension = 0°
	Frontal		None
	Transverse	Full extension	None
		70° flexion	45° rotation
Foot and ankle (triplanar)*	Sagittal	Supine	Plantarflexion = 45°; dorsiflexion = 20°
	Frontal		Supination = 45–60°; pronation = 15–30°
First metatarsophalangeal (MTP)	Sagittal	Supine	Plantarflexion = 45°; dorsiflexion = 70°

\*Refers to combined motion of the talocrual, subtalar, midtarsal and metatarsal break joints

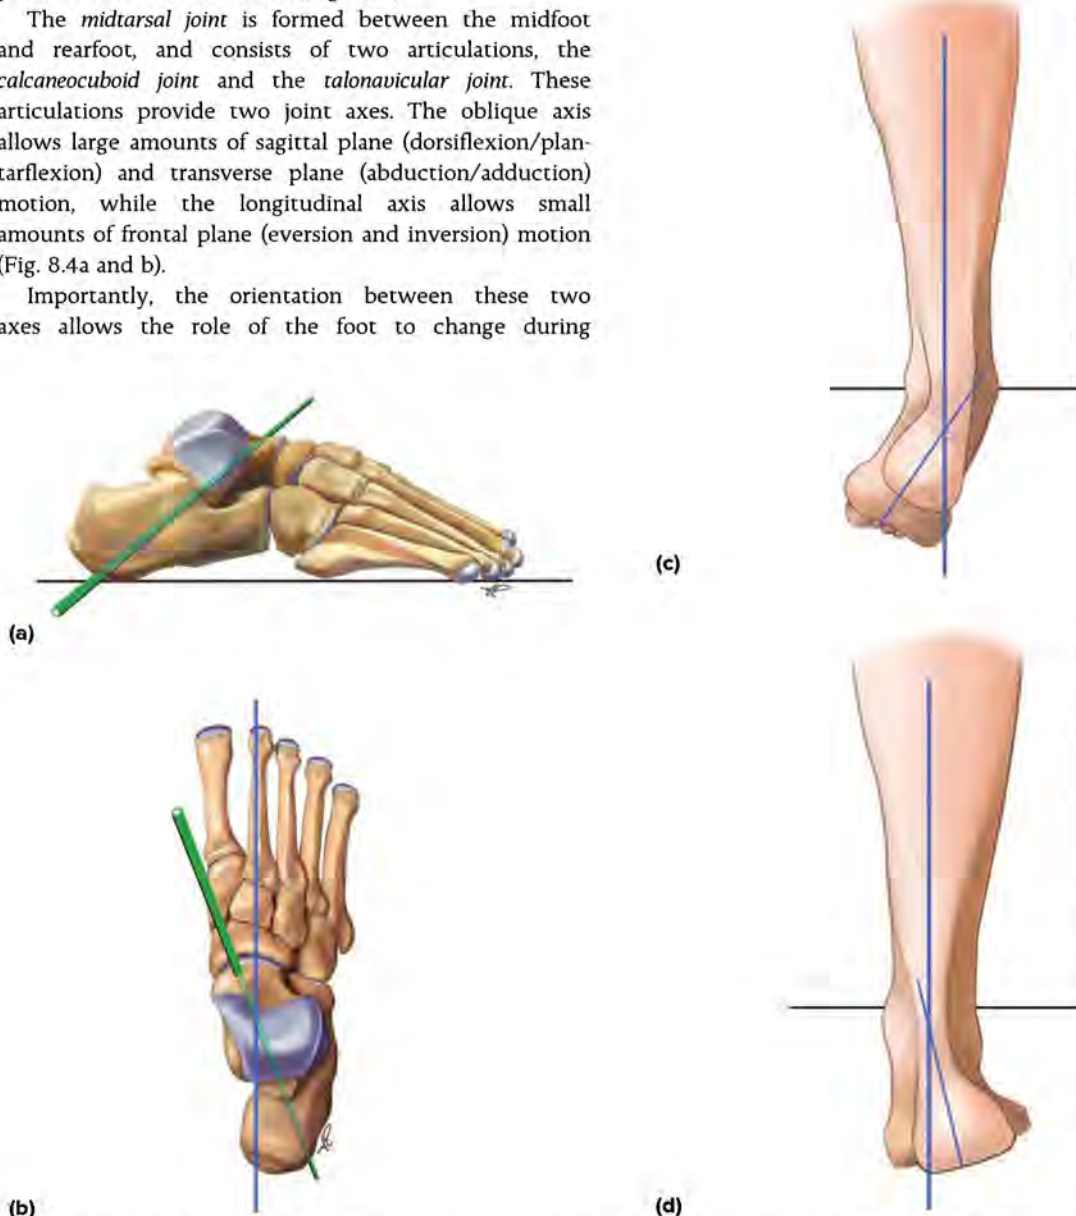

**Figure 8.1** Anatomical planes of the body**Figure 8.2** Axis of motion of the ankle joint (a) Superior view (b) Posterior view

The STJ is formed between the calcaneus and talus. The three articular facets of the STJ allow for complex triplanar motions of pronation and supination. The axis of motion runs posteriorly and inferiorly in the sagittal plane ( $40\text{--}50^\circ$ ), and laterally in the transverse plane ( $20\text{--}25^\circ$ )<sup>2</sup> (Fig. 8.3a-d). During pronation, the STJ axis provides primarily eversion, which is combined with dorsiflexion and abduction (Fig. 8.3d). During supination, the STJ axis provides primarily inversion, which is combined with plantarflexion and adduction (Fig. 8.3c).

The *midtarsal joint* is formed between the midfoot and rearfoot, and consists of two articulations, the *calcaneocuboid joint* and the *talonavicular joint*. These articulations provide two joint axes. The oblique axis allows large amounts of sagittal plane (dorsiflexion/plantarflexion) and transverse plane (abduction/adduction) motion, while the longitudinal axis allows small amounts of frontal plane (eversion and inversion) motion (Fig. 8.4a and b).

Importantly, the orientation between these two axes allows the role of the foot to change during

weight-bearing. As the rear foot everts, the two axes align so they are more parallel, unlocking the foot and allowing it to conform to the surface and/or absorb the ground reaction force (GRF). Conversely, as the rearfoot inverts, the two axes converge, locking the foot into a supinated position and allowing it to function as a rigid lever for propulsion.<sup>2</sup>

**Figure 8.3** Axis of motion of the subtalar joint (a) Lateral view. Angle of inclination approximately  $50^\circ$  to transverse plane (b) Superior view. Angle between axis of motion of subtalar joint and longitudinal axis of the rearfoot is approximately  $15^\circ$  (c) Supination at subtalar joint with  $20^\circ$  calcaneal inversion (d) Pronation at subtalar joint with  $10^\circ$  calcaneal inversion

(b)

**Figure 8.4** Oblique and longitudinal axis of midtarsal joint  
(a) Lateral view (b) Superior view

The *midtarsal* (or *Lisfranc*) joints are formed between the distal tarsal bones of the midfoot (cuneiforms and cuboid) and the five metatarsal bones (forefoot). The axis of motion for these joints runs primarily in the transverse plane in an oblique direction (Fig. 8.5a and b). This leads primarily to sagittal plane motion (flexion/extension), although some frontal plane motion (eversion/inversion) does occur medially (adduction, Fig. 8.5c) and laterally (abduction, Fig. 8.5d).

The *first metatarsophalangeal joint* (MTPJ) is formed between the head of the first metatarsal and the base of the proximal phalanx. The primary motion that occurs at this joint is in the sagittal plane (flexion/extension) (Fig. 8.6). In particular, extension of this joint is essential to optimise function of the windlass mechanism (see below) during gait.

### Ideal neutral stance position

To examine stance position, have the patient adopt a normal, comfortable, standing posture. Ideal neutral stance occurs when the joints of the lower limbs and feet are symmetrically aligned, with the weight-bearing

(a)

(b)

**Figure 8.5** (a) midtarsal joints—the joints between the distal tarsal bones of the midfoot (cuneiforms and cuboid) and the five metatarsal bones (forefoot) (b) The metatarsal break (frontal plane). The axis of motion runs as shown (green rod)

(c)

(d)

**Figure 8.5 (cont.)** Frontal plane motion of the metatarsal break showing that the forefoot can (c) adduct and (d) abduct

line passing through the anterior superior iliac spine, the patella and the second metatarsal (Fig. 8.7).

When the feet are in a symmetrical position, the subtalar (talocalcaneal) joint is neither pronated nor supinated, and the midtarsal joint (talonavicular and calcaneocuboid joints) is maximally pronated so that the first and second metatarsal heads are in contact with the ground. The long axis of the forefoot through the second metatarsal is perpendicular to the bisection of the heel (Fig. 8.8) and in line with the tibial tuberosity. The ankle joint is neither plantarflexed nor dorsiflexed, and the tibia is perpendicular

**Figure 8.6** Motion of the hallux around the transverse axis of the first metatarsophalangeal joint

**Figure 8.7** The alignment of the lower limb in neutral position. The weight-bearing line runs through the anterior superior iliac spine, patella and second metatarsal. The calcaneus is in line with the tibia, and the forefoot is perpendicular to the calcaneus

**Figure 8.8** Normal relationship between the forefoot and rearfoot when the foot is in neutral stance

to the supporting surface in the sagittal and frontal plane. The knee is fully extended (but not hyper extended) and in slight valgus alignment. The hips are in a neutral position (neither internally nor externally rotated, neither flexed nor extended). The left and right anterior superior iliac spines of the pelvis are level. A slight anterior tilt of the pelvis is normal. More specific objective descriptions of ideal alignment are outlined in the assessment section.

### 'IDEAL' BIOMECHANICS WITH MOVEMENT—RUNNING

As injury mechanisms for many overuse injuries can be associated with theoretically suboptimal lower limb biomechanics, the clinician must know how to assess lower limb biomechanics during running. We focus first on the heel strike pattern of running as this is the predominant pattern for the majority of runners.<sup>3</sup> We will then consider how biomechanics is altered when running with a forefoot strike pattern.

Although we focus on ideal running biomechanics, ideal walking biomechanics are similar to heel strike running patterns outlined below. The most important

biomechanical feature that distinguishes running from walking is the airborne or 'float' phase of running, where neither foot is in contact with the ground.<sup>2</sup> Additionally, vertical GRFs during running are double that of walking.<sup>2,4</sup> the pelvis is in greater anterior tilt,<sup>5</sup> and sagittal plane excursions of the knee and hip are increased. Ultimately, this leads to greater stress on structures of the lower limb.

The heel strike pattern of running can be split into a number of phases (Fig. 8.9), each of which will be discussed below.

### Loading (heel strike to foot flat)

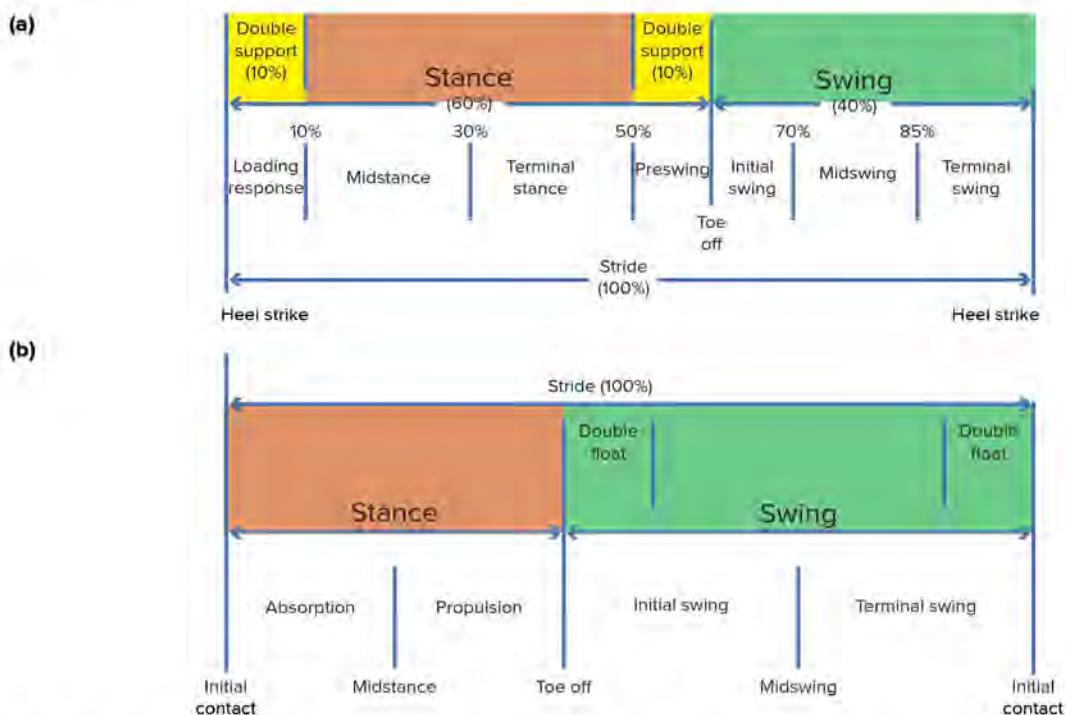

With the leg swinging toward the line of progression, and the foot supinated, the rearfoot (heel) contacts the ground in slight inversion (0–5°).<sup>2,6–8</sup> At heel strike, the pelvis is level, in slight anterior tilt (10°), and internally rotated; the hip is externally rotated (5–10°) and flexed (20–30°); and the knee is flexed (10°). Due to the laterally directed line of the GRF produced by heel strike, a cascade of events occurs to assist shock absorption. First, the rearfoot begins to evert, accompanied by tibial and femoral (hip) internal rotation, and hip adduction. This is combined with knee flexion, which peaks at around 45° as a result of the GRF line passing posterior to the knee joint.<sup>9,10</sup> Each of these motions is controlled by eccentric muscle activity which helps to dissipate the GRF. In addition, there may be contralateral pelvic drop, although this should be minimal (approximately 5°).<sup>10</sup> The gluteal musculature should actively control this motion and further dissipate the GRF.

Initial rearfoot eversion also results in more parallel alignment of the midtarsal joints (i.e. calcaneocuboid and talonavicular), causing them to unlock.<sup>2</sup> Importantly, this allows the forefoot to make solid contact with the ground at foot flat<sup>11</sup> and allows the foot to adapt during loading to potentially uneven or unstable terrain.<sup>2</sup>

Although motions that comprise foot pronation are normal, they should not be excessive or rapid (i.e. hyperpronation). Excessive motion will place strain on structures designed to control foot pronation, such as the plantar fascia, tibialis posterior muscle and intrinsic foot musculature.<sup>2</sup> Excessive pronation also increases medial GRF, accentuating more proximal motion at the knee, hip and pelvis, and increasing load on ligamentous and muscular structures responsible for proximal control.<sup>2</sup>

The clinician should carefully note proximal motion during this early phase of stance. Excessive contralateral pelvic drop and/or hip adduction/internal rotation may increase strain on structures required to control it, such as the iliotibial band (ITB), gluteal musculature and tensor fascia latae (TFL) muscle. Additionally, this may also place increased or altered loading on the lumbar spine, tibiofemoral joint and patellofemoral joint (PFJ). Any

**Figure 8.9** Gait cycle with phases and individual components (a) Walking (b) Running  
ADAPTED FROM DUGAN AND BHAT<sup>2</sup>

excessive anterior tilting of the pelvis may place excessive strain on the lumbar spine and/or hamstring musculature, and may impair gluteal function.

Conversely, inadequate pronation or excessive supination may lead to an excessive or prolonged laterally directed GRF,<sup>2</sup> resulting in a less mobile foot and poorer shock absorption capacity. This may be associated with lower limb stress fractures,<sup>12</sup> or increase the incidence of lateral ankle sprain and chronic ankle instability.<sup>13, 14</sup>

### Midstance (foot flat to heel off)

The beginning of midstance is indicated by the forefoot making contact with the ground, normally in a neutral transverse plane position (i.e. not abducted or adducted).<sup>6</sup> Lower limb biomechanical function during midstance involves a transition from biomechanics required for shock absorption following loading, to biomechanics required for propulsion. During this time, the ankle moves towards maximal dorsiflexion (approximately 20°) to allow forward motion of the tibia and the centre of mass (COM) to pass over the stance leg.<sup>15</sup> Excessive ankle dorsiflexion can lead to increased strain on the plantar fascia, Achilles tendon, and associated gastrocnemius and soleus musculature. At the same time, the hip and knee are moving from flexion towards extended positions, assisting forward motion of the body's COM.

Maximal foot pronation followed by maximal ankle dorsiflexion should be reached immediately after the body's COM has passed anterior to the stance limb.<sup>11</sup> Peak rearfoot eversion should reach approximately 10°,<sup>6, 16</sup> and peak forefoot abduction approximately 5°. The rearfoot then begins to invert and the forefoot adducts, causing the foot to supinate, and the tibia and femur to externally rotate.<sup>11</sup> This external rotation action is assisted by force transmission from the externally rotating pelvis, which results from momentum of the swinging contralateral limb.

There are a number of things for the clinician to consider during this phase. Excessive pronation, or delayed/failed transition from shock absorption to propulsion actions by the lower limb, may be detrimental to a number of structures. Firstly, this will place excessive strain on structures responsible for controlling pronation and may increase the risk of conditions such as plantar fasciopathy, Achilles and tibialis posterior tendinopathies, proximal tibial periostitis, or tibial stress fractures due to excessive pull of the tibialis posterior and long flexors. Also, continued instability of the foot may lead to development of first MTPJ abnormalities, including hallux valgus, sesamoid pain and/or excessive interdigital compression (Morton's neuroma). If left untreated,

over time this instability may also lead to metatarsal or sesamoid stress fractures.

More proximally, excessive or prolonged pronation may also result in abnormal transverse and frontal plane motion at the hip and knee due to a delay in external rotation. Ultimately, this can place excessive strain on many structures such as the PFJ, patellar tendon (both conditions discussed in Chapter 36), ITB (Chapter 37), and musculature that control this motion. Conversely, the same proximal anomalies may result due to inadequate pelvic and hip control. The source of the biomechanical dysfunction may need to be determined through further structural and functional tests (see assessment section below).

### Propulsion (heel off to toe off)

Following heel off, the foot continues to supinate. Importantly, as this occurs, inversion of the rearfoot causes the transverse tarsal joint axes to converge.<sup>2</sup> This convergence of joint axes causes the midfoot to lock into position, creating a rigid lever.<sup>2</sup> Concurrently, the stance limb continues to externally rotate, the hip reaches maximal extension of between 0 and 10°,<sup>5, 15, 17</sup> and the knee flexes once more due to hamstring muscle contraction.<sup>15, 17</sup> Additionally, acceleration of the stance limb is provided through plantar flexion at the ankle, produced by the gastrocnemius and soleus complex.<sup>18</sup> This same gastrocnemius and soleus activity, along with the tibialis posterior and intrinsic foot musculature activity, continues to actively assist supination of the foot, and maintain its function as a rigid lever.<sup>2</sup> Passively, rigidity of

the foot is supported by the windlass mechanism, that is, increased tension of the plantar fascia due to extension of the metatarsals, which pulls the calcaneus and metatarsal heads together (Fig. 8.10).<sup>2</sup> By toe off, the rearfoot should be inverted to approximately 10°, and the forefoot adducted approximately 5°.<sup>6</sup>

Failure of normal propulsion will cause an inefficient gait pattern. This can limit performance and predispose to injury for several reasons. First, the peroneal musculature may be forced to work harder to stabilise the medial and lateral columns of the foot which can lead to peroneal tendinopathy and/or stress fracture of the fibula.

Second, impaired supination may lead to toe off via the lateral rays instead of the first ray. This may compress the transverse arch of the foot excessively, and lead to interdigital nerve compression (Morton's neuroma) and risk of lateral forefoot stress fracture.

Third, reduced propulsion from the stance limb may increase reliance on the swing phase to produce forward momentum. To achieve this, the hip flexors, rectus femoris and iliopsoas will generate more rapid hip flexion, increasing the potential for tendinopathies. Additionally, to compensate for impaired propulsion, pelvic and trunk rotation may increase, leading to increased strain on spinal structures.

### Initial swing

Following ipsilateral toe off, the body is thrust into the first 'float' phase where neither limb is in contact with the ground. Rectus femoris and iliopsoas muscle activity continue the forward momentum of the now swinging

**Figure 8.10** The windlass mechanism comes into play after heel off. Metatarsal extension increases tension on the plantar fascia, and forces the transverse tarsal joint into flexion which increases stability at push off

limb.<sup>19</sup> As the limb advances, the pelvis moves with it, thrusting the hip into abduction and external rotation, which is in turn controlled by the hip adductors.<sup>19</sup> The tibialis anterior contracts to begin dorsiflexing the foot in preparation for terminal swing.<sup>19</sup> While these motions continue, they are aided by the addition of a new stable support when the contralateral limb strikes the ground and commences its own *loading* phase. Continuation of normal swing at this time relies on the ability of the contralateral gluteal musculature to dissipate the GRF produced by this event and prevent the pelvis dropping on the swing side. Failure to do so will increase the work required by the hip and knee flexors to clear the swinging limb, possibly leading to overuse injury.

### Terminal swing

Following contralateral toe off, the body is thrust into the second 'float' phase. During this time the ipsilateral swinging hip reaches maximal flexion (approximately 30°),<sup>5, 9</sup> before being brought under control by the hamstring and gluteal musculature.<sup>19</sup> The same hamstring activity slows the rapidly extending knee in preparation for heel strike. At the same time, the hip adductors, which have been working eccentrically to control abduction of the swinging limb, begin to work concentrically to adduct the hip and bring it toward the midline.<sup>19</sup>

### Angle and base of gait

The angle of gait is the angle between the longitudinal bisection of the foot and the line of progression (Fig. 8.11). The normal angle of gait is approximately 10° abducted

**Figure 8.11** The angle of gait is the angle between (a) the long axis at the foot and (b) the line of progression. (c) Base of gait is the distance between the medial aspects of the heels

from the line of progression in walking. Abducted gait describes an angle of gait greater than 10°. The angle of gait reflects the hip and tibial transverse plane positions. The base of gait is the distance between the medial aspect of the heels (Fig. 8.11). A normal base of gait is approximately 2.5–3 cm.

Changes from the normal angle and base of gait may be secondary to structural abnormalities or, more commonly, as compensation for another abnormality. For example, a wide base of gait may be necessary to increase stability. As running velocity increases, the angle and base of gait decrease. With faster running, the angle of gait approaches zero and foot strike is on the line of progression. This limits deviation of the COM as the lower limbs move beneath the body, thus allowing more efficient locomotion (Fig. 8.12).

**Figure 8.12** Angle and base of gait (a) Walking (b) Running

### Landing point relative to centre of mass

Greater distance between foot strike point and COM (i.e. overstride) has been reported to increase lower limb joint loads,<sup>20</sup> and as a result is thought to increase the risk of running injury development. When measuring this clinically, we suggest this distance should not exceed more than one third of a foot length (Fig. 8.13), with greater than a foot length considered a marked overstride. During sprinting, the foot should land almost directly under the COM.

### Influence of gait velocity

Increased gait velocity influences a number of biomechanical factors. As gait velocity is increased, greater emphasis is placed on the swinging actions of the upper limbs, trunk and lower limbs to produce forward momentum.<sup>2</sup> This difference has significant implications for the flexibility and eccentric muscle control requirements of these structures (e.g. ipsilateral hamstrings strain during late swing). Greater excursion of the proximal joints (knee, hip and pelvis) also occurs with increased velocity, placing increased reliance on eccentric muscle control.<sup>19, 21</sup> At the foot and ankle, the bones making up the rearfoot, midfoot and forefoot all

**Figure 8.13** Heel to COM distance at initial contact during running<sup>20</sup>

reduce their excursions in all three planes with increased velocity.<sup>22</sup> This indicates the need for stiffer joint structures with increased speed and a greater demand on intrinsic foot musculature control.<sup>22</sup>

In slower running, the stance phase takes longer than the swing phase. As running speed increases, stance phase and flight phase times approach each other until the stance phase becomes shorter than the swing phase in sprinting (Fig. 8.14).<sup>2</sup>

Additionally, as running velocity increases, foot strike patterns may be altered. As mentioned previously, foot strike patterns are similar between slow running and walking for most individuals (Fig. 8.15). During faster running (striding), the foot may strike with the heel and forefoot simultaneously prior to heel off (midfoot strike), or may strike with the forefoot initially followed by heel lowering to the surface prior to heel off (forefoot strike). In sprinting, weight-bearing is maintained on the forefoot from contact to toe off, although the heel may lower to the supporting surface at midstance. In some individuals, this pattern can commence even at slower running speeds, or immediately upon initiation of a run. In particular, some habitual barefoot runners often have a natural forefoot strike pattern regardless of velocity.<sup>3</sup>

### Comparing heel and forefoot strike patterns

Changing from a heel strike to a forefoot strike pattern has significant implications for lower limb biomechanics and assessment. This has become particularly important

**Figure 8.14** Pattern of the stance phase during different speeds of walking and running

A

**Figure 8.15** The swing and stance phases of running

to clinical practice with the recent popularity of *Born to Run*<sup>23</sup> and many runners choosing to transition from a habitual heel to a forefoot strike. Firstly, forefoot strike patterns result in slight plantar flexion of the foot at impact, followed by dorsiflexion as the heel lowers to the ground.<sup>2</sup> This means that the ankle joint is more compliant and able to absorb GRF in the sagittal plane, and can lead to a reduction in vertical GRF and loading rates following foot strike.<sup>3, 6</sup> Additionally, forefoot striking has also been reported to reduce knee and hip joint loads, and these changes are often used to justify transition toward a forefoot strike for hip and knee injuries.<sup>24</sup> However, concurrent increases to joint loads at the ankle indicate potential detrimental increases to tissue stresses distally,<sup>24</sup> which fits with many anecdotal reports of Achilles tendinopathy, plantar fasciopathy and metatarsal stress fractures as a result of transitioning from heel to forefoot strike.

### Influence of fatigue on running biomechanics

Some runners will report pain that only occurs following prolonged activity. For example, an individual with patellofemoral pain (Chapter 36) may report no pain during the early stages of a run, but cease running due to severe pain after five kilometres. This can make clinical assessment difficult, since the condition may result from suboptimal biomechanics that only occur with fatigue. For example, excessive hip adduction during running in the individual with patellofemoral pain may occur due to poor gluteal muscle endurance. Therefore, the clinician should evaluate functional biomechanics both at baseline and following fatigue and/or onset of pain. In the clinical setting, this means scheduling the appointment so that the patient can be seen before and immediately after a run, or having them run to a fatigued state before attending the clinic.

### LOWER LIMB BIOMECHANICAL ASSESSMENT IN THE CLINICAL SETTING

This section aims to help the junior clinician develop a routine for efficient lower limb biomechanical assessment. There is no single best way to assess biomechanics and the experienced clinician will vary his or her assessment depending on the clinical presentation.

For this example, consider the patient to have patellofemoral pain—a condition that warrants assessment of the entire kinetic chain.

#### PRACTICE PEARL

Two guiding principles will help with the efficiency of the office assessment and ensure it is appropriately comprehensive.

1. Examine from distal to proximal (start at the foot and then examine proximally to the pelvis and trunk).
2. Examine the patient in 'static stance' first before increasingly challenging him or her with 'functional' tests before moving to fully 'dynamic' or 'sport-specific' tests as appropriate (see Fig. 8.16 for the concept of the hierarchy). These terms are explained below.

Thorough biomechanical assessment may require the patient to stand, walk, run, land on two feet and land on one leg only. Assessment during 'function' (playing sports, executing certain sporting activities such as a kick or a pirouette) may also be relevant.

We explain each of these steps in the order that many experienced clinicians perform the assessment. The major elements in the assessment are:

- structural (static) biomechanical assessment (Fig. 8.17a–g)
- functional lower limb tests—single-leg stance, heel raise, squat and landing (Fig. 8.18a–g)

	POSITION	ACTIVITY
Static stance		A good starting place. The patient stands in a comfortable position, weight centrally distributed over both feet (see also Fig. 8.17a–g).
Simple functional		This refers to a group of simple movements in isolation—single-leg standing, single-leg heel raise, single-leg squat, step down, hopping and landing (see also Fig. 8.18a–g).
Dynamic movements		This refers to activities such as running. This may need to be done outside the office on an adjacent track, park or car park depending on what is available.
Sport-specific activity		If the athlete is a basketball player, ballet dancer, or pole vaulter (for example), the clinician may also need to observe the athlete performing sporting activities that are relevant to the presenting complaint.

**Figure 8.16** An overview to guide lower limb biomechanical assessment (See also Figures 8.17 and 8.18.)

- assessment of a patient's running biomechanics ('dynamic assessment')
- detailed sport-specific tests as indicated by the above tests and the clinical presentation.

### Structural ('static') biomechanical assessment

The clinician performs the assessment of static stance by critically viewing the foot, ankle, knee and pelvis (Fig. 8.17a).

### Foot

Inspect the foot subjectively (does it look abnormal?), quantify posture using the six item Foot Posture Index (FPI) below and also pay attention to first MTP range of motion (Fig. 8.17b).

### Foot Posture Index

Quantify standing foot posture objectively with the FPI, a test that reflects foot posture at the rearfoot, midfoot and forefoot, as well as an overall impression of foot

(a)

(b)

**Figure 8.17** Static assessment of the lower limb (a) With the patient in this comfortable position, static stance examination begins at the foot. The examiner then assesses the ankle, knee and hip/pelvis (b) Jack's test for first MTPJ dorsiflexion range of motion. Normal range of motion is approximately 50° relative to the floor

### The Foot Posture Index <sup>26</sup>—a rapid, quantitative measure of static foot biomechanics

Each of the six items in the FPI is scored as  $-2$  (highly supinated),  $-1$  (supinated),  $0$  (neutral),  $+1$  (pronated) or  $+2$  (highly pronated); this leads to sums between  $-12$  (highly supinated) and  $+12$  (highly pronated).<sup>26</sup>

#### Talar head palpation

The talar head is palpated on the anterior aspect of the ankle. If the head can be felt equally on the medial and lateral side, a neutral score ( $0$ ) is given. If greater prominence is felt medially, a pronated score is given ( $+2$  defined by only medial prominence felt) and if greater prominence is felt laterally, a supinated score is given ( $-2$  defined by only lateral prominence felt).

#### Supra and infra lateral malleolar curvature

A neutral score for this item is given if the curves above and below the lateral malleolus are equal when viewed posteriorly. If the curve above the malleolus is flatter, a pronated score is given ( $+2$  defined by completely flat) and if the curve below the malleolus is flatter, a supinated score is given ( $-2$  defined by completely flat).

#### Calcaneal frontal plane position

A neutral score is given if the rearfoot is perpendicular to the floor. A more valgus rearfoot relative to the floor is given a pronated score ( $+2$  defined by  $>5^\circ$ ) and a more varus rearfoot relative to the floor is given a supinated score ( $-2$  defined by  $>5^\circ$ ).

#### Bulging in the region of the talonavicular joint (TNJ)

A neutral score is given if the skin immediately superficial to the TNJ is flat. If the TNJ is bulging, a pronated score is given ( $+2$  defined by marked bulging) and if the TNJ area is concave (indented) a supinated score is given ( $-2$  defined by marked concavity).

#### Height and congruence of the medial longitudinal arch

A neutral score is given if the arch shape is uniform and similarly shaped to the circumference of a circle. If the arch is flattened and lowered, a pronated score is given ( $+2$  defined by the mid-portion of the arch making contact with the floor). If the arch is high, a supinated score is given ( $-2$  defined by an acutely angled posterior end of the arch).

#### Abduction/adduction of the forefoot on the rearfoot

A neutral score is given when the forefoot can be seen equally on the medial and lateral side when viewed from behind the axis of the rearfoot. If more of the forefoot is visible laterally than medially, a pronated score is given ( $+2$  defined by only lateral forefoot visible) and if more of the forefoot is visible medially than laterally, a supinated score is given ( $-2$  defined by only medial forefoot visible).

*The total FPI score for the normal healthy population is 2.4 (i.e. slightly pronated).<sup>28</sup> Thus, scores of  $0$  to  $+5$  are considered neutral. A score of  $+6$  to  $+9$  is considered pronated,  $\geq +10$  highly pronated,  $-1$  to  $-4$  supinated and  $-5$  to  $-12$  highly supinated.*

type. It requires no equipment and takes approximately 2 minutes to complete.<sup>25, 26, 27</sup>

Additional background information about the FPI, including definitions and pictures of various foot types for each item, are shown in the user guide and manual.<sup>25</sup> Note that, as with any clinical skill, training and experience are important. The clinician should rate at least 30 individuals with a broad range of foot types before applying the FPI clinically.<sup>29, 30, 31</sup>

#### Jack's test for first metatarsophalangeal joint (MTPJ) range (plantar fascia integrity)

The clinician can rapidly assess the first MTPJ and also the integrity of the plantar fascia using 'Jack's test' (Fig. 8.17b).<sup>32</sup> The normal range of first MTPJ dorsiflexion motion should be around 50° relative to the floor. As the first ray dorsiflexes, tightening of an intact plantar fascia should cause the rearfoot to invert. If the rearfoot does not move, it suggests poor plantar fascia integrity which can result in inadequate supination during the propulsive phase of gait. Additionally, increased resistance to or a reduction in

motion may result from the presence of a valgus aligned forefoot.<sup>33</sup> Both these structural issues can be corrected using orthoses, taping and/or corrective exercise.

#### Ankle dorsiflexion

Accurate ankle dorsiflexion in weight-bearing using an inclinometer provides a more useful measure of range of motion at this important joint than does a rough assessment when the patient is lying on a treatment couch. This ankle biomechanical assessment is best done with the knee both extended and flexed (Fig. 8.17c and d). Normal ankle dorsiflexion range with the knee flexed is 45° and with the knee extended is 40°.<sup>30</sup> We recommend that clinicians have an inclinometer readily available (Fig. 8.17c and d)—it adds a great deal of accuracy to measurements and reduces assessment time.

An alternative way of quickly assessing weight-bearing ankle dorsiflexion is to have the patient perform the 'knee-to-wall' test (Fig. 8.17e). This provides an efficient outcome measure for ankle dorsiflexion range when gastrocnemius tightness is not a concern and this can be

(c)

(d)

**Figure 8.17 (cont.)** (c) Assessing ankle dorsiflexion in weight-bearing with the knee extended (d) Assessing ankle dorsiflexion in weight-bearing with the knee flexed

(e)

**Figure 8.17 (cont.)** (e) The knee-to-wall test. It is useful to have a line on the floor that continues up the wall. The patient lines up their second toe and mid-calcaneus on the horizontal line and lunges their patella toward the vertical line. This minimises the likelihood of going into pronation to achieve greater range of motion (ROM). The distance from the wall to the second toe is recorded

#### PRACTICE PEARL

If ankle dorsiflexion range differs in knee extension and flexion by more than  $5^\circ$ , it suggests there is limitation of dorsiflexion with the knee extended; this points to gastrocnemius tightness. If foot pronation is excessive to achieve normal ankle dorsiflexion range (i.e.  $45^\circ$ ) with the knee bent, excessive pronation may be occurring during functional activities to achieve full functional movement (e.g. when running).

particularly useful following lateral ankle sprain. With the knee-to-wall test, clinicians can determine whether there are side-to-side differences or if ankle dorsiflexion is restricted. 'Normal' values will vary depending on the size of the patient and their sport-specific demands, but, as a general rule of thumb, the distance from the wall to the second toe should be greater than 8–10 cm.

### Assessment of tibiofemoral alignment at the knee

Tibiofemoral joint alignment may reflect genu varum or valgum (Fig. 8.17f and g). This can also be measured using an inclinometer, which compares favourably to the gold standard radiographic measure.<sup>34</sup>

### Leg length assessment

Discrepancies in leg length are extremely common, existing in up to 70% of the normal population.<sup>35</sup> Nevertheless, leg length discrepancy has long been thought to be a risk factor for a range of musculoskeletal conditions, including low back pain, hip and knee osteoarthritis, and lower limb stress fractures.<sup>35, 36</sup>

Laboratory studies have shown that leg length differences alter the distribution of mechanical stress within the body, particularly by increasing the magnitude of forces through the shorter limb.<sup>37</sup> However, prospective risk-factor studies in athletes are lacking and what constitutes a clinically significant leg length difference remains unknown. Subsequently, the extent to which leg length differences should be

(f)

**Figure 8.17 (cont.)** Static assessment of the lower limb—alignment at the knee (f) Genu varum

(g)

**Figure 8.17 (cont.)** (g) Genu valgum

corrected in athletes remains a source of controversy, with opinions ranging from 3 mm to 22 mm.<sup>38</sup> We recommend that clinicians take a 'treatment direction test' approach (see below) and adopt corrections if they substantially change symptoms.

Leg length can be measured in a variety of ways, including clinical measures using a tape measure in standing (anterior superior iliac spine or ASIS to floor) and in supine (ASIS to medial malleolus). However, these methods may be inaccurate, with reports of poor inter- and intra-rater reliability and errors of up to 20 mm compared to radiographic imaging.<sup>38</sup> There are a number of radiographic techniques to evaluate leg length differences, including magnetic resonance imaging (MRI), computed tomography (CT) 'scanograms' and standing full leg radiograph. Each of these methods has demonstrated high accuracy with average errors of less than 2 mm.<sup>39</sup>

### Summary of static assessment

The 'static' biomechanical assessment of the foot, ankle and knee provides a substantial amount of valuable clinical information and can be completed within 5 minutes.

Possible mechanisms that underpin common clinical observations are shown in Table 8.2.

### Functional lower limb tests

The next step is to assess simple functional movements. The patient should do these tests both with and without sporting footwear where appropriate. This will help the clinician determine whether the individual's footwear is detrimental, beneficial or has no effect on functional biomechanics.

### Single-leg stance with progressions

The single-leg stance test begins to challenge lower limb balance and proprioception (Fig. 8.18a). Inability to maintain the single-leg stance position is likely to carry over to suboptimal biomechanics during sporting activity. The patient performs this test with (i) eyes open, (ii) eyes closed and (iii) challenged further by also performing a single heel raise. Depending on the balance requirements for the individual, once balance can be maintained in single-leg stance for at least 10 seconds, balance can be assessed using more challenging activities, including variations in surfaces and ability to adapt to internal and external perturbations.

(a)

**Figure 8.18** Functional assessment of the lower limb.  
(a) Single-leg stance to evaluate alignment and control

**Table 8.2 Common lower limb biomechanical observations, possible mechanisms and confirmatory assessments**

Observations	Possible mechanisms	Confirmatory assessments
Excessive or asymmetrical pelvic or trunk movement (frontal, transverse, sagittal planes)	Inadequate ROM (hip)	Clinical ROM tests with inclinometer (Chapter 31); figure '4' test
	Inadequate strength (abdominals, lumbopelvic muscles, hip abductors)	Manual muscle tests
	Altered neuromotor control (hip abductors, lumbopelvic muscles)	Biofeedback
	Decreased muscle length (hamstrings, rectus abdominis, rectus femoris)	Muscle length tests
	Lumbar spine/sacroiliac joint stiffness/pain	Joint palpation
Increased hip adduction/femoral internal rotation	Structural (femoral anteversion)	Radiographic: MRI, X-ray Clinical assessment
	Inadequate ROM (hip)	Clinical ROM tests with inclinometer (Chapter 31); figure '4' test
	Inadequate strength (hip external rotators, abductors)	Manual muscle test (Chapter 31) or hand-held dynamometry
	Altered neuromotor control (hip external rotators, hip abductors)	Biofeedback
Increased apparent knee valgus	Structural (genu varum, tibial varum, coxa varum)	Imaging: MRI, X-ray Clinical assessment: goniometer, inclinometer
	Inadequate ROM (hip)	ROM tests: clinical (Chapter 31) inclinometer; figure '4' test
	Inadequate strength (hip external rotators, hip abductors, quadriceps, hamstrings)	Manual muscle test (Chapter 31) or hand-held dynamometry Active gluteal and tensor fasciae latae trigger points
	Altered neuromotor control (hip external rotators, hip abductors, lumbopelvic muscles)	Biofeedback Active gluteal and TFL trigger points
Ankle equinus	Inadequate ROM (ankle)	ROM tests
	Tight gastrocnemius or soleus	ROM tests with knee flexed and extended (Fig. 8.17c and d)
Excessive or prolonged foot pronation	Pronated foot type	FPI
	Impaired windlass mechanism	Jack's test (Fig. 8.17b)
	Tibialis posterior weakness	Single-leg heel raise; manual muscle test; inability to form arch
	Ankle equinus	Ankle dorsiflexion measures
Excessive or prolonged foot supination	Leg length discrepancy (structural or functional)	Clinical measurement and radiographic imaging
	Supinated foot type	FPI
	Chronic ankle instability	Ankle ligament integrity tests
	Leg length discrepancy (structural or functional)	Clinical measurement and radiographic imaging
Reduced propulsion	Impaired windlass mechanism	Jack's test (Fig. 8.17b)
	Tibialis posterior weakness	Single-leg heel raise; manual muscle test; inability to form arch
	Pronated foot type	FPI

ROM = range of motion; FPI = foot pronation index

### Single-leg heel raise (with a focus on tibialis posterior function)

Tibialis posterior is an under-recognised contributor to normal lower limb biomechanics—it is particularly important for control of foot pronation and helps stabilise the plantar arch during activity. Through its attachments to the navicular, cuneiforms, cuboid and bases of the second to fourth metatarsals, tibialis posterior inverts the subtalar joint. It is a primary dynamic stabiliser of the foot against eversion forces and is also important for propulsion.

A simple functional test, the *single-leg heel raise*, tests the ability of tibialis posterior to re-supinate the foot during propulsion of gait (Fig. 8.18b). Tibialis posterior muscle weakness will manifest as an inability to rise up through the medial aspect of the foot and invert the rearfoot toward the end of the heel raise. (Note that the same procedure can be prescribed as a therapeutic exercise when deficits are observed—this may initially require the use of support or starting in bilateral stance).

If tibialis posterior problems or excessive dynamic foot pronation are suspected, the 'arch form' test can be used

to evaluate the capacity of the intrinsic muscles of the foot and tibialis posterior to control the foot during stance in gait. The patient is instructed to gently lift up the inside arch while pushing the first metatarsophalangeal joint into the ground. The clinician can monitor performance by placing a finger underneath the joint to ensure sufficient downward pressure. The patient should be able to maintain this for 10 seconds. As above, the procedure provides a therapeutic exercise when deficits are observed. Note that the arch form test would not necessarily be part of a routine rapid biomechanical assessment—it provides additional information if this is warranted (e.g. if the patient demonstrates excessive or rapid foot pronation).

### Single-leg squat to assess knee, hip and trunk muscle function

The continuum of activities from single-leg squat (at approximately 45° knee flexion), step down, hopping, to landing, provides a logical progression to the lower limb biomechanical assessment. There are many variations for performing a single-leg squat, including depth (knee flexion angle), arm position (crossed, hands on hips, no constraints) and posture of the unsupported leg (in front, behind) (Fig. 8.18c and d). Clinicians should ensure that they always use the same technique.

### Assessment of hip and trunk function

Five main observations may indicate altered hip or trunk muscle function. The first four can be observed from in front of the athlete and the fifth is an overall assessment.<sup>40</sup>

#### Trunk

Trunk lean (and/or rotation) toward the stance leg may be an adaptation to altered control of hip abduction/rotation or trunk lateral flexion/rotation. This may be observed as a more lateral position of the shoulder, relative to the hip (Table 8.2, Fig. 8.18d).

#### Pelvis and hip

Altered control of hip abduction/rotation or trunk lateral flexion/rotation may present as either (a) inability to maintain a level pelvis or (b) ipsilateral shift of a level pelvis. Both presentations may be observed as a lateral hip (ASIS), relative to the knee (hip adduction) and may also be referred to as a 'Trendelenburg sign' (Table 8.2, Fig. 8.18d).

#### Knee

Does the centre of the knee remain over the centre of the foot? If the knee deviates toward a more medial position (relative to the foot), this is an indication of increased

(b)

**Figure 8.18 (cont.)** (b) Single-leg heel raise. Look for signs of tibialis posterior weakness, including (i) inability to rise up through the medial arch or (ii) failure of the heel to invert

(c)

(d)

**Figure 8.18 (cont.)** Single-leg squat (c) Good form (d) Poor form

hip internal rotation and/or adduction and appears as an apparent knee valgus posture. Increased hip internal rotation/adduction may result from altered control of hip muscles (e.g. hip external rotators) (Table 8.2).

### Overall impression

An individual with altered hip/trunk muscle function may exhibit global signs, such as poor quality of movement/coordination, inability to squat to the desired depth, or inability to control speed, depth and balance.

### Landing—specific considerations

There are a number of ways to evaluate single-leg and double-leg landing biomechanics in the clinical setting. The clinician should determine what is appropriate taking into account the individual's sporting requirements and injury history. It may be more appropriate to evaluate single-leg landing if a higher-functioning athlete presents with a lower limb injury. The single-leg landing may be the best way to identify biomechanical deficiencies such as increased knee abduction, and decreased knee, hip and trunk flexion.

Conversely, in individuals recovering from injury and/or surgery, double-leg landing may be a more appropriate

test so that healing tissue does not receive excessive stress. It may also be important to evaluate landing performance both pre- and post-exercise, since fatigue is associated with increased knee abduction and reduced knee flexion during landing.<sup>41, 42</sup>

We suggest evaluating both double-leg and single-leg landing using a drop landing assessment from a 30 cm high platform (Fig. 8.18e-g). The clinician should observe the landing pattern for signs of reduced knee and hip flexion and/or an abnormally erect landing posture. Apparent knee valgus is another movement to observe. Maximum knee valgus should reach approximately 10° for females and 5° for males for both tests from this height.<sup>43</sup> Excessive valgus and/or the presence of a heavy landing pattern involving minimal knee, hip and trunk flexion may increase the risk of future knee injury or re-injury, such as non-contact anterior cruciate ligament injuries.

As with running and squatting assessment, video footage can be used for more in-depth analysis of double-leg and single-leg landing. The clinician can use slow-motion replay and computer software packages to gain a more accurate picture of the degree of knee valgus during landing.

(e)

(g)

(f)

### Dynamic movement assessment (e.g. running biomechanics)

A key to clinical biomechanical assessment is careful observation of functional movement. Running is a component of many sports and the clinician should have an effective method to assess for biomechanical problems associated with running. As a clinician, look for obvious deviations from the ideal running pattern, and use this to guide further assessment and treatment decisions. Common deviations and possible implications to injury are outlined in the 'ideal' biomechanics with movement–running' section. If possible, observe athletes participating in their sport. If necessary, sport-specific skills can be broken down into component movements to simplify observation in the clinic. Furthermore, functional clinical tests outlined in this chapter may provide insight into biomechanics during more sport-specific tasks when they cannot be evaluated in the clinical setting. For example, excessive

**Figure 8.18 (cont.)** (e) Starting position for single-leg landing (f) View from the front (g) View from the side

hip adduction during the completion of a single-leg squat may be indicative of excessive hip adduction during running and landing.

To detect sub-optimal biomechanics with the naked eye takes years of training and experience. Video analysis can provide valuable information from multiple views and assist the clinician greatly. This is usually done by having the patient run on a treadmill. Reflective markers can be added to identify anatomical landmarks and bony alignment. Video footage can then be slowed on a replay and this may reveal otherwise hidden abnormalities. A number of freely available computer software programs can also assist with this analysis. Examples include Hudl and Kinovea. The source of any biomechanical abnormalities may be further investigated by a thorough clinical assessment.

### Sport-specific assessment

A detailed sport-specific assessment may help identify factors causing or contributing to injury. It is therefore important that clinicians understand the normal biomechanics of their patient's sport, as well as the normal range of variability between athletes. We encourage clinicians to collaborate closely with coaches and sport scientists when performing sport-specific assessments.

Sport-specific biomechanical issues thought to be associated with injury are examined in Chapter 9 for a range of different sports.

### Summary of the lower limb biomechanical assessment

To iterate how we opened this section, there is no single way to perform the lower limb biomechanical

assessment—it will vary by clinical specialty (e.g. physiotherapy, podiatry, medicine, exercise physiology). Also, the clinical problem will influence the order of the assessment and the relative emphasis on various elements. In this introductory chapter, we have focused on general lower limb biomechanics. This would apply, for example, to a patient with patellofemoral pain. The assessment may differ for other conditions.

### CLINICAL ASSESSMENT OF FOOTWEAR—THE FOOTWEAR ASSESSMENT TOOL

Footwear assessment is a vital component of the lower limb biomechanical evaluation. The Footwear Assessment Tool is a freely available six item template to guide the clinician when assessing footwear.<sup>44</sup> The tool focuses on general structure and fit (Table 8.3), motion control properties and wear patterns.

Motion control is particularly important for excessive pronators. Footwear properties that influence motion control include heel counter stiffness, midfoot torsional and sagittal stability, and type of fixation (e.g. lacing). These properties can be quantified using the motion control properties scale outlined below (Table 8.4).<sup>44</sup> Scores range from 0 to 9, with 9 indicating the highest level of motion control.

The wear pattern of a shoe can provide insight into the biomechanics of gait. Medial tilt of the upper, medial compression of the midsole and greater medial than lateral wear of the outsole (Fig. 8.19) indicate excessive pronation. Lateral tilt of the upper, lateral compression of the midsole, and greater lateral than medial wear of the outsole reflect excessive supination.

**Table 8.3 Footwear assessment—general structure and fit**

Item	Measurement	Potential issues
Fit	Inadequate width or depth	Joint compression (e.g. Morton's neuroma) Restriction of normal foot function
Pitch	Difference between heel height and forefoot height (typical range 0–14 mm)	Small pitch may not be suitable for someone with ankle equinus Large pitch may increase likelihood of overstride and impair attempts to transition to midfoot or forefoot strike
Last	Straight last (0–5°) Curve last (> 15°)	Accommodates a pronated foot Accommodates a supinated foot
Forefoot sole flexion point	Should line up with the first MTPJ	If too proximal, shoe stability may be impaired. If too distal, normal sagittal plane motion of the first MTPJ may be impaired, which can be problematic in the presence of poor intrinsic foot and tibialis posterior strength and function

**Table 8.4** Motion control properties scale<sup>44</sup>

Item	Score			
	0	1	2	3
Fixation (upper to foot)	None	Alternative to laces (e.g. strap, Velcro, zip)	Laces (at least 3 eyelets)	
Heel counter stiffness	No heel counter	Minimal	Moderate	Rigid
Midfoot sagittal stability	Minimal	Moderate	Rigid	
Midfoot torsional stability	Minimal	Moderate	Rigid	

Minimal =  $>45^\circ$ ; moderate =  $<45^\circ$ ; rigid =  $<10^\circ$

(b)

**Figure 8.19** Shoe wear patterns—running shoe (a) with medial compression of the upper (b) With excessive pronation, there is greater wear on the medial than the lateral sole

### CONDITIONS RELATED TO SUBOPTIMAL LOWER LIMB BIOMECHANICS

Conventional wisdom has linked suboptimal lower limb biomechanics with various injuries, but there is a lack of prospective empirical evidence to confirm that biomechanical factors increase risk for lower limb

injuries.<sup>45</sup> Thus, for now, most biomechanical 'risk factors' have only level 3 to 5 evidence (Chapter 2).

Table 8.5 lists common lower limb injuries, common clinical considerations and evidence to support these considerations. It contains the 'best available evidence' at March 2016.

**Table 8.5 Best available evidence for the association between common lower limb overuse injuries and biomechanics (as at October 2016)**

Injury/condition	Associated lower limb biomechanical risk factor
Sesamoiditis	Supinated foot type <sup>46, 47</sup> Pronated foot type Forefoot valgus, plantar flexed first ray <sup>47</sup> Decreased ankle DF/ankle equinus <sup>47</sup> Limited first ray range of motion
Plantar fasciopathy	Pronated foot type <sup>48–50</sup> Decreased ankle DF/ankle equinus <sup>49, 51, 52</sup> Increased ankle DF <sup>48</sup> Supinated foot type <sup>53</sup> Leg length difference <sup>53</sup>
Achilles tendinopathy	Increased subtalar joint inversion <sup>54</sup> Increased ankle DF <sup>55</sup> Decreased gastrocnemius length <sup>54</sup> Supinated foot type <sup>56</sup> Pronated foot type <sup>56, 57</sup>

## MANAGEMENT OF LOWER LIMB BIOMECHANICAL ABNORMALITIES

The next major theme of this chapter introduces management strategies to address biomechanical problems. There is increasing evidence about the role of therapies such as foot orthoses, footwear, taping, exercise and movement retraining to improve a patient's biomechanics. This section provides a background perspective and then chapters in Part B will address specific conditions. Here we focus mostly on interventions that affect the foot and lower leg.

### Biofeedback and movement pattern retraining

In this chapter, we have described a number of suboptimal biomechanics or movement patterns which may be identified during assessment of an injured athlete. Of particular note, ideal running biomechanics and potential abnormalities have been described in some detail. In recent years, evidence supporting movement pattern retraining during running to manage lower limb injuries has begun to emerge.<sup>83</sup> This includes case series supporting visual and verbal biofeedback to reduce peak hip adduction in individuals with patellofemoral pain (PFP),<sup>84, 85</sup> and to transition from rearfoot to forefoot or midfoot strike pattern in individuals with anterior chronic exertional lower leg pain.<sup>86, 87</sup>

Recent evidence suggests that exercise interventions are unlikely to change actual running mechanics. This highlights the potential importance of using biofeedback to facilitate movement pattern retraining. For example, hip abductor strengthening does not appear to reduce peak hip adduction during running,<sup>88-90</sup> a variable linked to PFP<sup>91</sup> and iliotibial band syndrome<sup>92</sup> injury risk. Importantly, movement pattern retraining can also be used for other activities such as walking, stair negotiation, squatting and sit to stand; the key is to identify a potential movement pattern which may be increasing stress on the injured tissue, and implement biofeedback to alter the movement pattern and reduce stress. This should be guided by both clinical reasoning and reported changes in symptoms from the patient. A number of suggestions for common running injuries are provided in Table 8.6. When teaching your patients movement pattern changes, it is vitally important to consider the effect this may have on other structures. For example, transition from heel to forefoot strike will reduce load on the knee and hip, but will likely increase load on the foot and ankle.<sup>83</sup>

Simple clinical biofeedback methods can be divided into visual (mirror, video, etc.) and verbal (i.e. instructions). Visual biofeedback can be very important in the early stages of movement pattern retraining to ensure that the patient understands their faults and how to change them. Previously

**Table 8.6** Running retraining considerations for common lower limb injuries based on current evidence and expert opinion (from Barton et al.)<sup>83</sup>

Condition	Suggested retraining strategies to consider
Exertional lower leg pain	Increasing step rate, strategies to reduce overstride and land softer, and transition from rearfoot to forefoot or midfoot strike
Plantar fasciopathy	Increasing step rate, strategies to reduce overstride and land softer
Achilles tendinopathy and calf pain	Strategies to reduce overstride, increase lower limb stiffness (i.e. reduce ankle dorsiflexion) and increase hip extension
Medial tibial stress syndrome	Increasing step rate, strategies to reduce overstride and land softer, reduce hip adduction and scissoring and increase hip extension
Patellofemoral pain	Increasing step rate, strategies to reduce overstride and land softer, reduce hip adduction and internal rotation, transition from rearfoot to forefoot or midfoot strike
Iliotibial band syndrome	Reduce hip adduction and scissoring
Patellar tendinopathy	Strategies to reduce overstride and land softer, and transition from rearfoot to forefoot or midfoot strike
Hamstring injury, including proximal hamstring tendinopathy	Strategies to reduce overstride and land softer, and reduce anterior pelvic tilt and knee extension at foot strike
Gluteal tendinopathy	Increasing step rate, strategies to reduce overstride and land softer, reduce hip adduction and internal rotation, and reduce contralateral pelvic drop

published case series supporting the potential effectiveness of movement pattern retraining during running have all used some form of visual biofeedback. However, continued use in the field (e.g. using mirrors during over-ground running to reduce hip adduction) may be impractical, meaning we recommend concurrent use of verbal cues (e.g. instruction to run with knees pointing out) which can be used both in the early stages of rehabilitation and following progression into the field. Follow-up to ensure appropriate changes is essential in these circumstances, so that an athlete does not develop new maladaptive movement patterns or revert to their habitual pattern.

More complex biofeedback options are becoming easier to access in clinical practice. Clinicians can now access simple, small and affordable technologies to quantify movement analysis during assessment and provide feedback to patients during rehabilitation. One example of this is the ViMove™ (dorsaVi). This system has integrated movement and muscle sensors, and comes with software to allow the clinician to quickly analyse collected data and provide results to patients. Clinical electromyography (EMG) has been used clinically for many years to provide patients with real-time feedback regarding muscle activation patterns and magnitude. With technology in this area continuously and rapidly evolving, clinicians who are interested in incorporating more quantitative measures of biomechanics into their clinical practice should regularly review the literature and the internet for emerging technologies.

## Foot orthoses

Foot orthoses (in-shoe devices) are used extensively in sports medicine to optimise lower limb function.<sup>93</sup> In this section we:

- review the various types of orthoses available
- introduce the debate about their mechanism of action
- highlight that there is high quality evidence for their effectiveness
- share three main approaches to deciding how to fit an orthosis for a specific patient.

## Types of foot orthoses

Foot orthoses range in material from soft or flexible to semi-rigid devices, and may be prefabricated or custom-fabricated. Prefabricated or 'off the shelf' foot orthoses (Fig. 8.20a) are usually fabricated from materials such as EVA, polyurethane, cork or rubber. The devices' generic shape can be customised a little to the individual via heat moulding or the addition of wedges or heel raises. Prefabricated orthoses provide a quick and cheap intervention, but their limited potential for customisation and inability to achieve total plantar contact may restrict their use in some patients.

Custom-fabricated foot orthoses (Fig. 8.20b) are manufactured from a three-dimensional representation of the individual's foot using plaster impressions or laser-scanning devices. Custom foot orthoses may accommodate specific structural anomalies more effectively than prefabricated orthoses. Most often, custom foot orthoses are manufactured from polypropylene and carbon-fibre

(a)

(b)

**Figure 8.20** Orthoses (a) Prefabricated or 'off the shelf' orthoses (b) Custom-fabricated or casted orthoses

composites. As such, they are generally more rigid than prefabricated orthoses and are often perceived to provide more effective biomechanical control. Their prescription requires a higher level of expertise and specific equipment. In the sports and exercise medicine setting, a podiatrist will typically prescribe custom-fabricated foot orthoses, which will be manufactured in a laboratory. The prescription will typically contain information regarding materials to be used, extent of accommodative postings and shoe fit. In the laboratory, a solid model of the foot is manufactured from the three-dimensional representation. Additional material is added to provide the appropriate level (degrees) of control. The material of choice is then vacuum-pressed onto the model and covered to suit the individual.

To date, no study has identified an advantage for custom-fabricated devices over prefabricated orthoses when managing lower limb conditions.<sup>93</sup> The following factors should influence the recommendation for a particular type of orthosis.

- If the patient wears a wide range of footwear during training and competition, the custom-fabricated orthosis has an advantage as it can be designed to fit a wide range of footwear; prefabricated devices may need to be modified to fit in specific footwear.
- If the patient participates in sports that involve repetitive landing, a softer or more flexible device minimises the risk of arch discomfort or blistering. Furthermore, many athletes do not tolerate large degrees of arch support from orthoses. In these circumstances, it is often helpful to reduce the arch contour.
- The difference in cost may be an important determinant for some patients, although the more expensive custom orthosis also has greater durability. It is not unusual for a custom orthosis to last 5 years or more.
- There is generally a several-week interval between fitting and supply of custom orthoses, particularly when manufactured off site. Once the patient has the

orthosis, there may be a further 'wearing-in' period to prevent adverse effects. This means that there may be a delay in attaining the full therapeutic benefits of the intervention. It may be appropriate to prescribe a prefabricated device for the interim period.

- Other considerations include the patient's body mass (a more rigid orthosis may be required for people with greater body weight, due to higher forces through the foot) and personal preference.

### Mechanism of action—an unfinished story

Traditional dogma was that foot orthoses controlled foot motion, and thus improved biomechanical efficiency and balanced loads on structures more appropriately. However, this is now in dispute. Some studies indicate that foot orthoses can influence foot motion,<sup>94-96</sup> while others show that they impart no systematic effects on foot motion.<sup>97, 98</sup> It is important to keep in mind that the majority of studies on foot orthoses, mechanisms of action have been conducted on healthy, asymptomatic participants, and that people with pain or injury may have different biomechanical responses to foot orthoses.

Alternative paradigms relating to shock absorption and neuromuscular effects<sup>99</sup> include: (i) that the cushioning effect of orthoses attenuates the impact force that occurs when the foot hits the ground;<sup>100-102</sup> and (ii) that the input provided by foot orthoses through their total contact with the plantar surface of the foot stimulates the neuromuscular system, which may reduce muscle activity and fatigue, and optimise performance.<sup>103-105</sup> This is an exciting area of investigation which we will follow closely over the next few years.

### Orthoses are effective—high quality evidence is accumulating

Irrespective of how foot orthoses exert their clinical effects, evidence from systematic reviews (level 1) and

controlled clinical trials (level 2) supports their use in a variety of conditions related to suboptimal lower limb biomechanics (Table 8.7). See Chapter 2 for a discussion of levels of evidence.

### Three contemporary approaches for fitting an orthosis

Although evidence is accumulating that specific types of orthoses are effective in specific settings to treat specific clinical conditions, it is still difficult to recommend a 'gold standard' approach to prescribing orthoses. This part of our clinical approach remains an art based on limited science—as it is in many situations across healthcare. Thus, the clinician should integrate the research findings that

provide support for some approaches (see below), and also take into account the clinical assessment findings, previous clinical experience with the condition and the type of patient, as well as the patient's preferred orthosis type.

The traditional approach—Root and the goal of 'subtalar joint neutral'

Merton Root developed the functional foot orthosis in the 1950s and 1960s.<sup>124</sup> He proposed that subtalar joint neutral served as a standard position to evaluate structural relationships in the foot<sup>124</sup> and that this position represented normal foot alignment during the midstance and heel-off phases of gait.<sup>125</sup> Unfortunately, the alignment measures proposed by Root are unreliable and the subtalar

joint is not in neutral during midstance.<sup>125</sup> Nevertheless, this approach to casting orthoses has been associated with many successful clinical outcomes and it remains one of the most common ways of prescribing orthoses.<sup>126</sup>

### Treatment direction test

Professor Bill Vicenzino<sup>127</sup> proposed a 'treatment direction test' (TDT) to prescribe and apply foot orthoses for lower limb musculoskeletal disorders that have a biomechanical association. The TDT complements the 'tissue-stress model' of McPoil and Hunt,<sup>125</sup> in that it seeks to identify symptomatic tissues under excessive loads and reduce these loads using an external physical modality. This may consist of adhesive strapping tape, temporary felt orthoses, or prefabricated foot orthoses with or without add-on wedges. The modality is selected based on what the clinician identifies as an aberrant movement pattern such as excessive or prolonged pronation.

The quality and pain-free quantity of a patient-specific aggravating activity is assessed with and without the external modality. For example, the single-leg squat is suitable for patellofemoral pain, while a single- or double-leg heel raise test is more appropriate for Achilles tendinopathy. An improvement in the quality of movement or an increase in pain-free repetitions of at least 75% indicates a high likelihood of success with subsequent prescription of orthoses. The reliability and validity of the TDT is under review.

### Comfort

Nigg et al.<sup>104</sup> proposed that comfortable devices (orthoses, footwear) that support the skeleton's preferred movement path could reduce muscle activity and resulting fatigue, and thus, improve performance. Vicenzino and colleagues<sup>128</sup> proposed a model of prescription for prefabricated foot orthoses based on patient comfort. Once the patient reports comfort, the clinician can further modify the device to improve pain-free performance of an aggravating functional task, while aiming to maintain comfort. The first clinical trial to utilise this method reported greater than 80% success with orthoses over a 1-year period.<sup>129</sup> Irrespective of the long-term outcome of this branch of research, comfort should always be an important consideration for all foot orthoses prescribed. If the device is not comfortable, there is a risk of skin blistering and/or new foot pain. Also, any device that is perceived to be uncomfortable is likely to lead to poor patient compliance.

### Footwear as a therapy rather than as a cause of injury!

When considering any intervention addressing suboptimal lower limb biomechanics, the potential influence of footwear should be considered (see also 'Clinical assessment

of footwear' earlier in this chapter). Consider how the current footwear influences the patient's condition, how footwear interacts with other treatment (e.g. foot orthoses) and whether altering footwear characteristics can help treat the condition.

Footwear fit is particularly important when prescribing orthoses. If an orthosis is added to a shoe that has inadequate room, it may result in forefoot pain or limit the time the orthosis is worn. Remember that athletes often wear a range of shoes in training and competition—check all of them!

If the patient's shoe has suboptimal motion control (e.g. minimal heel counter stiffness) leading to excessive foot pronation, shoe replacement may be the best treatment. Footwear with greater heel counter stiffness, midfoot sole rigidity, adequate lacing and possibly a multiple density sole (i.e. increased density on the medial aspect of the shoe) may reduce excessive foot motion. Footwear support can also be enhanced by education on how to complete loop lacing (Fig. 8.21). Such changes in relation to footwear may reduce the need for foot orthoses.

### Taping

Adhesive strapping tape (Chapter 17) is a temporary intervention to address lower limb biomechanical issues. Anti-pronation tape is commonly used to treat plantar fasciopathy (Chapter 43) and patellofemoral pain (Chapter 36).

One of the most commonly used techniques for lower limb musculoskeletal pain is the Augmented low-Dye. This consists of the original low-Dye<sup>130</sup> (anchor running horizontally around the heel from the head of the fifth to the head of the first metatarsal, with strips of tape under

(a)

**Figure 8.21** (a) Lock-lacing to prevent heel slippage. Lace the shoe normally until the second set of eyelets. Then feed the laces into the top eyelet on the same side. Now cross each lace over, and feed through the loop formed between the first and second eyelet on the opposite side. Laces should then be pulled and tied as normal

(b)

**Figure 8.21 (cont.)** (b) Loop to create a snug fit. After lacing, put each lace end back through the last hole to create a small loop on the top side of the shoe. Then thread each loose end through the loop on the opposite side and tighten

the foot directed laterally to medially to support the arch, Fig. 8.22a), which is augmented with reverse sixes and calcaneal slings anchored to the lower leg<sup>127</sup> (Fig. 8.22b).

Anti-pronation tape has both biomechanical and neuromuscular effects during static and dynamic tasks.<sup>131</sup> Specifically, it increases navicular and medial longitudinal arch height, reduces tibial internal rotation and calcaneal eversion, alters patterns of plantar pressure, and reduces activity of particular leg muscles.<sup>131</sup>

Techniques such as patellar taping may also alleviate symptoms associated with PFJ biomechanics.<sup>132, 133</sup> It is important to be aware of skin breakdown associated with prolonged use of tape, particularly in athletes involved in vigorous activity and implement appropriate strategies to prevent this.

(a)

(b)

**Figure 8.22** (a) Low-Dye taping can be used to restrict subtalar pronation (b) The addition of calcaneal slings and reverse sixes anchored to distal leg can augment low-Dye taping<sup>127</sup>

## A team approach to biomechanical correction

*In this box, we emphasise that clinicians working together can address biomechanical factors more effectively than one clinician working alone.*

### Exercises and functional retraining

Exercises and functional retraining should always be considered when managing lower limb biomechanical issues. All clinicians in sport and exercise medicine should appreciate the influence of muscle imbalance to biomechanical abnormalities. Thus, excessive tightness of muscles such as the psoas, tensor fascia latae, hip adductors, hamstrings and gastrocnemius can be addressed using exercises such as static and dynamic stretches, in conjunction with other modalities such as massage, heat or dry needling.

Muscle weakness or incoordination requires strengthening and retraining exercises, as follows.

- Dysfunction of the abdominals, gluteus medius and minimus, hip external rotators, vastus medialis obliquus and tibialis posterior should be considered in the patient with suboptimal lower limb biomechanics. While non weight-bearing exercises may be used initially, they should be progressed to functional weight-bearing positions as soon as possible.
- Once optimal static muscle activation has been achieved, exercises can be progressed by adding lower limb movements, resistance (e.g. dumbbells, resistance bands) or stability challenges (e.g. exercise balls, single-limb stance).

*continued*

- Motor control exercises of the hip and foot are useful to promote optimal alignment of the lower limb in the sagittal, frontal and transverse planes, as well as ideal muscle recruitment patterns.
- Exercises that incorporate the lower limb in its closed kinetic chain function include the single-leg squat, single-leg heel raise, single-leg stance and arch form.
- The next stage involves integration of this new control into functional activities, such as running, landing or sport-specific skills. Small components of the overall movement should be incorporated initially, along with specific instruction and feedback. These movements may need to be performed slowly to allow them to be integrated successfully into the functional activity (Chapter 18).

#### Attend to the entire kinetic chain

It is important to consider the potential causes and effects of suboptimal biomechanics on the entire neuromusculoskeletal system. For example:

- ankle joint stiffness may contribute to altered biomechanics during gait or occur as a consequence of calf muscle imbalance
- joint pain or stiffness can be addressed with active or passive mobilisation of peripheral or vertebral joints or 'mobilisation with movement'<sup>134</sup>
- increased neural mechanosensitivity can be managed with appropriate exercises, as well as correction of possible causes such as spinal hypomobility.

Other interventions aimed at reducing pain, such as pharmacotherapy, electrotherapy and dry needling may facilitate optimal performance of exercises (Chapter 17).

## UPPER LIMB BIOMECHANICS

with W. BEN KIBLER

Correct biomechanics is as important in upper limb activities as it is in lower limb activities. For example, repeated throwing places tremendous stresses on the upper limb, especially the shoulder and elbow joints.<sup>135</sup> Throwing, however, is a 'whole body activity', involving the transfer of momentum from the body to the object being thrown. The following section uses baseball pitching as a model; however, the principles described are relevant to other overhead sports activities, such as the javelin throw, volleyball spike and tennis serve.

### The biomechanics of throwing

Throwing is a whole body activity that commences with drive from the large leg muscles and rotation of the hips, and progresses through segmental rotation of the trunk and shoulder girdle. It continues with a 'whip-like' transfer of momentum through elbow extension and through the small muscles of the forearm and hand, transferring propulsive force to the ball.

The skilled clinician should assess both the scapulohumeral and the truncal mechanics in a throwing athlete. The role of the scapula in throwing is discussed in more detail below, and the back, trunk and hips serve as a centre of rotation and a transfer link from the legs to the shoulder.

Throwing can be divided into four phases:

- |                                |   |                   |
|--------------------------------|---|-------------------|
| 1. Preparation/wind-up         | } | 80% time sequence |
| 2. Cocking                     |   |                   |
| 3. Acceleration                |   | 2% time sequence  |
| 4. Deceleration/follow-through |   | 18% time sequence |

### Wind-up

Wind-up (Fig. 8.23) establishes the rhythm of the throw. During wind-up, the body rotates so that the hip and shoulders are at 90° to the target. The major forces arise in the lower half of the body and develop a forward-moving 'controlled fall.' In pitching, hip flexion of the lead leg raises the centre of gravity. The wind-up phase lasts 500-1000 milliseconds. During this phase, muscles of the shoulder are relatively inactive.

### Cocking

The cocking movement (Fig. 8.24) positions the body to enable all body segments to contribute to ball propulsion. In cocking, the shoulder moves into abduction through full horizontal extension and then into maximal external rotation. When the scapula is maximally retracted, the acromion starts to elevate. With maximal external rotation, the shoulder is 'loaded', with the anterior capsule coiled tightly in the apprehension position storing elastic energy. The internal rotators are stretched.<sup>136</sup> At this stage, anterior joint forces are maximal and can exceed 350 newtons (N).

Toward the end of cocking, the static anterior restraints (anterior inferior glenohumeral ligament and anterior inferior capsule) are under the greatest strain. Because of the repetitive nature of throwing, these structures can become attenuated, leading to subtle instability.<sup>137</sup> In the trunk, tensile forces increase in the abdomen, hip extensors and spine, with the lead hip internally rotating just prior to ground contact.

The cocking phase ends with the planting of the lead leg, with the body positioned for energy transfer through the legs, trunk and arms to the ball. This phase also lasts 500-1000 milliseconds. The wind-up and cocking phases

**Figure 8.23** Throwing—wind-up

**Figure 8.24** Throwing—cocking

together constitute 80% of the duration of the pitch (approximately 1500 milliseconds).

Shoulder cocking continues with the counterclockwise rotation of the pelvis and trunk (when a right-handed thrower is viewed from above), which abruptly places the arm behind the body in an externally rotated position.

Lateral trunk flexion determines the degree of arm abduction. When viewed in the frontal plane, the relative abduction of the humerus to the long axis of the trunk is a fairly constant 90–100°, regardless of style. The overhand athlete leans contralaterally, while the ‘side-arm’ or ‘submarine’ thrower actually leans toward the throwing arm. Rotation of the trunk also aids in abduction. Although the muscles of the shoulder produce little abduction during the early cocking phase of a well-executed throw, the periscapular muscles are quite active. The force couple between the upper trapezius and serratus initiates acromial elevation and the lower trapezius maintains elevation at abduction angles greater than 65°.

### Acceleration

The acceleration phase (Fig. 8.25) is extremely explosive. It consists of the rapid release of two forces—the stored elastic force of the tightly bound fibrous tissue of the

capsule, and forceful internal rotation from the internal rotators (subscapularis, pectoralis major, latissimus dorsi and teres major). This generates high forces at the glenohumeral articulation,<sup>138</sup> creating high demands on the cuff musculature to keep the humeral head located in the glenoid.

Large muscles outside the rotator cuff are responsible for the subsequent acceleration of the arm. This includes muscles of the anterior chest wall as well as the muscles and fascia that surround the spine. The critical role of the muscles controlling scapulothoracic motion—scapular positioning and stabilisation against the thorax—is discussed below.

At the shoulder, acceleration is the shortest phase of the throwing motion, lasting only 50 milliseconds (2% of the overall time). In both the acceleration and the late cocking phases, muscle fatigue (which is accelerated if there is mild instability due to attenuated static restraints) can lead to loss of coordinated rotator cuff motion and, thus, decreased anterior shoulder wall support.

The acceleration phase concludes with ball release, which occurs at approximately ear level. The movements involved in acceleration place enormous valgus forces on the elbow, which tends to lag behind the inwardly rotating shoulder.

**Figure 8.25** Throwing—acceleration

### Deceleration/follow-through

Not all the momentum of the throw is transferred to the ball. In the deceleration/follow-through phase (Fig. 8.26), large forces pull forward on the glenohumeral joint following ball release, which stresses the posterior shoulder structures. During this time both intrinsic and extrinsic shoulder muscles fire at significant percentages of their maximum, attempting to develop in excess of 500 N to slow the arm down. The force tending to pull the humerus out of the shoulder socket can exceed 500 N (roughly equivalent to 135 kg). The eccentric contraction of the rotator cuff external rotators decelerates the rapid internal rotation of the shoulder, as does eccentric contraction of the scapular stabilisers and posterior deltoid. In the properly thrown pitch, the spine and its associated musculature have a significant role as a force attenuator.

Toward the end of the pitching motion, the torso, having decelerated so the arm could acquire kinetic energy in the arm acceleration phase, begins to rotate forward. The forward rotation of this larger link segment helps to reacquire some of this energy. This theoretically reduces the burden on the serratus anterior and other stabilisers, which are attempting to eccentrically maintain

**Figure 8.26** Throwing—deceleration/follow-through

the position of the scapula and maintain the humeral head within the glenoid.

In addition to the high stresses on the posterior shoulder structures, this phase places large stresses on the elbow flexors that act to limit rapid elbow extension. This phase lasts approximately 350 milliseconds and constitutes approximately 18% of the total time.

The role of the trunk in throwing is clear. When trunk motion is inhibited or the potential GRF reduced, throwing velocity is markedly lower. With a normal overhead throw rated at 100%, peak velocities dropped to 84% when a forward stride was not allowed and down to 63.5% and 53.1% when the lower body and lower body plus trunk were restricted, respectively.<sup>139</sup> Peak ball-release velocities attained by water polo players are approximately half the velocity that a thrown baseball might reach on land where a GRF can be generated.

### The kinetic chain

The 'kinetic chain' is a term clinicians use to make the point that optimal function of a distal structure relies on well-functioning proximal elements. Consider the hand/fingers in throwing as a 'distal' structure. The kinetic chain that underpins successful throwing includes the

lower limb (the very beginning of the 'chain'), the muscles that envelop the torso, the scapula and shoulder muscles and finally the upper arm and forearm that connect to the hand (Fig. 8.27). It does not require much imagination to see these elements (links) working like a 'whip' or a dynamic 'chain' to allow very speedy release of a baseball, cricket ball or tennis ball (with the racquet extending the chain even further).

Let us illustrate the concept more specifically using the scapula as a model. It links the proximal-to-distal sequencing of velocity, energy and forces that optimise shoulder function. For most shoulder activities this sequencing starts at the ground. Individual body segments, or links, move in a coordinated way to generate, summate and transfer force through various body segments to the terminal link. Large proximal body segments provide the bulk of the force.

Why is the kinetic chain concept important for clinicians? Because it highlights that treatment cannot merely address local symptoms. Right shoulder tendon pain in a right arm bowling/throwing athlete may arise because of calf muscle weakness, hip joint tightness and in coordination of the scapular movements. Clinicians must look for causes of symptoms along the entire kinetic chain and treat all contributing links.

### Normal biomechanics of the scapula in throwing

In recent years, the importance of the scapula in normal throwing biomechanics has been increasingly recognised. For optimal shoulder function and to decrease injury risk, the scapula must move in a coordinated way (Fig. 8.28). This section outlines Ben Kibler's<sup>140</sup> description of the role of the scapula in throwing (Table 8.8). If the clinician understands the normal scapular biomechanics,

Figure 8.27 The kinetic chain in throwing

Figure 8.28 Normal scapulothoracic rhythm allows the scapula to rotate upwardly during abduction, bringing the glenoid fossa directly under the humeral head to lend stability to the glenohumeral joint

Table 8.8 Scapular function in normal shoulder mechanics

1. Provides a stable socket for the humerus
2. Retracts and protracts along the thoracic wall
3. Rotates to elevate the acromion
4. Provides a base for muscle attachment
5. Provides a key link in the kinetic chain

he or she will be then able to detect abnormal scapular biomechanics in patients with upper limb injuries.

### The scapula provides a stable socket for the humerus

In normal shoulder function, the scapula forms a stable base for glenohumeral articulation. The glenoid is the socket of the ball-and-socket glenohumeral joint. Thus, the scapula must rotate as the humerus moves so that the centre of rotation of the glenohumeral joint remains optimal throughout the throwing or serving motion.

This coordinated movement keeps the angle between the glenoid and the humerus within the physiologically tolerable or 'safe zone', which extends about 30° of extension or flexion from neutral. In this range, there is maximal 'concavity/compression' of the glenohumeral joint, and the muscle constraints around the shoulder are also enhanced. The maximal concavity/compression results from the slightly negative intra-articular pressure of the normal joint, with optimal positioning of the glenoid in relation to the humerus and coordinated muscle activity.

### **The scapula must retract and protract along the thoracic wall**

In the cocking phase of throwing (as well as in the tennis serve and swimming recovery), the scapula retracts (see above). Once acceleration begins, the scapula protracts smoothly laterally and then anteriorly around the thoracic wall to keep the scapula in a normal position relative to the humerus and also to dissipate some of the deceleration forces that occur in follow-through.

### **The scapula rotates to elevate the acromion**

As almost all throwing and serving activities occur with a humerus-to-spine angle of between 85° and 100° of abduction, the scapula must tilt upwards to clear the acromion from the rotator cuff.

### **The scapula provides a base for muscle attachment**

Stabilising muscles attach to the medial, superior and inferior borders of the scapula to control its position and motion. The extrinsic muscles (deltoid, biceps and triceps) attach along the lateral aspect of the scapula and perform gross motor activities of the glenohumeral joint. The intrinsic muscles of the rotator cuff attach along the entire surface of the scapula and work most efficiently with the arm between 70° and 100° of abduction. In this position, they form a 'compressor cuff' locating the humeral head into the socket.

### **The scapula provides a key link in the kinetic chain**

The scapula is pivotal in transferring the large forces and high energy from the legs, back and trunk to the arm and the hand. Forces generated in the proximal segments are transferred efficiently and are regulated as they go through the funnel of the shoulder when the scapula provides a stable and controlled platform. The entire arm rotates as a unit around the stable base of the glenohumeral socket.

Thus, the scapula performs various interrelated functions to maintain the normal glenohumeral path and

provide a stable base for muscular function. Abnormalities in scapular function that predispose to injury are discussed below.

## **Abnormal scapular biomechanics and physiology**

The scapular roles can be altered by many anatomical factors to create abnormal biomechanics and physiology, both locally and in the kinetic chain (Table 8.9).

### **Clinical significance of scapular biomechanics in shoulder injuries**

Abnormal shoulder biomechanics can compromise normal shoulder function. This observation has been given various descriptive titles, such as 'scapulothoracic dyskinesis', 'floating scapula' or 'lateral scapular slide'. It is important for the clinician to recognise that these are merely titles for the same phenomenon, that is, abnormal scapular function. We provide examples of how abnormal biomechanics can cause shoulder and elbow problems.

Lack of full retraction of the scapula on the thorax destabilises the cocking point and prevents acceleration out of a fully cocked position. Lack of full scapular protraction increases the deceleration forces on the shoulder and alters the normal safe zone between the glenoid and the humerus as the arm moves through the acceleration phase. Too much protraction because of tightness in the glenohumeral capsule causes impingement as the scapula rotates down and forward. These cumulatively lead to abnormalities in concavity/compression due to the changes in the safe zone of the glenohumeral angle.

Loss of coordinated retraction/protraction in throwing opens up the front of the glenohumeral joint and, thus, provides an insufficient anterior bony buttress to anterior translation of the humeral head. This increases shear stress on the rest of the anterior stabilising structure—the labrum and glenohumeral ligaments—which further decreases the stability of the glenoid for the rotating humerus.

Lack of acromial elevation leads to impingement in the cocking and follow-through phases. Impingement can also occur secondary to painful shoulder conditions that inhibit the function of the serratus and lower trapezius muscles. As these muscles normally act as a force couple to elevate the acromion, their inhibition commonly causes impingement. Thus, detecting and, if necessary, reversing serratus and trapezius inhibition is an important step in treating shoulder conditions.

If the scapula is unstable, the lack of an anchor affects the function of all scapula muscles. Muscles without a stable origin cannot develop appropriate or maximal torque and are predisposed to suffering muscular imbalance. If the scapula is truly unstable on the thoracic

**Table 8.9 Alterations to scapular function**

Scapular function alteration	Effect on scapular function
<i>Anatomical factors</i>	
Cervical spine lordosis	Excessive scapular protraction—leads to impingement with elevation
Thoracic spine kyphosis	Excessive scapular protraction—leads to impingement with elevation
Shoulder asymmetry (i.e. drooping of the shoulder or 'tennis shoulder')	Impingement/muscle function and fatigue
Injuries of scapula, clavicle	Alters orientation of scapula, length of clavicular strut—painful conditions that inhibit muscle function
<i>Abnormalities in muscle function</i>	
Overuse, direct trauma, glenohumeral causes (instability, labral lesions, arthrosis)	Muscle weakness or force couple imbalances. Serratus anterior and lower trapezius particularly susceptible. Can be a non-specific response to a variety of glenohumeral pathologies (this can be seen as analogous to the knee in that weakness of the vastus medialis obliquus can result in patellofemoral syndrome)
Glenohumeral inflexibility, posterior (capsular or muscular)	Limits smooth glenohumeral joint motion and creates wind-up effect so that the glenoid and scapula get pulled forward and inferiorly by the moving arm. This leads to excessive protraction, which, in turn, holds the scapula and, importantly, the acromion inferiorly and, thus, makes it prone to impingement
Nerve injury (causes less than 5% of abnormal muscle function in shoulder problems)	Long thoracic nerve—serratus anterior function inhibited. Accessory nerve—trapezius function inhibited

wall, as in spinal accessory nerve palsies or in extremely inhibited muscles, then the muscle origins and insertions are effectively reversed, and the distal end of the muscle becomes the origin. The scapula is then pulled laterally by the muscle, which contracts from the more stable distal humeral end rather than from the proximal scapular end. A further problem of the unstable scapula is that it does not provide a stable base for glenohumeral rotation during link sequencing. Therefore, the arm works on an unstable platform and loses mechanical efficiency.

One of the most important scapular biomechanical abnormalities is the loss of the link function in the kinetic chain. The kinetic chain permits efficient transfer of energy and force to the hand. The scapula and shoulder funnel forces from the large segments, the legs and trunk, to the smaller, rapidly moving small segments of the arm.

Scapular dysfunction impairs force transmission from the lower to the upper extremity. This reduces the force delivered to the hand or creates a situation of 'catch up' in which the more distal links have to overwork to compensate for the loss of the proximally generated force.

The distal links have neither the size, the muscle cross-sectional area, nor the time in which to develop these larger forces efficiently. For example, a 20% decrease in kinetic energy delivered from the hip and trunk to the arm necessitates an 80% increase in muscle mass or a 34% increase in rotational velocity at the shoulder to deliver the same amount of resultant force to the hand. Such an adaptation would predispose to overload problems.

This explains why injuries apparently unrelated to the upper limb, for example, decreased push off due to Achilles tendinopathy, decreased quadriceps drive after a muscle strain, or decreased segmental trunk rotation secondary to thoracic segmental hypomobility, can affect upper limb throwing mechanics and predispose to further or more serious, upper limb injury.

### Changes in throwing arm with repeated throwing

Repeated throwing causes adaptive changes to gradually develop in the shoulder and elbow. Changes occur in flexibility, soft tissue/muscle strength and bony contour.

At the shoulder, long-term throwing athletes have increased range of external rotation. This arises because of the repeated stress to the anterior capsule in the cocking phase, and stretch or breakdown in the anterior static stabilisers of the shoulder joint (the inferior glenohumeral ligaments). This may compromise the dynamic balance that exists between shoulder function and stability. The combination of increased shoulder external rotation range of motion and breakdown of the static stabilisers may lead to anterior instability of the shoulder and secondary impingement.

The normal strength ratio of internal rotators to external rotators is approximately 3:2, but in throwers this imbalance is exaggerated and, over time, lack of external rotation strength may increase vulnerability to injury. These dynamic changes in the shoulder joint highlight the need for a structured exercise program to prevent or correct muscle imbalances.

Throwing also produces structural changes at the elbow. Due to the valgus stress applied in the throwing action, there is a breakdown of the medial stabilising structures (medial collateral ligament, joint capsule, flexor muscles). This leads to the development of an increased carrying angle at the elbow.

Less frequently, the eccentric overload on elbow structures causes anterior capsular strains, posterior impingement or forearm flexor strains and subsequently, a fixed flexion deformity.

### Common biomechanical abnormalities specific to throwing

One of the most common biomechanical problems seen in throwing sports such as cricket, baseball and water polo is caused by the throwing athlete 'opening up too soon'. Normally the body rotates out of the cocking phase when the arm is fully cocked (externally rotated). If the body opens up too soon, the arm lags behind and is not fully externally rotated. This results in increased stress to the anterior shoulder structures and an increased eccentric load to the shoulder external rotators. It also results in increased valgus stress at the elbow.

The other common abnormality seen in throwing athletes is known as 'hanging', which is a characteristic sign of fatigue. Decreased shoulder abduction leads to dropping of the elbow and a reduction in velocity. There is an associated increase in the likelihood of injury, particularly to the rotator cuff as well as to the shoulder joint and the elbow. It is normally related to excessive intensity, frequency or duration of activity.

In baseball, the type of pitch is determined by the spin imparted onto the ball by the hands and fingers at ball release. The normal follow-through involves forearm pronation. In 'breaking' pitches, the forearm is relatively supinated at release and then pronates. 'Breaking' pitches are associated with an increased risk of injury. Some pitchers incorrectly forcefully supinate against the normal pronation of follow-through.

# Biomechanical aspects of injury in specific sports

with BEN CLARSEN

*Nothing compares to the simple pleasure of riding a bike.*

John F. Kennedy (1917–1963)

This chapter outlines the relationship between biomechanics and injury for a number of sports—cycling, cricket fast bowling, golf, rowing, swimming and tennis.

## CYCLING

with PHIL BURT

The demands and injury risks differ greatly across the various disciplines of cycling. Traditional road cycling involves long-duration submaximal effort, and places stresses on the body due to monotonous loading and maintenance of static postures for extended periods. In contrast, BMX and track sprint cycling require maximal effort over a short duration. Riders from these disciplines are more likely to suffer injuries related to strength and power training, such as weightlifting and plyometrics. The various subdisciplines of mountain biking encompass a wide range of demands, and both acute and overuse injuries are common. This section focuses on the main overuse injury problems affecting cyclists across all disciplines—knee and low back pain.

### Relationship between risk factors and loading

Overuse injuries in cycling are commonly blamed on extrinsic factors such as bike position or shoe and pedal setup, as well as intrinsic factors such as anatomical anomalies, poor cycling technique, or reduced neuromuscular control. These factors may certainly be important due to the repetitive, uniplanar nature of the sport. However, it is important to recognise that even among top professionals, a wide variation of anatomy, techniques, and bike setups is normally well-tolerated without injury occurring. In almost all cases of cycling-related overuse injury, symptom onset can be linked to a

mismanagement of training and racing loads. Cyclists are most likely to develop injury following a rapid increase in load, such as when pre-season training is resumed after a winter break, as well as during intense periods of the season. When injuries are apparently 'caused' by a change in equipment, it is normally because the change was made at an inappropriate time of the season when the cyclist was already close to their limit of load tolerance.

The key to successful management of cycling injuries, therefore, is load management. The clinician, cyclist and coach should establish the volume, intensity and frequency of cycling that the rider can tolerate and create a systematic plan to increase these parameters over time. Wherever possible, loading should be quantified using a power meter and training software should be used to monitor the acute and chronic training load during rehabilitation (Chapter 12).

Once an appropriate training plan is established, intrinsic and extrinsic risk factors should be assessed. The following section covers biomechanical factors thought to be associated with the most common cycling injuries. It is important to note that there is little high-level evidence in the field of cycling injuries, with current practice largely based on indirect evidence and expert opinion. It is therefore necessary to take a trial-and-error approach; to be worthwhile, modification in technique or equipment should lead to an obvious improvement in symptoms.

### Knee pain

The knee is the most common site of overuse injury among cyclists of all levels.<sup>1–5</sup> A majority of knee complaints are related to the patellofemoral joint.<sup>6</sup> However, there is a range of differential diagnoses including iliotibial band syndrome (ITBS), infrapatellar fat pad impingement, medial plica irritations and medial patellofemoral ligament

strains.<sup>6-8</sup> Although tendinopathy is generally rare in cyclists, pain can also arise from the quadriceps tendon enthesis on the superolateral or superomedial patella.

### Three biomechanical factors to assess in patellofemoral pain

Various biomechanical factors may play a role in the development of patellofemoral pain in cyclists, including patellofemoral joint compression forces, knee kinematics in the frontal plane and rotational torques in the lower limb.<sup>9-12</sup>

#### 1. Saddle height

Patellofemoral joint contact pressure is inversely related to saddle height,<sup>9</sup> leading to the common belief that cycling with lower bicycle saddle heights increases the risk of patellofemoral pain development.<sup>8, 11, 13</sup> However, this remains to be confirmed in high-quality risk factor studies of competitive cyclists and one study found that altering the saddle height within the normal ranges used in rehabilitation led to negligible changes in patellofemoral joint contact pressure.<sup>14</sup> Nevertheless, it is advisable that cyclists with patellofemoral pain ride in a relatively high saddle position, with maximal knee extension of approximately 30° (Fig. 9.1).

#### 2. Medial knee motion

Excessive medial motion of the knee in the frontal plane (Fig. 9.2a) may also be a risk factor for patellofemoral pain, as this position encourages lateralisation of the patella

**Figure 9.1** Maximum knee extension is a key bike fitting parameter, which typically ranges from 35–40° among professional riders. Patellofemoral joint contact pressures may be minimised by selecting a higher saddle position, with maximum knee extension between 30° and 35°.

**Figure 9.2** Frontal-plane knee motion in cycling  
(a) Excessive valgus motion of the knee is thought to contribute to a range of knee injuries (b) Improving the alignment of the hip, knee and ankle may lead to symptomatic improvement

in the femoral trochlea, increased lateral joint contact pressure and increased stress on medial soft tissues. This theory is supported by studies showing that cyclists with a history of knee pain adopt a more medial knee position compared to uninjured cyclists,<sup>10</sup> and that 'normalising' frontal plane motion (Fig. 9.2b) can lead to symptomatic improvement.<sup>15</sup> Knee motion may be altered by motor control training or through manipulation of the cyclist's shoes and pedals. For example, foot position can be adjusted using small angled wedges between the shoe and the pedal cleat or underneath the forefoot or by using custom-made insoles. However, manipulation of cycling shoes and pedals has an extremely unpredictable effect on knee motion.<sup>16, 17</sup> It is therefore important to test each individual's response, making sure that adjustments lead to symptomatic improvement.

#### 3. Rotational torque

Rotational torque at the knee caused by the fixation of shoes to the pedals may also be a factor in patellofemoral pain in cycling. After the introduction of modern cleated pedals in the 1980s, there were anecdotal reports of an increase in the prevalence of knee injuries among cyclists.<sup>6, 12</sup> It was thought that the natural rotation of the lower limb during the pedalling cycle was constrained by fixing the shoe, leading to increased stress at the knee joint. Therefore, 'floating' pedals were designed that allowed a small degree of axial rotation, which attenuated the rotational torque at the knee.<sup>12</sup> Although there is no

direct evidence that floating pedals reduce injury, their design has been widely accepted and they remain the most popular type used by cyclists today.<sup>1</sup>

### Iliotibial band syndrome

ITBS, often called 'runner's knee', is also common among cyclists.<sup>6, 18</sup> Intrinsic factors thought to contribute to ITBS include large leg length discrepancies, external tibial torsion of greater than 20° and excessive subtalar pronation.<sup>18</sup> High saddle height, a *toe-in, heel-out* foot position and excessive medial knee motion also increase the stress on the ITB.<sup>19</sup>

#### PRACTICE PEARL

Therefore, cyclists with lateral knee pain should be instructed to ride with a relatively low saddle (maximum knee extension approximately 40°), keep their feet straight or pointed slightly outwards and avoid a knee-in position.

### Low back pain

Although transient back discomfort is normal in cycling, studies have shown that performance-limiting low back pain is common among amateur<sup>20</sup> and elite cyclists.<sup>1, 21</sup>

Cyclists with low back pain typically present with non-specific symptoms provoked by the maintenance of sustained flexion positions and they can often be classified as having a flexion-pattern motor control dysfunction (Chapter 29).<sup>22</sup> Using a remote posture monitoring system, Van Hoof et al. showed that cyclists with low back pain

adopt a more flexed position in their lumbar spine than do pain-free cyclists (Fig. 9.3).<sup>23</sup> This may be related to a number of pathomechanical mechanisms of low back pain,<sup>22, 24</sup> such as flexion/relaxation inhibition, or fatigue of the erector spinae muscles and mechanical creep of the spine's viscoelastic tissues. However, these theories remain largely untested in cyclists.

Encouraging a relaxed, anteriorly tilted pelvic position, with an even distribution of flexion throughout the spine, is often important in the overall management of cyclists with low back pain. A number of equipment modifications may help facilitate this, including lowering the saddle, raising the handlebars and shortening or lengthening the overall reach.

#### PRACTICE PEARL

Adjusting the saddle to a slightly nose-down position (2–4°) may also be helpful in achieving greater anterior pelvic tilt and reducing back pain.<sup>25</sup>

Excessive lateral flexion and/or rotation of the spine while cycling may also contribute to back pain, particularly if it is asymmetrical. This can be caused by a range of factors, such as large leg length differences, hip range of motion limitations and asymmetrical muscle activation patterns. These should be considered as a part of the comprehensive management of the cyclist with low back pain. Bike fit is a critical element in such a comprehensive assessment (see box).

**Figure 9.3** Spinal position in cycling (a) Ideally, forward bend should be achieved evenly (b) Cyclists with low back pain often adopt a more flexed lumbar spine, with less anterior pelvic tilt and a more extended thoracic spine

## Bike fitting

There are many approaches to bike fitting, ranging from simple anthropometry-based formulae to dynamic approaches utilising high-tech equipment (Table 9.1 and Fig 9.4).

As bike fitting involves the optimisation of a wide range of competing variables, such as aerodynamics, comfort and control, it always involves compromise. Despite the recent rapid pace of technological development in the cycling

industry, there remains little research into bicycle equipment and injury, and bike fitting remains just as much an art as it is a science. We encourage clinicians to work closely with bike fitters who take a trial-and-error approach, considering the cyclist's previous and current injuries, cycling goals and physical limitations.

**Table 9.1** Advantages and limitations of modern bike fitting methods

Formula-based approach	
Description	There are a number of formula-based approaches that convert anthropometric measurements (e.g. inseam height) to bicycle set-up parameters. The most well-known approach is named after two-time Tour de France winner, Greg LeMond.
Advantages	Quick and easy. Cyclists can perform measurements themselves.
Limitations	One-size-fits-all approach that does not consider the cyclist's physical limitations. Highly unreliable and variable results. <sup>26</sup>
Static angle-based approach	
Description	The cyclist's major joint angles are measured with a goniometer while he or she sits on the bike without cycling. The bike is adjusted to position each joint within a predetermined 'optimal' range of motion. Sometimes referred to as the Holmes method.
Advantages	Good reliability. <sup>27</sup>
Limitations	Does not consider dynamic cycling technique. 'Optimal' angles are not evidence-based.
Dynamic angle-based approach	
Description	Dynamic measure of joint angles collected with two-dimensional or three-dimensional motion analysis over a period of time and averaged as rider is actually riding.
Advantages	Good reliability. <sup>27</sup> Accounts for the rider's technique and physical limitations.
Limitations	Does not consider kinetic variables such as power distribution between legs.
Combined-input approach	
Description	Combination of data streams such as power, pedal forces, saddle pressure with motion analysis.
Advantages	Multiple sources of data can lead to more-informed clinical-reasoned decisions.
Limitations	More data does not always lead to better clinical decisions. Little research to assist data interpretation. Validity and reliability unknown.

**Figure 9.4** Modern bike fitting is an interactive process incorporating data from a variety of sources such as three-dimensional motion analysis, shoe and saddle pressure distribution, and pedal force application

## CRICKET FAST BOWLING

with ALEX KOUNTOURIS

Cricket fast bowling combines rapid near-end-range trunk movements (rotation, side flexion and extension), with high vertical and horizontal impact forces.<sup>28-30</sup> Elite fast bowlers bowl in excess of 300 deliveries in a single 4-5 day game, and have a higher rate of injury than any other players in cricket.<sup>31</sup>

Soft tissue and bone injuries are typically reported in injury surveillance studies of fast bowlers.<sup>32</sup> Lumbar spine injuries have received the most attention mainly because bone stress injuries of the posterior vertebral elements (pedicle, pars interarticularis and lamina) require lengthy recovery periods and are particularly common.<sup>31</sup>

### PRACTICE PEARL

The most important risk factors are bowling biomechanics, age and workload.

Research into cricket fast bowling injuries has identified a number of possible modifiable and non-modifiable risk factors, particularly for lumbar spine injuries.<sup>32, 33</sup> It is likely that a combination of these factors determines the injury risk for fast bowlers, although a clear association between the three factors has not been established.

### Age and risk of bowling injury

To highlight this important interplay between risk factors, younger fast bowlers, for example, are affected by biomechanical (technique) errors because they have an immature skeletal system that cannot cope with the high forces associated with fast bowling. As such, younger (adolescent) fast bowlers have a higher incidence of lumbar bone stress injuries than adult bowlers and have a disproportional high rate of lumbar spine radiological abnormalities and soft tissue injuries for their age.<sup>34,35</sup> Technique (biomechanical) faults that increase the amount of trunk rotation, extension and side flexion increase the load on the already susceptible musculoskeletal structures like the intervertebral disc and posterior vertebral arch.

### Bowling workload and injury

Bowling workload is a modifiable factor associated with fast bowling injuries in both adolescent and adult fast bowlers. High bowling workloads in a single session, in a match or over a cricket season, have caused injuries in fast bowlers.<sup>29, 36-38</sup> More importantly, workload 'spikes' (a rapid increase in workload) have also been associated with fast bowling injuries and particularly lumbar spine injury.<sup>39, 40</sup>

The relationship between bowling technique and workload is not entirely clear, but it is likely that bowlers with a technique that is considered to be biomechanically sound may be able to tolerate higher workloads than those with other 'less safe' techniques because they are better equipped to dissipate forces. This relationship could be further complicated when considering age and that some structures may not have the resilience to absorb repetitive load (e.g. the posterior vertebral arch) until full maturity is reached. For example, in the lumbar spine, important geometric parameters that influence bone strength are not fully developed until the mid-twenties. In long bones, increases in bone mineral density (BMD) and bone mineral content (BMC) occur between pre-puberty and 18 years of age, but in the lumbar spine the increases in BMD, BMC, vertebral height and vertebral width continue to develop until 25 years of age.<sup>41</sup> This age (25 years) seems to be an important time in the development of lumbar bone stress and other lumbar spine injuries.

The relative impact of workload and age as risk factors needs to be considered along with bowling technique, because technical faults that result in exaggerated spinal positions and higher impact forces can magnify the impact of other risk factors.

### PRACTICE PEARL

Biomechanical errors are arguably the most important risk factor for fast bowling injury.

Like other sporting activities, fast bowling technical faults are considered modifiable factors although making meaningful technical changes can be difficult.<sup>42</sup> To fully understand the biomechanical faults it is important to review the patterns of movement (kinematics) and forces (kinetics) that occur during the fast bowling action.

### Fast bowling technique and injury

The simplest description of the fast bowling action is that it involves a combination of trunk rotation, and lateral flexion and extension during the delivery stride.<sup>28-30</sup> The sequence of movements and the associated ground reaction forces (GRF) during the fast bowling delivery stride are unique to every bowler, but can be broadly categorised into one of four bowling techniques: front-on, side-on, semi-open (semi-on) and mixed (Fig. 9.6).<sup>43</sup> These bowling techniques are defined by position of the feet, pelvis, trunk and shoulders at specific times during the delivery stride, and assessed using video (two-dimensional) or ideally, three-dimensional computer analysis.<sup>43</sup>

The fast bowling action can be broken down into three components that are interrelated and

important for both performance and injury.<sup>44</sup> The main components are the run-up, the delivery stride and follow-through. The run-up is important as it allows bowlers to gain the momentum required to deliver the ball at a desired velocity and can pre-set the body position that occurs during the delivery stride. The delivery stride is the last ground contact of the back foot, known as back foot contact (BFC), and then the transition to front foot contact (FFC) and ends with ball release (Fig. 9.5). The highest GRF, between six to nine times body weight, occur during the period between FFC and ball release.<sup>28, 29, 45</sup> The follow-through begins at ball release and involves deceleration of the bowler until they come to a stop.

**Importance of biomechanics of the delivery stride**  
Bowlers can be categorised into the four bowling techniques based on the positions and movements that occur during the delivery stride.<sup>44</sup> The four main bowling techniques are outlined in Figure 9.6.

Of the four bowling actions, the mixed technique has been identified as having the greatest association with lumbar spine injury and abnormal radiological features (Fig 9.6d).<sup>35, 46</sup> The maximum amount of shoulder-pelvis separation angle occurs just after FFC,<sup>43</sup> and possibly represents the period that places the bowler at greatest risk of injury, especially as it is also the time when the greatest ground impact forces are being absorbed.<sup>29, 45</sup> The mixed technique also typically involves higher rates of trunk contralateral side flexion and hyperextension compared to other bowling actions and therefore places greater stress through the lumbar spine.<sup>47</sup>

Another biomechanical aspect that has been associated with lumbar spine injuries in fast bowlers is shoulder counter-rotation (SCR), which is also closely associated with the mixed bowling technique. Bowlers with higher rates (greater than 30°) of SCR during the delivery stride have been associated with higher incidence of lumbar spine bone stress injuries and abnormal radiological features.<sup>28, 29, 35, 44, 48</sup> SCR (Fig. 9.7) is the change in shoulder alignment between BFC and FFC, from a more front-on to a more side-on alignment.<sup>43, 44</sup> The measurement of SCR is made using both two-dimensional and three-dimensional motion analysis and can vary slightly depending on the definition of BFC (first-foot contact with the ground versus foot flat on the ground).<sup>43</sup>

It is still unclear whether one particular bowling trunk position causes the most stress on the lumbar spine or if a combination of movements is required to exceed load tolerance. Cadaver studies indicated that lumbar extension was most likely to be associated

**Figure 9.5** Cricket fast bowling components (a) Back foot contact (BFC) (b) Front foot contact (FFC)

DRAWING ADAPTED FROM PORTUS ET AL.<sup>44</sup>

with lumbar bone stress injury in fast bowlers, because of increased load on the posterior vertebral arch in a hyperextended position.<sup>28, 49</sup> Since then, the role of trunk side flexion and rotation has also received attention. Ranson et al. proposed that the amount of contralateral side flexion and ipsilateral rotation at FFC were important factors in the development of lumbar spine injury in fast bowlers.<sup>50</sup> They found that the greatest range of motion in the lower lumbar spine at FFC was contralateral lumbar side flexion and not lumbar extension as first thought. They concluded that the combination of high rates of contralateral side flexion, ipsilateral rotation and the large impact forces would be associated with lumbar spine bone stress in fast bowlers.<sup>50</sup> It is most likely that a combination of trunk positions is responsible for the high force required to develop lumbar spine injuries, in particular, bone stress injuries and the individual contribution of each movement to injury risk could be associated with the bowling technique used.

Apart from the spine and trunk positions adopted during the delivery stride, lower limb joint kinematics have also been linked with fast bowling injuries. The amount of knee extension at FFC influences the distribution of forces and influences the height at which the ball is released, so that a higher release height requires less knee flexion (straighter knee).<sup>29, 51</sup> The increase in front foot knee extension leads to a stiffer knee segment and greater impact forces.<sup>44, 51</sup>

**Figure 9.6** Cricket fast bowling techniques

(a) *Front-on technique* involves the alignment of the pelvis and shoulders parallel to the batsman at back foot contact (BFC)

(b) *Side-on technique* involves the alignment of the bowler's shoulders and pelvis perpendicular to the batsman at BFC

(c) *Semi-on or semi-open technique* is defined as both shoulder and pelvis alignment somewhere between front-on and side-on positions at BFC

(d) *Mixed technique* involves dissociation between the shoulder and pelvis alignment at BFC, known as the shoulder–pelvis separation angle. For example, a front-on pelvis alignment and side-on shoulder alignment at BFC, or side-on pelvis position and front-on shoulder position at BFC. A shoulder–pelvis separation angle of  $30^\circ$  has been used to classify bowlers as having a mixed technique

DRAWING ADAPTED FROM PORTUS ET AL.<sup>44</sup>

Portus et al.<sup>44</sup> reported a relationship between a more extended front knee at FFC and ball release, and higher braking and vertical impact forces. They also demonstrated that bowlers with greater knee extension also reached peak forces more quickly than those with a more flexed knee at ball release. The higher forces associated with a more extended front knee may increase injury risk but also allow bowlers to deliver the ball at faster bowling speeds.<sup>44</sup> This is an important performance benefit and needs to be considered if technique modification is contemplated. It is therefore possible that there may be a trade-off between faster bowling speeds and higher injury risk.

In summary, it is important to consider bowling biomechanics as a critical risk factor for fast bowling injuries. The relative impact of biomechanical errors on injury risk should be considered along with bowling workload and the age of the fast bowler, as there is a delicate interplay between these key risk factors.

**Figure 9.7** Shoulder counter-rotation during delivery stride

DRAWING ADAPTED FROM PORTUS ET AL.<sup>44</sup>

## GOLF

with ROGER HAWKES

Although injury rates are generally low, golf-related injuries are still common because of the popularity of the sport. It can be played into old age where the health and social benefits lead to increased longevity.<sup>52</sup>

Golf relies on a coordinated and repeated action in which energy is generated in the lower body and trunk. In long hitters, the force is transferred efficiently into the upper limbs and ultimately the club head, which can travel at speeds of 190 km/h. Professional tournaments are usually comprised of four rounds of 18 holes over a 4 day period during which the player also includes considerable practice. It is estimated that the average tour professional will hit around 200 shots per day. In addition, there has been an emphasis on hitting the ball as far as possible. It is not surprising therefore that, in spite of improving equipment and better conditioning, vulnerable tissues remain susceptible to injury. For instance, peroneal tendons in the leading ankle are used during the follow-through to prevent excessive inversion. Overuse can lead to tenosynovitis and lateral ankle pain and swelling. In addition, any deficiency in the kinetic chain may lead to compensation elsewhere and injury is more likely to occur. For instance, a player who is not able to rotate their thoracolumbar spine during the backswing may compensate by increasing the horizontal adduction of the leading shoulder in order to reach the top of the backswing. This may lead to shoulder injury.<sup>53</sup> Furthermore, fatigued players will have a reduced club head speed but an increased range of movement and this adds to injury risk.<sup>54</sup>

This chapter focuses on wrist, shoulder, hip and low back pain in golfers. Medial elbow pain, which is also common, is covered in Chapter 25.

**Wrist pain**

Good amateurs and professional players require considerable practice and intentionally take divots in order to impart backspin on the ball. In the winter they often practice on mats. As a result, the leading wrist can be painful.<sup>55</sup> This is particularly common in periods of the year when the ground is hard.

**The leading wrist**

The leading wrist is the more vulnerable of the two wrists during the golf swing because it moves from radial deviation at the top of the backswing (Fig. 9.8a) to ulnar deviation during follow-through. The trailing wrist follows a less stressful extension/flexion movement pattern (Fig. 9.8b). At impact, the ulnar side of the leading wrist is protected by the extensor carpi ulnaris

tendon, which is susceptible to overuse synovitis. When a player hits an obstruction, the impact can rupture the sub-sheath which holds its position at the lower end of the ulna. This structure is particularly vulnerable in supination, which occurs during the golf swing and results in a large angle between the muscle axis and the tendon as it inserts into the fifth metacarpal.<sup>56</sup>

As a result of repetitive movement into ulnar deviation during the backswing, the leading wrist is also susceptible

(a)

(b)

**Figure 9.8** (a) The leading wrist (left) is in maximal radial deviation at the top of the backswing (shown) and moves into ulnar deviation during the follow-through (b) The trailing wrist (right) is in maximal extension at the top of the backswing (shown) and moves into flexion during the follow-through

to bone stress reactions, particularly of the hamate. Older players may develop osteoarthritic changes in the carpus, and players with long ulnas (either constitutionally or acquired after radial fracture) may be susceptible to ulnar-sided wrist pain as a result of impaction.

Fractures of the hook of hamate are rare, but 35% of them occur in golfers.<sup>11</sup> The hook of hamate is particularly vulnerable when a tall player uses standard length clubs. As a result, the end of the club may press onto the hook of hamate or piso-hamate ligament. Acute fractures can occur if the club hits the ground or an object, and with repetitive impacts the hook is also susceptible to bone stress injuries.

### The trailing wrist

The trailing wrist extends during the backswing (Fig. 9.8b) and flexes during the follow-through. Players with dorsal rim impaction syndrome<sup>57</sup> pinpoint pain at the radial carpal joint in loaded extension, but often have no pain in passive extension. It is usually thought to occur as a result of nipping of the synovium, which can become chronically inflamed and hypertrophied. In some cases it can be due to loose bodies. Ultrasound is a good starting investigation but can be normal. Magnetic resonance imaging (MRI) can also show hypertrophy of the synovium (Fig. 9.9) and computed tomography (CT) scans can show loose bodies.

Players with tenosynovitis will need to reduce practice in order to reduce their symptoms. Amateur players may also choose a more forgiving shaft such as those made of graphite. They may improve the sweet spot by using hollow back clubs rather than blades. Other general treatments are covered in Chapter 26. Players who acutely sublux their extensor carpi ulnaris (ECU) tendons

generally prefer to have operative repair of the subsheath, but conservative treatments have been used in tennis players with good results with no apparent increased time away from their sport. Some players have asymptomatic subluxing ECU tendons and do not require treatment.<sup>55</sup>

Players with dorsal rim impaction syndrome respond well to corticosteroid injection. However, the condition can return and arthroscopic resection of the thickened synovium can be indicated.

Finally, players who have had hook of hamate stress reactions or fractures will need to use longer clubs. If there is non-union of a fractured hook of hamate, resection is usually preferred in order to reduce the risk of injury to the ulnar nerve and artery injury, which can complicate pinning.<sup>58</sup>

### Shoulder pain

The forces acting on the leading shoulder in golf are almost completely opposite to those involved in throwing (Chapter 8). The shoulder hyperadducts during the backswing, which can over stretch the posterior structures. During the follow-through, anterior structures work eccentrically to slow the shoulder down. The resultant combination of anterior capsular tightness and posterior laxity pushes the humeral head backwards, placing stress on the posterior labrum which can lead to posterior instability.<sup>53</sup> Players typically complain of pain or clunking at the top of the backswing. Clinical examination may show signs of posterior instability and MRI may show injury to the posterior labrum.

Players with a history of anterior instability in the leading shoulder may develop pain and apprehension toward the end of the follow-through when the shoulder is abducted and moving into external rotation. In the trailing shoulder, the movement (and injury) pattern is more similar to throwing sports.

Acromioclavicular joint pathology may occur in golfers. It is aggravated by joint compression, which occurs during the backswing for the leading shoulder and during the follow-through for the trailing shoulder.

In recent years there has been considerable interest in the phenomenon of glenohumeral internal rotation deficit (GIRD) in throwing athletes (Chapters 8 and 24). In golfers, however, the main focus is on identifying and addressing deficits in external rotation. Professional players are regularly screened for glenohumeral external rotation deficits (GERD) in an attempt to prevent posterior instability in the leading shoulder, although there is currently little research to show this as an effective prevention strategy.

Players with shoulder pathologies often need to limit golf participation in the early phases of rehabilitation. Resumption of practice should begin with putting and small chips with high irons, before gradually increasing the swing and playing with progressively longer clubs.

**Figure 9.9** Dorsal rim impaction syndrome—Sagittal MR image showing synovial/capsular hypertrophy (arrows) of the dorsal aspect of the radiocarpal synovium. Normal capsule would be a thin low signal line

## Hip pain

A recent survey of professional golfers found that 19% of players complained of current, significant hip and groin pain.<sup>59</sup> Common hip diagnoses in golfers include labrum pathology/femoroacetabular impingement and, in older players, osteoarthritis.

A majority of golf-related hip problems are located in the leading hip,<sup>59</sup> which undergoes higher rotational velocities and moves through a much greater range of motion than the trailing hip.<sup>60, 61</sup> However, both hips need to be able to move freely to facilitate an effective swing—particularly into internal rotation. The trailing hip goes into internal rotation at the top of the backswing and the leading hip is at maximum internal rotation at the end of the follow-through. Players with osteoarthritis and femoroacetabular impingement may present with 'hip pain' at either end of the swing.

Occasionally, players will present with reduced internal rotation in the leading hip without hip joint pathology. This may be due to tightness of the posterior structures that work eccentrically during the follow-through. Limited internal rotation of the leading hip can have a range of consequences on swing mechanics, such as causing the player to 'stand up' during the follow-through. Maximising hip internal rotation range of motion is therefore important for all golfers.

The effective internal rotation range of motion may also be increased by encouraging players to take a more externally rotated stance. This is recommended for players with femoroacetabular impingement and osteoarthritis, as well as for players who have had hip replacement surgery.

## Low back pain

Younger players may be vulnerable to spondylolysis, especially if they end their swing with a 'reverse C' shaped thoracolumbar spine (Fig. 9.10). In addition, recent trends towards a more aggressive swing involving a larger separation between the hips and the shoulder may also lead to back injury. Both these technique factors should be reviewed in players with low back pain.

Reduced hip internal rotation in the leading hip increases stress on the thoracolumbar spine, as rotational demands of the follow-through are transferred higher up the kinetic chain. Tight hip flexors are also a risk factor because this leads to more anterior pelvic tilt and therefore more 'jamming' of the facets in the lumbar spine.<sup>62</sup>

## ROWING

with FIONA WILSON

The biomechanics of rowing are complex with many variables contributing to the speed of the boat. Each of

**Figure 9.10** Follow-through position (a) Reverse C position increases stress on the lumbar spine, predisposing the player to spondylolysis (b) Ideal follow-through position for the lumbar spine. Note the large range of hip internal rotation in the leading hip

the three body segments contributes approximately one third of the stroke length. The legs execute their work when the force exertion is maximal in the first half of the stroke and produce nearly half the rowing power, with the trunk producing around one third and the arms only one fifth of the power output. Thus, contrary to common belief, the legs are the greatest source of power in rowing, increasing their contribution as the stroke rate increases.<sup>63</sup> High forces are generated at several specific points of loading on the rower's body. Due to the cyclical movement pattern and high volume of training, these forces are repeated hundreds of times during a typical training session. It is this combination of high forces acting on the rower, large training volume and type of training that places the rower at risk of injury.

This section will focus on three of the most common regions of rowing-related pain—the lower back, chest wall and wrist/forearm.

## Low back pain

Between 32% and 50% of rowers experience rowing-related low back pain per year,<sup>64, 65</sup> and there are a number of biomechanical factors thought to contribute to the development of low back pain. The spine is maximally loaded at the front of the stroke—known as the 'catch' position—where the blade of the oar is placed in the water and force is applied through the trunk, arms and legs.

Ideally, forward reach at the catch is achieved through maximal hip, knee and ankle flexion, with the lumbar spine in slight flexion and the pelvis in anterior rotation (Fig. 9.11a). However, inadequate lumbopelvic control or limitations in hip, knee or ankle range of motion may lead to a position of extreme lumbar flexion at the catch, with the pelvis in posterior rotation (Fig. 9.11b). In this position the intervertebral discs and posterior elements of the spine may be more vulnerable to injury.<sup>66-68</sup>

Good lumbopelvic control is also important in the finish position. Here, a neutral lumbar spine is ideal (Fig. 9.12a), whereas collapsing into lumbar flexion increases stress on the spine (Fig. 9.12b). Some rowers may also have inadequate posterior rotation of the pelvis, leading to hyperextension of the lumbar spine in the finish position.

Rowing technique deteriorates during continuous rowing leading to increased lumbar flexion and frontal

(a)

(b)

**Figure 9.11** The catch position (a) Pelvis in relative anterior rotation with an even distribution of flexion throughout the spine (b) Pelvis in relative posterior rotation increases the stress on the lumbar spine

(a)

(b)

**Figure 9.12** The finish position (a) Lumbar spine in a neutral position (b) Lumbar spine collapsed into flexion

plane motion, which is attributed to fatigue.<sup>69-73</sup> However, this could be dependent on rowing ability and experience. Novice rowers use high levels of lumbar flexion with limited pelvic rotation, deteriorating further with higher work intensities.<sup>74</sup> While similar changes are seen in elite rowers, these are of a much lower magnitude.<sup>75</sup> A number of factors have been identified as a predictor of lumbar spine injury in rowers. As with most cases of low back pain, a previous episode increases risk.<sup>76</sup> This is important to note at pre-season screening and those considering entry to the sport. Another factor is time spent ergometer training. Studies have shown that lumbar kinematics may be different in ergometer rowing compared to the boat, specifically that the increased lumbar flexion associated with prolonged rowing and fatigue is of greater magnitude in ergometer rowing.<sup>72</sup> Therefore, rowers with lower back pain should reduce their exposure to the ergometer and pay close attention to their lumbopelvic control while

rowing, ideally using some form of biofeedback (mirror, video or electrogoniometer).

A majority of rowers with low back pain present with flexion-pattern motor control dysfunction.<sup>77</sup> As for other patient groups, a multi-dimensional cognitive functional approach (Chapter 28) has been shown to have the best efficacy in rowers.<sup>78, 79</sup> However, a number of specific considerations should be applied to the rowing population. An exercise approach, which focuses on optimal position of the trunk and pelvis throughout the stroke, should underpin rehabilitation. Excellent range of motion, particularly at the hips, knees and ankles, should be emphasised.

A mistake made by many rehabilitating low back pain in rowing is poor specificity in exercise prescription, particularly overemphasis of isometric exercise in the trunk such as the 'plank' exercise. Rowing is a dynamic sport and rehabilitation exercises aimed at improving trunk endurance should allow fluid movement. The ability to hold static positions affords limited benefits.

### Chest wall pain

Chest wall pain is particularly common in elite rowers,<sup>80</sup> but may occur in rowers of all levels. Most often it is caused by rib stress fractures (RSF), in particular in the anterolateral portion of the fourth to eighth ribs.

### Risk factors for rib stress fracture

The mechanism of this injury is not well understood, but it is likely to include mechanical loading of the chest wall as well as individual intrinsic factors such as gender and bone mineral density.<sup>81</sup> A combination of force vectors acting on the ribs from scapula retractors, external obliques and rectus abdominis may initiate a stress response leading to RSF. Training volume (particularly a sharp load increase) and equipment issues such as blade size and type have also been implicated.<sup>82</sup> Thoracic hypomobility, particularly extension, is common in those sustaining RSF.

The incidence is higher in females and may be hormonally driven or may be associated with upper body strength differences from male rowers. As with any stress fractures, low energy availability is implicated in RSF pathogenesis. This may be particularly relevant in lightweight rowers. Emerging research has noted increased risk of RSF in paralympic rowing athletes.<sup>83</sup> This may reflect low thoracic bone mineral density in spinal-cord-injured athletes because of a reduced skeletal loading.

### Clinical features

Rowers with RSF typically present with pain in the anterolateral chest wall that is initially aggravated by rowing. As the condition worsens, other activities become painful, point tenderness develops, and pain is aggravated by deep breathing, coughing, rolling over in bed and rising

from supine. Examination may reveal a positive rib spring and reproduction of pain during movements mimicking the rowing stroke,<sup>81</sup> particularly on isometric resistance. Diagnosis is primarily from symptoms and examination and may be confirmed with a bone scan or MRI.

### Management

Management is challenging and relative rest is the primary approach for 2–6 weeks. A symptom-dependent approach should be taken and the athlete should make a graduated return to training depending on pain. Many rowers report ongoing symptoms for many months (sometimes intermittently for longer) despite achieving good function. During rest, non-rowing exercise such as cycling can be maintained. Biomechanical factors such as poor thoracic extension or altered movement control should be corrected. Manual therapy of the thoracic spine can be very useful, although compression of the rib cage should be avoided. Taping for proprioceptive feedback may aid comfort. Liaison with the coach and video analysis can be very useful in identifying correctable faults such as 'over-reaching' or poor scapula control at the catch position.

The medical staff of the Great Britain rowing team have published clinical guidelines for the diagnosis and management of rib stress injuries in rowers.<sup>84, 85</sup>

### Wrist and forearm pain

Common wrist and forearm injuries in rowers include intersection syndrome (also known as 'oarsman's wrist'), de Quervain's tenosynovitis and exertional compartment syndrome (Chapters 25 and 26). All three conditions are related to excessive use of the forearm musculature, which is influenced by a variety of factors. Rowing requires the athlete to rotate the oar handle after taking it out of the water ('feathering the blade') and again prior to re-entering the water ('squaring the blade'). Ideally, the blade should be feathered and squared using a combination of wrist and metacarpophalangeal joint movement. However, a common technique fault, particularly among novice rowers, is to use wrist motion only during this action.

High grip pressure is also linked with forearm pain. This is a particular problem when rowing in poor weather conditions and among beginners, who tend to grip the oar more firmly. Oar handle size and grip should be considered. Modern oar handles have rubber grips and may be custom-fitted in different sizes; however, non-elite rowers are more likely to use older oars with wooden and 'one-size-fits-all' handles.

Sweep-oar rowers (i.e. those who row with only one oar), are more likely to suffer from intersection syndrome and de Quervain's tenosynovitis on their inside arm as that wrist is in a greater degree of ulnar deviation. Changing

sides of the boat may help alleviate symptoms and allow for greater participation during rehabilitation.

### Knee pain

Rowing-specific knee pain is rare. However, lateral knee pain may occur in rowers who steer coxless boats using a rotating shoe that is connected to a rudder wire. Tendinopathy of the distal biceps femoris tendon may also occur in rowers who actively use knee flexion to 'pull up the slide' rather than swing over from the hips with a stable trunk.

## SWIMMING

with ELSBETH VAN DORSEN

The clinical management of swimmers is a challenge. Swimmers begin their career earlier than many other athletes—typically between 8 and 12 years—and often train twice a day for a total of 3 to 6 hours. As elite swimmers perform a staggering 1.5 million strokes per arm every year, overuse injuries are common.

### Swimming biomechanics

Swimmers use both the upper limbs and the lower limbs, but in freestyle, backstroke and butterfly the arms generate approximately 80% of the propulsion. Swimmers try to generate propulsive force while reducing the resistance to forward motion. Drag forces (friction drag, form drag and wave drag) are extremely important at all swimming speeds; when you double the speed in water, you quadruple the form drag force. Achieving a hydrodynamically efficient swimming position (long and lean body position, aligned with the direction of travel), while still being able to generate propulsive forces, requires specific strengths, flexibilities and skills. Swimmers will try to increase the length of the propulsive phase (when the arm is in the water), combined with a fast but 'relaxed' recovery phase (above the water).

Swimmers compete in four strokes: freestyle, butterfly, backstroke and breaststroke. However, irrespective of a swimmer's preferred stroke, more than 50% of their training will be spent doing freestyle.<sup>86</sup>

### Freestyle technique

The freestyle stroke can be divided into four phases (Fig. 9.13):

1. hand entry
2. reach/glide
3. pull-through
4. recovery phase.

**Figure 9.13** Phases of freestyle swimming (a) Hand entry (b) Reach/glide (c) Pull-through (d) Recovery

### Shoulder pain

The shoulder region accounts for 31–39% of all swimming injuries.<sup>87, 88</sup> The prevalence of shoulder pain in elite swimmers has been found to be as high as 91%,<sup>86</sup> with 10–31% forced to stop training for some time during the year due to shoulder pain.<sup>87–91</sup>

There is a higher risk for shoulder injuries:

- after an abrupt increase of training volume or intensity<sup>92</sup>
- with training volume >35 km (or 15 h) per week<sup>86</sup>
- when a unilateral breathing pattern is used<sup>93</sup>
- after recent change of stroke technique; ask about any technical flaws that have been pointed out by the coach<sup>94</sup>
- when crossing the midline with the hand during pull-through (Fig. 9.13)
- with a history of shoulder injuries<sup>90</sup>
- with a recent change in coach (and therefore likely changed training loads)

### Shoulder pain in swimmers—diagnostic labels

The term 'swimmer's shoulder' was introduced by Kennedy and Hawkins.<sup>96</sup> This is, however, a nondescript and confusing catch-all which does not advance our understanding. We believe the term should be replaced by an individualised and more specific diagnosis, which accounts for the contributing factors (extrinsic and intrinsic) and suspected pathology of each injured swimmer.

Instead we propose **Supraspinatus tendinopathy** with:

- *hypomobility of the cervicothoracic junction*
- *loss of internal rotation of the glenohumeral joint*
- *greater internal rotation strength due to sudden increase of intensity of training and possible overload in the use of hand paddles and drag suits.*

This will promote a patient-specific, problem-oriented approach to treatment.

- after increased use of hand paddles<sup>89, 95</sup>
- with the use of drag-increasing training devices (bags, elastic cords, drag suits, etc.).

Rotator cuff tendinopathy is the most common shoulder pathology seen in swimmers.<sup>86</sup> Tendinopathy of the long head of the biceps and impingement against the anterior third of the coracoacromial arch are also frequent diagnoses. However, a clear pathoanatomical diagnosis is often difficult to achieve; it is more important to diagnose and understand the underlying functional or pathomechanical reasons for the 'structural failure' and address these in the management plan.

A thorough clinical examination of the entire kinetic chain is important to assess the intrinsic contributing factors. Swimmers must be capable of extreme ranges of motion, especially in the shoulder girdle,<sup>93</sup> and they must be able to reach these positions easily. Mechanical cost to achieve this position will result in (i) unnecessary extra movements and drag, and (ii) suboptimal use and possible overload of musculoskeletal structures. Modelling studies suggest that, on average, the supraspinatus tendon is already in a position of potential mechanical impingement for nearly 25% of the freestyle arm stroke cycle.<sup>93</sup>

If swimmers are not flexible enough in the glenohumeral joint, they tend to pass this motion requirement to the scapulothoracic joint or the spine. On the other hand, hypermobility can also increase the potential for injury due to excessive translation of the humeral head. There might be a range of 'optimal motion' in swimmers. One study found that those with more than 100° or less than

93° of external rotation had a greater risk of shoulder impingement symptoms.<sup>90</sup> Internal rotation is the most important, as it allows the swimmer to have an early catch and high elbow. A measure between 40–50° seems to be necessary for freestyle, backstroke and butterfly. Breaststroke swimmers can have a little less.

Testing abduction with internal rotation gives important information about the swimmer's ability to achieve and maintain a high elbow. The swimmer sits on a bench, both arms are passively abducted, with the elbows maintained in 90° flexion (Fig. 9.14). The forearm must be perpendicular to the plane of abduction (causing internal rotation). The angle measured is the line of the humerus to the straight spine. An appropriate range for this measure is between 150° and 170°.<sup>97</sup>

The combined elevation test can give more information about the ability to achieve a high elbow position at the start of the stroke, recovery and streamline. The athlete lies in a prone position with both arms (with locked thumbs together and extended elbows) elevated above the head. The swimmer then elevates the arms as high as

**Figure 9.14** The abduction with internal rotation test.<sup>97</sup>

The elbows should be kept in 90° flexion, and the upper arms should be prevented from moving forward as the shoulders are elevated. Swimmers should aim for 150–170° of abduction.

possible while keeping the head, chest and legs in contact with the bench (Fig. 9.15). An angle between the line of the humerus and the horizontal axis of between 5° and 15° is appropriate.<sup>97</sup>

To maintain a streamlined position, core stability is important. Swimmers need to transfer load efficiently between the arms and the legs under internally generated flexion torques.

### Management of shoulder pain in swimmers

Individualised rehabilitation programs emphasising range of motion, flexibility, muscle balance, and motor control of the glenohumeral and scapulothoracic joints are the key features in the management of shoulder pain in swimmers (Chapter 24).<sup>98</sup> Modification of training load is often necessary.

Most commonly, the entire kinetic chain is involved, with multiple intrinsic and extrinsic contributing factors such as:

- reduced rotation and/or extension of the thoracic spine—important in relation to body roll
- tightness or improper motor control around the scapula
- muscular imbalance around the shoulder, in particular, internal and external rotators
- incorrect swimming technique (Table 9.2)
- too much training with hand paddles or drag-increasing devices
- improper land training, weight training or stretching
- suboptimal core strength and/or control.

A team approach: technical stroke analysis and adjustment with the coach, physiotherapist, doctor and sports scientists, keeping the clinical findings in mind.

**Figure 9.15** The combined elevation test—a test for thoracic extension, shoulder elevation and scapular retraction.<sup>97</sup> The swimmer lies in a prone position and is asked to lock their thumbs together, extend their elbows and elevate the arms as high as they can while keeping their head, chest and legs in contact with the bench. The humerus angle is measured relative to horizontal

**Table 9.2** Technique factors related to shoulder pain in freestyle swimming

Presentation	Possible cause	Solution
Shoulder pain at hand entry	Thumb-first hand entry—excessive internal rotation in full elevation	<ul style="list-style-type: none"> <li>• Palm-down hand entry</li> <li>• Ensure adequate abduction/internal rotation range of motion</li> </ul>
	Crossing the midline with the hand at hand entry	<ul style="list-style-type: none"> <li>• Avoid crossing the midline</li> </ul>
	Lateral deviation of the trunk	<ul style="list-style-type: none"> <li>• Improve mobility in the kinetic chain, improve core stability</li> </ul>
	Insufficient upward rotation of the scapula	<ul style="list-style-type: none"> <li>• Address scapulohumeral muscle flexibility</li> <li>• Train scapular upward rotation in overhead exercises</li> </ul>
Shoulder pain during pull-through	Dropped elbow—elbow-first water entry or elbow below the level of shoulder and wrist during early pull-through	<ul style="list-style-type: none"> <li>• Improve internal rotation ROM—sleeper's, stretch and cross-body stretch—check kinetic chain</li> </ul>
	Crossing the midline with the hand during pull-through	<ul style="list-style-type: none"> <li>• Avoid crossing the midline</li> </ul>
	Insufficient or excessive body roll	<ul style="list-style-type: none"> <li>• Body roll should be approximately 45°; this can be limited by thoracic rotation and core stability</li> </ul>
Shoulder pain during recovery	Excessive horizontal abduction due to insufficient body roll—posterior cuff impingement	<ul style="list-style-type: none"> <li>• Increase body roll</li> <li>• Optimise mobility of cervicothoracic spine</li> </ul>
	Unilateral breathing pattern (pain on same side)	<ul style="list-style-type: none"> <li>• Strive for a bilateral breathing pattern</li> </ul>

Swimmers with shoulder complaints should avoid the following drills:

- long leg drills with a kick board, as arms are maintained in maximum shoulder flexion; this can aggravate impingement symptoms
- hand paddles, as these increase the load on the shoulder during the pull-through
- pull buoy; the legs are held together without kicking, so 100% of the propulsion is generated by the arms.

### Medial knee pain

Medial knee pain is common in breaststroke swimmers.<sup>99</sup> In one study, 75% of the surveyed breaststroke swimmers reported at least three episodes of knee pain per season and 47% of these swimmers reported weekly episodes of knee pain.<sup>100</sup>

Although the term 'breastroker's knee' is nonspecific, it usually refers to overuse injury of the medial collateral ligament. However, the medial patellofemoral joint, pes anserine tendon, or bursa and adductor muscles may also be involved.<sup>101</sup>

The medial knee is highly loaded at the beginning of the breaststroke thrust phase, where the knee is flexed and externally rotated and the hips are flexed and internally rotated. The knee undergoes valgus loading throughout the leg thrust. A number of intrinsic factors and technique flaws can increase the valgus load and contribute to medial knee pain:

- valgus alignment of the lower limb
- inadequate or asymmetrical hip internal rotation or tibial external rotation
- large abduction angle of the hips during the kick (>30°)
- ineffective arm-leg coordination may increase loads on the lower limb
- sudden increase in amount or intensity of training
- hip extension and ability to achieve core and pelvic stability.

Clinical assessment of the lower back, hips, knees, and ankles is important, particularly the range of hip internal rotation and tibial external rotation. These two measures should add up to approximately 90°, so that at the beginning of the thrust phase the feet are square to the line of progression. This results in the biggest area to use to propel in the kick with the knees closer together, thus reducing form drag.<sup>97</sup>

As for shoulder injuries, the clinician should focus on both intrinsic and extrinsic factors during the rehabilitation process. Breaststroke training should be reduced, and exercises which place a valgus load on the knee should be avoided during land and weight training. Hip rotation range of motion should be optimised and the load capacity of the

knee should be increased through progressive lower limb strengthening.

## TENNIS

with BABETTE PLUIM

In a typical hour of tennis, players hit the ball between 150 and 250 times and run between 2.5 and 3.5 km in high-intensity 3-metre bursts. Due to the game's explosive, intermittent and repetitive nature, both acute and overuse injuries are common. Groups particularly at risk include elite players, who often train up to 5–6 hours per day, deconditioned players who suddenly increase their training loads and young players who play more than four matches per week.<sup>102</sup>

The main biomechanics-related tennis injuries are lateral elbow pain ('tennis elbow') and overuse shoulder injuries. These represent approximately 15–25% of all tennis injuries.<sup>103</sup>

### Lateral elbow pain

Lateral elbow tendinopathy is colloquially referred to as 'tennis elbow' as it has been estimated to affect up to 50% of active tennis players at some point throughout their career.<sup>104, 105</sup> The prevalence among tennis players seems to be declining, which may be related to increasing use of the two-handed backhand across all levels of tennis. The condition is caused by a tendinopathy of the common extensor tendon, in particular the extensor carpi radialis brevis, at the insertion on the lateral humeral epicondyle. Here, forces are greatest during one-handed backhand shots, as the wrist extensors contract eccentrically on impact with the ball.

Lateral elbow pain is much more common in beginners and players over 40 years of age,<sup>106</sup> and is usually attributed to a combination of overuse and poor stroke biomechanics. Skilled players hit the ball with an extended wrist and extend the hand through impact (Fig. 9.16a), whereas novice players often hit the backhand with a flexed wrist, resulting in an eccentric contraction and less strength at impact (Fig. 9.16b).<sup>107, 108</sup> However, the relationship between this technique flaw and elbow injury remains unclear,<sup>109</sup> and other potential factors include hitting the ball off-centre and squeezing the grip too tightly during follow-through.<sup>110</sup> The topspin backhand usually provokes more complaints than the slice backhand.<sup>111</sup>

#### PRACTICE PEARL

Tennis elbow is very rare in players with a two-handed backhand.

**Figure 9.16** One-handed backhand technique (a) An extended wrist at impact reduces stress at the lateral epicondyle (b) A flexed wrist at impact increases stress at the lateral epicondyle

Tennis racquet grip size is traditionally considered to be a risk factor for lateral elbow pain, as grip sizes that are too small or too large may lead to extra strain on the forearm muscles. It is therefore important to optimise the racquet grip size to the player.<sup>112</sup> Other common recommendations to reduce load on the forearm muscles include using a larger racquet head, a flexible racquet, lower string tension (with high quality strings) and pressurised tennis balls. Playing with heavy, wet tennis balls, long hours of play, or a sudden increase in volume or intensity of play may lead to sudden overuse and the development of lateral elbow problems.

The general management principles for lateral elbow tendinopathy are detailed in Chapter 25. However, tennis-specific management should include developing muscular strength to better cope with the racquet-ball impact, and an analysis of backhand technique, with effort focused on using the right grip and achieving concentric wrist extension at the point of impact. Slow-motion video analysis may be a useful biofeedback tool to help players change technique. Low compression balls should also be considered during the early phase of treatment.

### Shoulder injuries

The shoulder is subjected to high loads in tennis, particularly during the serve where the shoulder is abducted to 140–160° and rotates 160–180° at a rate of up to 2400°

per second.<sup>113</sup> As a player serves approximately 100 times in an average match,<sup>114</sup> overuse shoulder injuries are common. Both the causes and the pathology of shoulder injuries in tennis are similar to other overhead and throwing sports (Chapter 8); common diagnoses include internal impingement, rotator cuff and biceps tendinopathy and glenoid labrum injuries.<sup>115, 116</sup>

During the cocking phase of the serve, the supraspinatus, infraspinatus and serratus anterior all contract concentrically to stabilise the scapula and glenohumeral joint. This is followed by a rapid eccentric contraction of the rotator cuff and serratus anterior to decelerate the arm during the follow-through. These repetitive concentric and eccentric demands, which occur during both serving and groundstrokes, may lead to muscular fatigue and so-called 'eccentric failure' of the tendons. Adding further stress, the supraspinatus and infraspinatus tendons can become compressed between the humeral head and the posterosuperior rim of the glenoid during the cocking phase of the serve, when the glenohumeral joint is in maximal external rotation and horizontal abduction. This is often referred to as *internal impingement*.

Local factors that contribute to internal impingement include muscular imbalances (external rotator weakness or dysfunction compared to the internal rotators), weakness or dysfunction of the scapular stabilisers (scapular dyskinesis) and tightness of the posterior capsule resulting in reduced internal rotation range of motion (GIRD). These factors should all be considered when treating shoulder injuries in tennis (Chapter 24).

Remote factors also play an important role in the development of shoulder injuries in tennis. To generate power during the serve, there should be coordinated activation of a number of body segments (legs, hips, trunk, shoulder, arm and hand)—the so-called 'kinetic chain'—to achieve a high racquet speed at impact.<sup>117</sup> Suboptimal kinetic chain mechanics may overload the upper limb as it tries to make up for lost energy production.<sup>118</sup> This is referred to as the 'catch-up phenomenon'.<sup>116</sup>

Common clues that point to poor kinetic chain mechanics during serving (Fig. 9.17) include:<sup>119</sup>

- insufficient knee bend—the front knee should flex more than 15° during the loading phase
- inadequate rotation—the player should be coiled enough that they show their back to the opponent
- inadequate shoulder and pelvis tilt during the loading phase.

**Figure 9.17** Tennis serve technique—loading phase. Look for a deep knee bend, rotated trunk, and tilted shoulders and pelvis

# Training programming and prescription

with DARREN BURGESS

*In football as in watchmaking, talent and elegance mean nothing without rigour and precision.*

Lionel Messi

The sports medicine clinician should understand the different elements of training and their possible relationship to injury. This facilitates the practitioner's obtaining a full training history from an injured athlete, learning about training strategy from a coach or fitness practitioner and enhances a clinician's understanding of the phases of rehabilitation outlined in Chapter 18. This chapter reviews the principles of training and outlines some more common training programming and assessment practices. The reader is directed to other sources for more detailed outlines of the various types of training.

## PRINCIPLES OF TRAINING

'Training' is the pursuit of activity that will ultimately lead to an improved performance in a given sport. A number of general principles of training apply to all sports:

- periodisation
- overload
- specificity
- individuality.

## Periodisation

Periodisation is an important component of all training programs, in both the long and short term. Training can be divided into three distinct phases: conditioning (preparation), pre-competition (transitional) and competition.

Generally, the conditioning phase emphasises developing aerobic and anaerobic fitness, strength and power. Often during this period, the athlete is training under fatigue and if required to compete would probably perform poorly. During the pre-competition phase of training, the emphasis switches from pure conditioning to more technical work. During the competition phase, the emphasis is on competitive performance while maintaining basic conditioning (Table 10.1).

In many sports (e.g. football, basketball, hockey), a 4-6-month competition season is usual. In some instances, an athlete is required to undertake two periods of competition in the one year. A suggested program for athletes in these two situations is outlined in Figure 10.1. In other instances, the competition period may last as long as 8-10 months and conditioning work can extend into the competitive season. However, in all of these scenarios the same principles of training periodisation apply.

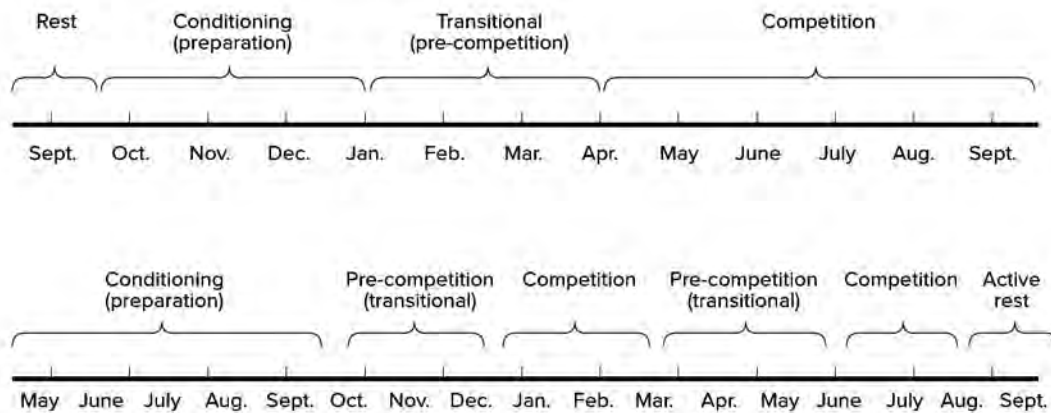

To ensure complete recovery from the physical and mental stress of competition, adequate time should be allowed between the end of one season or competition phase and the start of the next season or phase. This period may last 4-6 weeks but is dependent on when the next competition begins.

In the intermediate time frame, it is important to introduce easy weeks into the training program; these give the athlete time to recover (Chapter 13) and diminish

**Table 10.1** Different types of training are performed during the three phases of the yearly cycle

Training phase	Aerobic training	Anaerobic training	Plyometrics training	Weight training	Technique training
Preparation/conditioning	+++	++	++	+++	+
Transitional/pre-competition	++	+++	++	++	+++
Competition	+	+	—	+	++

**Figure 10.1** Periodisation of training showing a single cycle annual program (above) and a dual cycle annual program (below)

risk of injury. During these easy weeks, the volume of training is typically reduced; however, intensity should be maintained to prevent detraining.<sup>1</sup>

In the short term, the training program must allow for adequate recovery between training sessions. This ensures the athlete is able to train at appropriate intensities throughout the week and reduces the risk of injury.<sup>1</sup>

### Overload

Overload is a variable that coaches manipulate to allow the athlete to perform work at a greater intensity or to perform a greater volume of work at a given intensity. Practically speaking, overloading an athlete involves applying stress to the body over and above that which is normally, or has been recently, encountered. If increased stress is not excessive and adequate adaptation time is allowed, the work capacity of the athlete will be increased ('supercompensation'). Athletes should be carefully monitored during periods of overload to prevent injury, overtraining and even poor performance from occurring.

### Specificity

Specificity refers to the principle of directing training to performance in the athlete's given sport. It is important, therefore, to identify the most important components of fitness for each particular sport and to tailor the athlete's

training toward improving these particular components. For example, there is no advantage for a strictly power athlete in doing large amounts of endurance training.

Specificity can refer to both training the specific fitness demands of a sport as well as training the direct movement patterns of the sport to improve the fitness of the athlete. Those choosing the latter method argue that specific training in this way has the advantage of training skills and decision making while improving fitness.<sup>2</sup> Most field sports (e.g. football) require a complex combination of both strength and endurance training and therefore specificity should include a combination of specific fitness training as well as training the specific movements of a sport.

### Individualisation

As individual differences between athletes are great, training must be tailored to the individual's needs. Individuals differ in their tolerance of particular training loads, response to specific training stimuli, speed of recovery, psychological make-up, nutritional intake and lifestyle habits. Individual responses to training are influenced by previous training history, age, current state of fitness, genetic make-up and so on. Even in a team setting, it is vital that players are treated as individuals and trained accordingly.

## The Central Governor Model (CGM) for the limits of performance and its relevance to interval training

The concept of maximum oxygen consumption ( $\text{VO}_{2\text{max}}$ ) and lactic acidosis limiting athletic performance has undergone much critical evaluation. The 'classical' model of Hill,<sup>3</sup> which still enjoys support among a substantial number of exercise physiologists, suggests that:

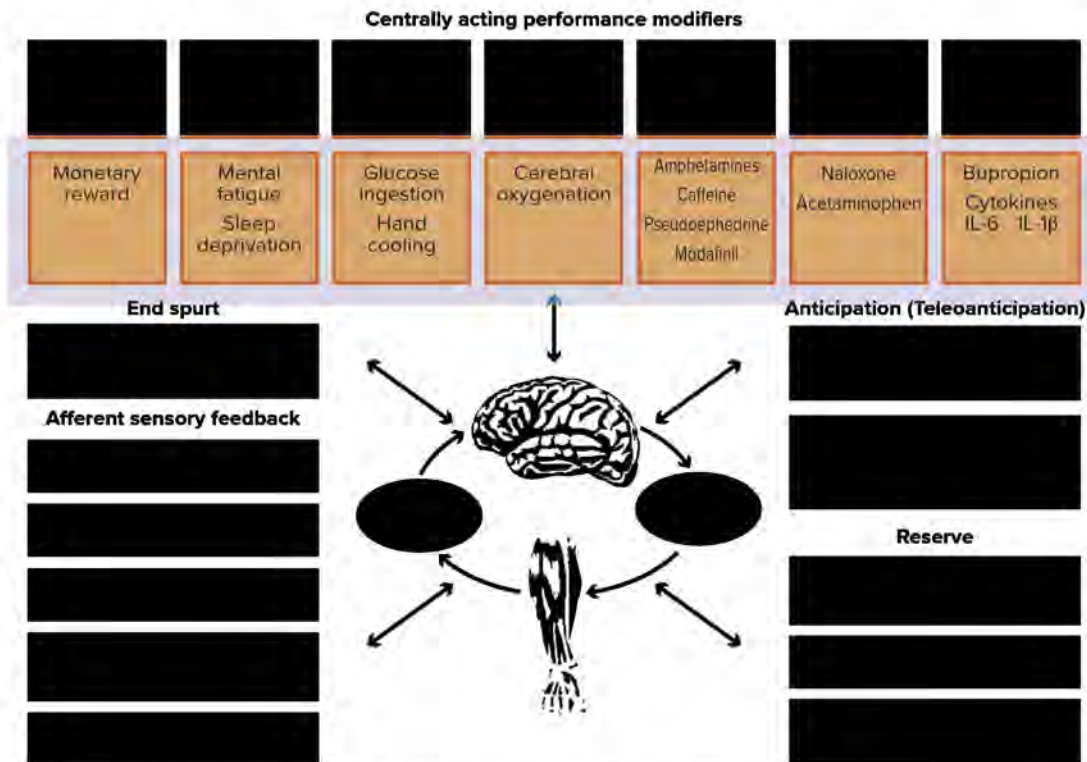

- Progressive muscle hypoxia limits maximal exercise performance. As a result, the main determinant of exercise performance is the heart's ability to supply sufficient blood (and oxygen) to the exercising muscles.

- Anaerobiosis (lack of muscle oxygen) secondary to the inability further to increase the cardiac output (producing a 'plateau' in cardiac output) explains the onset of lactate production by skeletal muscle at the 'anaerobic threshold'.
- Mitochondrial adaptation in the exercising muscles, associated with an increased ability of the heart to pump a larger cardiac output, are the exclusive biological changes that explain changes in performance with endurance training.

This model has been challenged by the contemporary, but certainly not universally accepted, model of Professor Timothy Noakes. Noakes' data refute the classical model. Instead, he proposes that skeletal muscle recruitment and contractile function are regulated by a hierarchy of controls (conceptually 'the central governor') specifically to prevent damage to any number of different organs.<sup>4-14</sup> He, and subsequently others, argues that according to the Hill model in which a plateau in cardiac output precedes the development of skeletal muscle anaerobiosis and lactic acidosis, the first organ to be threatened by the plateau in cardiac output would be the heart, not skeletal muscle. The plateau in cardiac output would prevent any further increase in blood flow to the heart, leading

to myocardial ischaemia, the onset of chest pain (angina pectoris) and heart failure.

He also provides evidence that this was, in fact, the belief of the early exercise physiologists, including Hill in England and Dill at the Harvard Fatigue Laboratory in the United States and was a central component of their teachings. Since Hill understood that the heart could not survive a prolonged period of ischaemia, he conceived the presence of a 'governor' in either the heart or the brain that would reduce heart function and spare the heart by causing a 'slowing of the circulation' as soon as myocardial ischaemia developed. Noakes and colleagues have extended this interpretation to suggest that the governor exists in the central nervous system, hence it is called the central governor and that it responds to multiple sensory inputs from all the organs in the body (Fig. 10.2). In response to those inputs, the central governor regulates the number of motor units that can be recruited in the exercising limbs on a moment-to-moment basis, reducing or limiting the number that can be recruited when their continued recruitment, necessary to maintain the work output or exercise intensity, threatens whole-body homeostasis.

**Figure 10.2** The central governor responds to multiple sensory inputs from all organs of the body

*continued*

Hence, Noakes writes that 'during maximal exercise, progressive myocardial ischaemia preceding skeletal muscle anaerobiosis must be thwarted, so that neither the heart nor the skeletal muscle develop irreversible rigour and necrosis with fatal consequences'. The reader is directed to the publications that summarise this argument to date,<sup>4, 7-14</sup>

#### Relevance to interval training

Irrespective of the theoretical background that underpins the physiology, the most efficient method of increasing anaerobic fitness is a form of intermittent exercise or interval training. Interval training involves a number of bouts of exercise separated by periods of rest or recovery.

The principle of such training is to achieve a level of lactic acidosis with one individual effort and then allow the body to recover from its effects before embarking on another bout of

exercise. There is scope for enormous variation in the intensity and duration of the exercise bouts and the duration of the recovery period. Anaerobic training will also reset the central governor mechanism, perhaps teaching the governor that it can allow a slightly higher exercise intensity without risking a catastrophic bodily failure. In addition, interval training will also increase the ability of the skeletal muscle fibres to produce more force. There is some evidence suggesting that differences in skeletal muscle contractility may modify athletic performance by determining the shortest possible duration the foot is in contact with the ground. This is because faster running requires shorter foot contact times and hence greater skeletal muscle contractility and the recruitment of a greater number of muscle fibres.<sup>15</sup> In contrast, skeletal muscle contractility may be impaired in certain disease states.<sup>16</sup>

## CONDITIONING TRAINING

The maintenance of fitness is not only crucial to sporting success and injury prevention it is also an essential component of the rehabilitation process. Regardless of the injury the athlete has sustained, exercises to maintain fitness should be incorporated as soon as possible. For example, with injuries to the lower limb, cardiovascular fitness may be maintained by performing activities such as swimming with a pool buoy or arm 'grinder' work. Depending on the athlete's particular sport, this may include a combination of endurance, interval, anaerobic and power work. It is important to maintain alternative training methods for cardiovascular fitness, to encourage motivation and compliance with general fitness goals.

We have divided conditioning into five separate types of training—endurance, speed, agility, resistance and flexibility—and will discuss each of these separately. In practice these methods are often combined for a more global conditioning effect.

### Endurance training

Technically, endurance training aims to increase oxygen delivery to the working muscles and thereby increase aerobic capacity. Adaptations to endurance training include an increase in maximal oxygen uptake ( $\text{VO}_2\text{max}$ ) and an increased ability of skeletal muscle to generate energy via oxidative metabolism.<sup>17, 18</sup> (For a more detailed discussion of the debate on  $\text{VO}_2\text{max}$  and the role of lactic acidosis in limiting training, see box below).

The long-term consequences of prolonged endurance training have been debated in recent years, with proposed cardiovascular risks associated with cardiac fatigue.<sup>19, 20</sup> However, a study of young Olympic athletes subjected to extreme uninterrupted endurance training over prolonged periods (up to 17 years) found that endurance training was

not associated with significant changes in left ventricular morphology, deterioration in left ventricular function, or occurrence of cardiovascular symptoms or events.<sup>21</sup> Endurance sports include long-distance running (greater than 5 km), cross-country skiing, cycling, rowing and triathlon.

It is important here to be aware of the many benefits an increased aerobic capacity can have to a range of different sports. An enhanced aerobic capacity will not only improve the efficiency of oxygen delivery but will also improve the regeneration of anaerobic energy pathways. This means performance in intermittent sports such as ice hockey, soccer, American football and netball, all traditionally thought of as strictly anaerobic sports, will be improved with an enhanced aerobic capacity. This is important to remember when prescribing or reviewing rehabilitation programs for these sports.

### Endurance training methods

There are numerous methods to train endurance capacity. This section focuses on the more popular techniques.

#### Interval training

Interval training involves numerous bouts of high intensity efforts of set times or distances. Both effort duration and recovery time in between efforts dictate the intensity of each bout. An endurance interval session might be 6 sets of 1 minute running efforts. For a high-intensity session, 2 minutes recovery could be prescribed in between efforts. To challenge the aerobic capacity to recover more quickly, 1 minute recovery between sets could be prescribed. These repeat-effort intervals have been shown to dramatically increase  $\text{VO}_2\text{max}$ .<sup>22</sup>

#### Fartlek training

'Fartlek', which means 'speed play' in Swedish, is a popular form of endurance training that involves high-intensity efforts

interspersed between constant paced exercise. A typical fartlek session on a bike might involve 30 seconds of high-intensity cycling every 2.5 minutes for 30 minutes. This example would provide the cyclist with 10 high-intensity efforts during a 30-minute ride. In some sports, athletes may be unaware of the duration and intensity of efforts and have to respond to the coach's feedback during the session.

### Maximal aerobic speed (MAS) training

MAS training involves calculating an athlete's maximal aerobic speed and then prescribing a certain percentage of this within an interval training session.<sup>23</sup> Typically, the speed an athlete can complete a 2 km (or similar distance) time trial is used as that athlete's MAS. Precise distances and expected times can then be calculated for each athlete. The most common time periods for MAS are 15 seconds of work followed by 15 seconds of exercise (15:15).

### Cross-training

To prevent injury, it may be beneficial to reduce the amount of weight-bearing exercise. Cross-training enables the athlete to maintain aerobic fitness while reducing stress on weight-bearing joints, muscles and tendons. In athletes with a chronic condition such as articular cartilage damage to a weight-bearing joint, cross-training may be used to reduce the impact load while maintaining adequate training volume. Similarly, in a patient returning to sport from an overuse injury (such as a stress fracture), cross-training can reduce the risk of recurrence. Runners may wish to introduce one to two sessions per week of activities such as cycling, swimming or water running. These alternative work-outs can mirror the athlete's usual training session (e.g. interval, fartlek).

### Skill training as endurance

It is important to realise that a skill drill or indeed entire skill session can enhance endurance capacity. In particular, there are numerous ways to alter skill drills to emphasise endurance, while maintaining the important aspects of the skill (e.g. decision making, team combinations, specific skill execution). For example, a simple soccer game could be altered in any of the following ways to increase the aerobic requirements of the exercise:

- Increase the size of the field.
- Decrease the playing numbers.
- For a goal to be scored all players must be over the half-way line.
- Every 1 minute the coach blows a whistle and one player from each team must run to a specified marker outside of the field.

## Speed training

Running speed, which is an important component of many sports, is a largely inherited ability. However, athletes can

improve their speed by enhancing muscular power and strength, as well as by improving technique, which increases the efficiency of ground coverage. Therefore, running speed can be increased by undertaking resistance and power training as well as by performing technical running drills.

### Speed training methods

There is much debate about how much speed can be developed or improved in the mature athlete. Speed can arguably be enhanced, or at the very least maintained, with an appropriate strength and power program—this will be discussed later in this chapter. However, debate remains about the extent to which speed can be improved through either technical modification or repeated exposure to a speed stimulus. Both of these will be discussed briefly below.

### Technique training

Improving the technical aspect of speed requires significant time spent analysing athlete running mechanics and then performing extensive corrective exercises as required. Within most sports, time spent dedicated specifically to technical speed work might often be at the expense of other conditioning, strength training or even skill training. As a result, most speed technique work is often confined to small amounts of time with large groups of players and/or warm-up activities pre-training/strength sessions. This requires a fairly broad approach where emphasis is placed on high knee drive, exaggerated heel lift and horizontal foot position throughout the sprint motion. An ideal opportunity exists to improve speed technique during the rehabilitation process where a more individualised approach can be taken. Of course, in sports such as running and long jump, a large percentage of training time should be devoted to technical speed drills.

### Speed intervals

Appropriate exposure to speed will not only maintain speed qualities but may also prevent soft tissue injury,<sup>24</sup> particularly in the hamstrings. These 'unpractised' movements that occur in games often cause muscle injury.

#### PRACTICE PEARL

Regular speed interval work, particularly during weekly competition cycles will ensure the muscles and tendons are not 'shocked' into unfamiliar explosive movements that may occur during games.

Practitioners should remember that absolute speed intervals should be performed while the athlete is fresh; however, speed exposure in training should also occur under fatigue to prepare the body to what it may encounter during competition.

### Skill training as speed

In most sports, speed training can and should be integrated into skill training. This can be easily achieved by using execution of simple skills at the end of sprinting activities. Care should be taken in programming these drills as they can be quite physically and structurally demanding.

### Agility training

Agility can be defined as the ability to alter direction to achieve a specific goal (e.g. evade/deceive/react to an opponent, create space). Agility and rapid reflexes are often inherited characteristics. However, like speed, they can be improved somewhat by training and, thus, are included in training programs of all sports. Agility training has also been implemented in seniors to prevent falls.<sup>25</sup>

### Agility training methods

Agility is often incorrectly trained using stationary objects (e.g. cones, poles, ladders). This may allow the coach to teach the athlete the correct foot placement or stride mechanics; however, agility training requires a reaction and therefore a decision-making component.<sup>26</sup>

### Technique training

Training agility technique may be appropriate in the initial stages of rehabilitation or perhaps within adolescent programs. The coach can spend some time on effective techniques to approach a known object. However, this type of training should be limited as it often leads to inappropriate habits such as a player keeping their head down to review foot placement.

### Agility drills

A reaction component should always be included in agility drills. This can be reacting to a coach movement, coach command, opponent or teammate. Advanced agility drills should also include a decision-making element.

### Skill training as agility

Most sports skill training could be counted as agility training. This is because the majority of field sports training involves reacting to opponents, the ball or teammates. This means any additional agility-specific training should be programmed carefully as repeated changes of direction could cause some overload issues to the pelvic region.

### Resistance training

Resistance training can be used to enhance athletic performance, improve musculoskeletal health and correct muscle imbalances.<sup>27</sup> Resistance training is often used in rehabilitation when weakness compromises function and sports performance. This is particularly true

following periods of immobilisation or injury and in pain presentations.

The primary goals of resistance training are normally to increase muscle size (hypertrophy), strength or power. Increases in muscle hypertrophy and strength are dependent on five biochemical and physiological factors that are all stimulated and enhanced by appropriate resistance training:

- increased glycogen and protein storage in muscle
- increased vascularisation
- biochemical changes affecting the enzymes of energy metabolism
- increased number of myofibrils
- recruitment of neighbouring motor units.

It is important that the athlete is provided with the correct environment in which to perform resistance training. The following factors will help maximise gains during resistance training:

- adequate warm-up to increase body temperature and metabolic efficiency
- good quality, controlled performance of the exercise
- pain-free performance of exercise
- use of slow, controlled exercise initially, with little or no resistance, to develop a good base for neural patterning to occur
- comprehensive stretching program to restore/maintain full range of motion
- muscle strengthening throughout the entire available range of motion.

Additionally, there is a training crossover effect—when one limb is trained, strength gains will also be recorded in the contralateral limb.<sup>27, 28</sup> This phenomenon is termed 'central adaptation' and reflects the important role the central nervous system plays in motor unit firing, as well as the bracing role the contralateral limb plays in most single-limb exercises.

### Types of resistance exercises

The three main types of exercise used in resistance training are:

- isometric
- isotonic
- isokinetic.

#### Isometric exercise

An isometric exercise occurs when a muscle contracts without associated movement of the joint on which the muscle acts. Isometric exercises are often the first form of strengthening exercise used after injury, especially if the region is excessively painful or if the area is immobilised. These exercises are commenced as soon as the athlete can perform them without pain.

**Figure 10.3** Isometric co-contraction of the hamstrings, gluteal and quadriceps muscles with the patient pushing foot into wall

Isometric exercises are used when a muscle is too weak to perform range of motion exercises, in conditions where other forms of exercise are not possible (such as patellar dislocation and shoulder dislocation) or when isometric contraction is required in activities (e.g. stabilising). Isometric exercises can minimise muscle atrophy associated with immobilisation and injury by maintaining or improving static strength, minimising swelling via the muscle pump action, and enhancing neural and proprioceptive inputs to the muscle.

Ideally, isometric exercises are initially held for 5 seconds with contraction time increasing as the athlete becomes more tolerant. They can be performed frequently during the day as pain permits. The number of sets will vary at different stages of the rehabilitation program. If an athlete has difficulty, exercises may be performed against resistance or against an immovable object. It is important to remember that the quality of exercise is more important than the quantity.

Isometric exercises should be carried out at multiple angles if possible, as strength gain can be specific to the angle of exercise. The athlete should progress from submaximal to maximal isometric exercise slowly within the limitations of pain and function.

Isometric exercises have demonstrated success in the rehabilitation of tendon injuries (see Chapter 4) and should form a large component of any musculotendinous rehabilitation program.<sup>29</sup>

When significant isometric effort is tolerated at multiple joint angles, dynamic exercises may begin. An example of an isometric exercise for the lower limb is shown in Figure 10.3.

#### Isotonic exercise

Isotonic exercises are performed when the joint moves through a range of motion against a constant resistance

or weight. Isotonic exercises may be performed with free weights, such as dumbbells, pulleys or sandbags (Fig. 10.4).

Free weights encourage natural movement patterns and require muscle coordination and joint stability in all planes of movement and therefore may transfer strength gains more readily to the playing field.<sup>30</sup> With free weights it is possible to simulate athletic activities as the body position can be varied. Isotonic exercises may be:

- concentric—a shortening isotonic contraction in which the origin and insertion of the muscles approximate. Individual muscle fibres shorten during concentric contraction

(a)

(b)

**Figure 10.4** Isotonic exercises (a) Dumbbell (b) Sandbag

**Figure 10.5** Concentric (white arrow) and eccentric (black arrow) quadriceps exercises

- eccentric—a lengthening isotonic contraction where the origin and insertion of the muscles separate. The individual muscle fibres lengthen during eccentric contraction.

Concentric and eccentric exercises for the quadriceps are shown in Figure 10.5.

The intramuscular force produced per motor unit during an eccentric contraction is larger than that during a concentric contraction.<sup>28</sup> Eccentric contractions may generate high tension within the series elastic component, which consists of connective tissue and the actin-myosin cross-bridges in muscles. It has been observed that eccentric exercise results in higher rates of delayed onset muscle soreness (DOMS) and even muscle damage if used inappropriately.<sup>31, 32</sup> Consequently, eccentric programs should commence at very low levels and progress gradually to higher intensity and volume. The use of eccentric exercise programs may help prevent recurrence of musculotendinous injuries.

Eccentric training has been advocated in the rehabilitation of tendon injuries, due to the proposed facilitation of tendon remodelling through promotion of collagen fibres within the injured tendon.<sup>32-34</sup> There is evidence that Achilles, patellar and lateral elbow tendinopathies respond well to an eccentric rehabilitation program.<sup>31, 32, 34, 35</sup>

However, not all tendon injuries benefit from eccentric exercises. Specifically, eccentric exercises have shown poor success rates for rotator cuff tendinopathy<sup>36</sup> and for insertional Achilles tendinopathy, compared to mid-tendon Achilles lesions.<sup>32</sup> Therefore, the site of tendon pathology should be considered when prescribing eccentric exercises.

Practically, there are some potential dangers of isotonic resistance training such as:

- Athletes require adequate supervision in the gymnasium.
- Athletes should never attempt to lift a maximal weight without a 'spotter' (an assistant who is able to help the athlete if problems arise).
- Isotonic machines such as Keiser<sup>®</sup> equipment may provide a safe alternative to free weights, but these machines limit the range of motion and are generally unable to provide truly constant resistance through the lift.

Isotonic exercises in which the body weight of the individual is used as resistance are also safer than free weights and are often more convenient to perform. Exercises such as sit-ups, push-ups and chin-ups can be done almost anywhere and require no supervision. However, it is difficult to increase the resistance of the exercise and the only way to increase the effort is to increase the number of repetitions performed.

### Isokinetic exercises

Isokinetic exercises are performed on devices at a fixed speed with a variable resistance that is totally accommodative to the individual throughout the range of motion. The velocity is, therefore, constant at a preselected dynamic rate, while the resistance varies to match the force applied at every point in the range of motion. This enables the patient to perform more work than is possible with either constant or variable resistance isotonic exercise.

Isokinetic testing can highlight imbalances, such as scapular muscle imbalances in overhead athletes with chronic impingement signs.<sup>37</sup> A number of isokinetic devices are available and include the Ariel<sup>®</sup>, Biodex<sup>®</sup>, Cybex<sup>®</sup>, KinCom<sup>®</sup>, Lido and Merac<sup>®</sup> machines. However, these machines do come at a cost, which may explain why they are more commonplace in research than in clinical settings.

### Classification of resistance exercises

#### Open chain and closed chain exercises

An open kinetic chain exercise often involves single joint movement performed in a non weight-bearing position where the distal extremity freely moves through space.<sup>38</sup> Closed kinetic chain exercises involve multiple joints and

**Table 10.2** Advantages and disadvantages of open chain and closed chain exercises

	Advantages	Disadvantages
Open chain exercises	Decreased joint compression Can exercise in non weight-bearing positions Able to exercise through increased ROM Able to isolate individual muscles	Increased joint translation Decreased functionality
Closed chain exercises	Decreased joint forces in secondary joints (e.g. less patellofemoral force with squat) Decreased joint translation Increased functionality	Increased joint compression Not able to exercise through increased ROM Not able to isolate individual muscles

ROM = range of motion

are performed in weight-bearing positions with a fixed distal extremity. Closed kinetic exercises are thought to be more functional, provide more proprioceptive feedback and cause less shear joint forces than open kinetic chain exercises.<sup>38</sup>

**Open and closed chain exercises in rehabilitation**  
Although some studies promote closed chain over open chain exercises,<sup>38, 39</sup> others advocate that both types of exercises play beneficial roles in rehabilitation, especially in regards to anterior cruciate rehabilitation and patellofemoral pain.<sup>40, 41, 42</sup> Proposed advantages and disadvantages of open and closed kinetic exercise are shown in Table 10.2.

Examples of these exercises are shown in Figure 10.6. Figure 10.6c shows an example of open (right arm) and closed (left arm) chain exercises for the shoulder girdle.

(a)

**Figure 10.6** Open and closed chain exercises (a) Open chain knee extension with the foot moving freely

(b)

(c)

**Figure 10.6 (cont.)** (b) Closed chain knee extension with the feet immobile (c) Open chain (right arm) and closed chain (left arm) exercises on an unstable surface

Closed chain upper limb exercises are particularly useful during the early recovery period from shoulder surgery (Chapter 24). Excessive mobility and compromised static stability within the glenohumeral joint have been linked to capsular, labral and musculotendinous injuries in throwing athletes.<sup>43</sup> The positive benefits of closed kinetic chain exercises, performed under load-bearing positions, are thought to stimulate joint receptors and facilitate muscle co-contractions around the shoulder and therefore enhance joint stability.<sup>37, 43</sup>

### Qualities of resistance training

This section will briefly describe the various resistance training qualities and outline the methods the clinician or coach may employ to train these qualities.

#### Strength

Muscle strength is the muscle's ability to exert force. Strength gains can be seen quickly, even before physiological hypertrophy occurs. The initial strength gain in response to exercise is thought to be related to increased neuromuscular facilitation (i.e. the nervous system enhances the motor pathways so that the muscle group becomes more neurologically efficient).<sup>27, 28, 44</sup> Neural adaptations facilitate changes in coordination and learning that enhance the recruitment and activation of muscles during a strength task.<sup>27</sup>

Typical loading patterns for strength training can be seen in Table 10.3. Most importantly the resistance needs to be at or near maximal levels with large rest periods in between sets. This enables the muscles to recuperate adequately in between sets.

Strength training is generally the base from which all other resistance training emanates and therefore it generally occurs at the beginning of pre-season training.

#### Power

Muscle power is the muscle's rate of doing work. Similar to strength training, the initial power gains observed with power training result from improvements in neuromuscular efficiency.<sup>45</sup> Specifically, initial improvements in power can be attributed to improved muscle coordination between agonist and antagonist muscles. Power exercises may include:

- fast-speed isotonic or isokinetic exercises (concentric and/or eccentric)
- increased speed of functional exercises (e.g. faster reverse calf raise, drop squat)
- plyometric exercises (e.g. hopping, bounding).

Power exercises often involve functional and sport-specific exercises. Exercises should be made appropriate to the athlete's sport to gain optimal benefits (e.g. bounding for a sprinter, jump and land for a basketballer).

Another technique of increasing power is plyometric training. Plyometric exercises (plyometrics) use the natural elastic recoil elements of human muscle and the neurological stretch reflex to produce a stronger, faster muscle response. Plyometrics combine a rapid eccentric muscle contraction with a rapid concentric contraction to produce a fast forceful movement. It must be performed in conjunction with a resistance training program, as athletes need to have minimum basic strength levels before commencing plyometrics.

#### PRACTICE PEARL

Because of their explosive nature, plyometrics have a great potential for injury. Therefore, an athlete's plyometrics program should be carefully supervised.

Plyometric exercises include hopping and bounding drills, jumps over hurdles and depth jumps. These activities emphasise spending as little time as possible in contact with the ground. This form of exercise can cause DOMS (Chapter 4). Plyometric training should only be performed when the athlete is fresh and the volume of work should be built up gradually. The training surface must be firm but forgiving, such as sprung basketball floors. When technique begins to deteriorate, the exercise should be stopped.

Olympic-type weightlifting is often used as part of a power training program. Olympic lifting involves explosively lifting a weight from the floor to a position above the ground using the entire body. Typical Olympic lifts include the power clean, snatch, and clean and jerk. These lifts exercise a greater number of muscle groups

**Table 10.3 Resistance training loading patterns**

	Sets	Reps	Rest (s)	%RM	Speed
Strength	3–5	3–6	90–120	90–100	Controlled
Power	3–4	8–12	45–60	40–60	Explosive
Hypertrophy	2–3	8–12	60–75	70–90	Slow on eccentric
Endurance	1–2	15–30	45–60	50–70	Sport-specific

than conventional weightlifting, exercising them both concentrically and eccentrically. The potential for injury is high and athletes must learn correct lifting techniques before attempting these lifts.

When injury has decreased muscle power or the athlete's sport includes periods of explosive power, the rehabilitation program should incorporate power exercises. Commonly, power-focused exercises are incorporated into the later stage of rehabilitation due to the potential for re-injury and explosive nature of this training.

Typical loading patterns for a power program can be seen in Table 10.3. The most important factor in a power development program is the speed of movement which must be as explosive as possible.

### Muscular endurance

Muscle endurance is the muscle's ability to sustain contraction or perform repeated contractions. The aim of muscular endurance training is to increase the capacity to sustain repetitive, high-intensity, low-resistance exercise such as running, cycling and swimming.<sup>17</sup> Excessive bouts of muscular endurance training can result in fatigue and reduced sporting performance. Therefore, care should be taken in incorporating this type of training into a resistance training program, especially during prolonged pre-season training.

Typical loading patterns for muscular endurance training can be seen in Table 10.3. This type of training involves high repetitions with very little rest.

### Hypertrophy training

Hypertrophy training aims to increase the muscle size. This quality is important particularly for combative sports where an increased muscle mass can be advantageous. Generally, hypertrophy occurs through an increase in the size or cross-sectional area of the muscle cells rather than an increase in the number of muscle cells.

Typical loading patterns for hypertrophy can be found in Table 10.3. As this table demonstrates, the eccentric or lowering component should be slower than the concentric component. This will create additional muscle damage and therefore take greater time for the muscle to repair and regenerate. As a result care must be taken when prescribing additional speed or resistance training around hypertrophy sessions.

### Flexibility training

An athlete is susceptible to injury if they lack sufficient flexibility to meet their sport-specific demands. Stretching and range of motion exercises are performed to increase joint range of motion. The acute effects of stretching include:<sup>46, 47</sup>

- decreased muscle stiffness through viscoelastic deformation of the muscle tissue (this is likely to be extremely transient)
- increased muscle length through serial addition of sarcomeres
- altering sensation, thereby increasing stretch tolerance.

Traditionally, stretching has been widely promoted for injury prevention and performance enhancing for sporting activity. However, some authors have suggested stretching does not prevent injury in otherwise healthy individuals.<sup>48</sup> Others have noted that it is important to differentiate between pre-exercise stretching (where stretching does not appear to prevent injury)<sup>49</sup> and regular stretching outside periods of exercise (where there is some clinical and basic science evidence suggesting stretching may prevent injury).<sup>50, 51</sup> Additionally, stretching does not seem to reduce the effects of DOMS.<sup>52</sup>

Furthermore, the acute effects of stretching can cause temporary strength deficits and hence reduce sporting performance.<sup>53</sup> This deficit seems to be associated with stretches performed for more than 60 seconds, while stretches of shorter duration may have less significant deficits.<sup>53</sup> As traditional stretching routines are performed during warm-up sessions prior to playing sport, the amount of time athletes stretch should be taken into consideration.

Stretching is often promoted as having a number of beneficial effects,<sup>54, 55</sup> although not all of the following have been appropriately studied:

- increases muscle and joint flexibility
- increases muscle relaxation
- decreases muscle soreness
- improves circulation
- helps prevent excessive adhesion
- promotes a flexible, strong scar.

### Types of stretching

There are three main types of stretching: static, dynamic and proprioceptive neuromuscular facilitation.

#### Static stretching

Static stretching involves moving the muscle or joint into an elongated position and holding the position for an extended period. Historically, this type of stretching has been used to prepare the muscle for exercise; however, research has consistently demonstrated a reduction in power immediately after static stretching.<sup>56</sup> As a result the more contemporary practice for athletic populations is to use static stretching both post training for recovery and away from training to improve flexibility.

### Recommendations for effective stretching

- A gentle warm-up before stretching increases tissue temperature and facilitates stretching. This may include activities such as jogging or cycling.
- As with warm-up, superficial or deep heat modalities may be applied to the area prior to stretching to increase tissue temperature.
- Cryotherapy may reduce pain and muscle spasm and thereby enhance the overall stretch of a muscle in the initial stages after an injury, even though the temperature is decreased (i.e. opposite to heat).
- Athletes should be carefully instructed regarding the correct stretching position, as incorrect positioning may cause injury.
- Different muscles seem to require different durations of stretch. In general, a slow sustained stretch should be held for a minimum of 10–15 seconds and progressed for 1 minute or longer. The athlete should feel stretch in the appropriate area.
- As the athlete's flexibility improves, increases in intensity, duration, frequency and type of stretch can be considered.
- Stretching should always be pain-free, that is, 'tightness' without pain.

### Dynamic stretching

Dynamic or ballistic stretching is when the muscles and joints are taken through their range of motion during movement. This type of practice is more specific to preparation for exercise and sports in particular. During the rehabilitation process care should be taken to not 'bounce' the muscle that is recovering from injury. Dynamic stretches have been shown to significantly increase tendon flexibility and elasticity and have been promoted for end-stage rehabilitation for tendon injuries. However, ballistic stretching involves eccentric contractions during the stretch phase, which may result in soreness or injury and therefore care should be taken when incorporating such stretches.

### Proprioceptive neuromuscular facilitation (PNF) stretching

PNF stretching involves the combination of contracting the antagonist (opposite) muscle and excessively stretching the agonist muscle. This type of stretching is quite aggressive but can result in rapid increases in flexibility. PNF flexibility sessions should not be performed more than 1–2 times per week and should be cycled into and out of training as it can cause some muscle damage.

### Flexibility in the rehabilitation process

Regaining or maintaining full flexibility of joints and soft tissues is an essential component of the rehabilitation process. Following injury, musculotendinous flexibility often decreases as a result of spasm of surrounding muscles. Inflammation, pain and/or stiffness can limit joint range of motion and the normal extensibility of the musculotendinous unit can be compromised. This may result in dysfunction of adjacent joints and soft tissues.

For example, the lumbar spine may be restricted in range of motion and the paraspinal muscles may spasm following knee or hip surgery, especially after periods of restricted mobilisation. Adequate soft tissue extensibility after injury is essential to encourage pain-free range of movements. Stretching muscles and joints is one way of improving tissue and joint extensibility.

### TRAINING LOAD MANAGEMENT FOR PERFORMANCE ENHANCEMENT

The ability to effectively periodise and manage training load will obviously have a large impact on athlete success. Long-term, gradually progressive training plans should be made, including periods of higher and lower loading to avoid improvement plateaus, injuries, illnesses or burn-out. This process, commonly referred to as *periodisation*, should consider time periods consisting of several months (macrocycles), weeks (mesocycles) and days (microcycles).

Load management not only comprises sound knowledge of training periodisation, but also an intimate awareness of when players are fatigued, undertrained, stressed or fresh. Typically, team-sport athletes have been advised to avoid strenuous mid-week training to 'freshen up' for the next game and/or avoid injury. However, recent evidence suggests that too little training can be a significant risk factor for injury.<sup>57</sup> This suggests a delicate balance exists between fitness, fatigue and freshness, with the ability to identify each state being crucial to performance enhancement and injury prevention.

To successfully manage load, it needs to be quantified. There are, of course, many influences on the total load placed upon an athlete, and the ability to identify these and alter training load accordingly is both an art and a science. Certainly, technology may assist the practitioner in quantifying load; however, just as important is the

ability to 'sense' or 'feel' when players are fatigued or fresh. This 'sense', however, typically requires intimate knowledge of the players/athletes and much experience in this domain.

Training load is typically defined as either internal or external. Internal load refers to the impact the training has on the athlete and can be measured by subjective wellness questionnaires,<sup>58, 59</sup> as well as a range of objective metrics such as heart rate, blood markers (e.g. creatine kinase, testosterone, cortisol), RPE and heart rate variability.<sup>59</sup> External load refers to the estimation of the actual load the players are placed under and is usually measured using GPS devices, power meters or simply calculating training duration.<sup>59</sup>

Maximising training output (external load) while minimising training cost (internal load) is usually the goal of most training programs. Effectively estimating both of these, therefore, becomes a crucial element of the sports practitioner's role. RPE-load (also called session-RPE) has subsequently gained much popularity in both research<sup>60</sup> and practice as it represents both internal and external load and allows different forms of training (e.g. football and weightlifting) to be measured in the same units. RPE-load is calculated by multiplying player RPE (internal) with training or match duration (external) and has been shown to relate effectively to measures of internal load.<sup>61</sup>

The role of load monitoring in injury prevention is covered in Chapter 12.

# Core stability

by PAUL HODGES

*Core strength and stability is very important to me. Tennis is all about rotation of the body and my ability to create power. I incorporate a lot of abdominal, back and glute exercises into my gym sessions.*

Samantha Stosur

## INTRODUCTION

'Core stability' refers to control of proximal regions of the body during movements and function. Although the concept appears straightforward, different interpretations or misconceptions of the term, and differences in applying this concept to the design of exercise programs for lumbopelvic pain, have led to substantial confusion and debate.

'Stability' has been interpreted to mean many things and, commonly, a simple objective to *restrict* motion. This has led to the development of many exercise programs that emphasise static maintenance of a specific lumbopelvic position during loading. Although this may be appropriate for some functions, restriction of motion does not necessarily assure stability of a system.

A stable system is one in which its intended *position* or *trajectory* (i.e. movement path) can be maintained, despite perturbation or disturbance.<sup>1</sup> This may be achieved by restricting motion in some tasks (e.g. restriction of spinal motion during lifting), but requires movement to manage, reduce or transfer internal and external forces in others (e.g. counter-rotation of the shoulders and pelvis during walking) (Fig. 11.1). Further, in a complex dynamic system such as the spine, the stability of many goals (e.g. spine control, breathing, balance) must be maintained concurrently.<sup>2</sup>

The 'core' refers to proximal regions of the body, which can include the spine, pelvis, scapulothoracic region and even the hips and shoulders. These regions are functionally distinct from the distal limbs, which have a critical role in fine controlled, goal-directed movements. The principal functions of the core are to provide a foundation for limb movements, a stable base for limb muscle contraction and a major contribution to overall postural control of the

**Figure 11.1** Optimal control of the spine depends on a balance between movement and stiffness. At one end of the spectrum are functions such as lifting that require high stiffness of the trunk; at the other are functions such as running and walking that demand movement to meet the demands of the task. Both too much and too little movement and stiffness could underlie suboptimal loading

body. This latter aspect is particularly important as the trunk contributes about 70% of body weight. The focus of this chapter is consideration of the lumbopelvic region, but clinical management must involve consideration of the adjacent regions, as they cannot act independently.

When the concepts of 'stability' and the 'core' are fully appreciated, it is clear that the design of exercise programs for lumbopelvic pain require the term 'core stability' to be applied in its broadest sense to encompass all features that might be necessary to ensure optimal control. This requires a motor control or learning approach, whereby muscle activation patterns, postures or alignments, and movements are trained, tuned or optimised to meet the demands of function<sup>3</sup> (Fig. 11.2). Although restriction of motion may be encouraged for some functions and some patients, this

**Figure 11.2 Contribution of body and mind to persistent pain.** (a) The experience of pain involves peripheral and central components. Individual patients will vary in the relative contribution of peripheral and central contributions to their pain presentation. Some will maintain a major contribution of ongoing nociceptive input from suboptimal loading of tissues; others will have little input from tissues and major contribution from central processes. Motor control training is likely to be most effective for individuals with an ongoing contribution from peripheral afferents. (b) Different treatments will be required along the spectrum from treatments that target the body such as motor control training for core stability at one end, to psychologically grounded treatments for the mind at the other end

depends on the presentation of the individual patient, whereas for other functions and other patients the exercise may aim to increase motion. 'Motor control training' is a general term used to describe a comprehensive approach that uses a range of strategies (from low load training of precise control of muscles, posture and movement; progression of exercise with increasing load and complexity; and functional retraining; through to strength and endurance training, as required) in combination with education and behavioural strategies to promote pain management.

Training must:

- optimise the balance between movement and stiffness (which differs between tasks)
- consider the coordination of the multiple functions of the trunk and of the trunk muscles

- individualise the program to match the patient's unique presentation.

This chapter provides an overview of the rationale for motor control training to optimise core stability in the management of lumbopelvic pain, outlines key principles underlying this approach and discusses common misconceptions. It also describes the typical process for planning a motor control training program; from detailed assessment of motor control, formulation of the clinical hypothesis, development of an exercise program to optimise loading, and planning for progression of exercise.

## RATIONALE FOR MOTOR CONTROL TRAINING FOR LUMBOPELVIC DYSFUNCTION

The premise underlying the effectiveness of motor control training to optimise core stability is that for many individuals with lumbopelvic pain, suboptimal loading of structures of the spine and pelvis (as a result of the muscle activation, posture or alignment, and movement typically adopted by an individual) places the tissues at risk of trauma or microtrauma, and drives peripheral nociceptive input which contributes to the development and persistence of pain (Fig. 11.2).

Motor control training of core stability aims to optimise tissue loading to prevent further injury and to reduce nociceptive afferent discharge.<sup>3</sup> Although it is acknowledged that symptoms may persist in the absence of ongoing nociceptive input, and it is widely agreed that central sensitisation will contribute to the pain experience for many<sup>4</sup> (Fig. 11.2), individuals who retain a peripheral component to their symptoms are likely to benefit from reduction of this input through optimisation of the manner in which the individual loads their tissues and body.

With the link between loading and pain in mind, it is clear that the exercise must be individualised to modify the features that are specific to the individual's unique presentation. Examples of suboptimal loading that could cause ongoing nociceptive input include reduced muscle activation leading to insufficient constraint or control of joint motion; sustained alignment of the pelvis and spine at the end of range of motion placing excess load on passive tissues;<sup>5</sup> excessive motion of the spine and pelvis rather than the hip during leg movement;<sup>6</sup> and excessive compressive load on the spine from augmented co-contraction of trunk muscles (e.g. during lifting<sup>7</sup>). Motor control training aims to change the suboptimal features of muscle activation, posture and movement to achieve optimal core stability with optimal tissue loading.

Although it would be impossible to test the validity of every permutation of suboptimal tissue loading, evidence is beginning to emerge that loading can be related to symptoms,

and optimisation of loading may be necessary for recovery. For instance, training that aims to restore activation of the deep abdominal muscle, transversus abdominis, is more effective for individuals found to have poor activation of this muscle on clinical assessment at baseline, and recovery of symptoms is related to recovery of function of this muscle in those individuals.<sup>8,9</sup> Further, low back symptoms are reduced when spine position is controlled during hip rotation in individuals who present with early and excessive lumbopelvic motion during this task.<sup>10</sup>

A thoughtful clinical reasoning approach is essential to:

- determine whether the patient's pain presentation includes a component that is maintained by peripheral nociceptive input
- identify any features of muscle activation, posture/alignment and movement that underpin the suboptimal tissue loading for the individual through detailed clinical assessments
- develop a clinical hypothesis to account for the relationship and inform treatment planning
- develop an exercise program to target the motor control changes to optimise tissue loading.

Of course it is critical to recognise that the presentation of lumbopelvic pain generally involves features within multiple domains of the biopsychosocial model (Chapters 15 and 23). In addition to peripheral nociceptive input from abnormal tissue loading, there may also be sensitisation of pain processing at multiple levels of the nervous system and some features of unhealthy pain cognitions and social features (Fig. 11.2). Depending on the individual patient's presentation, treatment is likely to be optimised when all factors relevant for the patient's presentation are considered in treatment design. This will include considering additional measures to manage attitudes and beliefs about pain, as well as other aspects such as pain-coping skills.

### MOTOR CONTROL TRAINING TO OPTIMISE CORE STABILITY— KEY PRINCIPLES AND COMMON MISCONCEPTIONS

Key principles that underlie the application of motor control training to lumbopelvic pain are reviewed below to clarify the basis for clinical decisions when designing an exercise program to optimise core stability. A number of misconceptions regarding the approach also require clarification.

#### Optimal motor control requires a balance between movement and stiffness

The primary focus of many exercise programs for core stability has been to restrict motion (e.g. exercises that target maintenance of lumbar and pelvic position during limb movement or side-bridging). Although these

strategies to brace the trunk are appropriate and necessary for some tasks (e.g. lifting a 100 kg weight from the floor, which requires high stiffness of the spine), they are not appropriate for other functions, such as walking and running, where movement is essential for optimal task performance. Most functions require a balance between movement and stiffness to optimise tissue loading; the optimal balance depends on the task being performed.

Sufficient stiffness is necessary to prevent collapse and maintain alignment. Movement is required to absorb impact, transfer load, minimise energy expenditure, allow some variation to share load between related structures, and to move along a trajectory. Even static tasks generally involve some movement (e.g. standing involves small movements to compensate for a range of challenges, including the cyclical postural disturbance from breathing<sup>11</sup>). A healthy system has the capacity to shift along a continuum from high stiffness at one end and high mobility at the other to match the balance between movement and stiffness required by task demands (Fig. 11.1). Individuals with lumbopelvic pain often present with inaccuracy in matching task demands.

#### PRACTICE PEARL

Evidence is emerging for poor control across this stiffness-mobility spectrum in people with lumbopelvic pain. This can present as excessive motion,<sup>12</sup> excessive stiffness<sup>13</sup> or elements of both.

A tennis player may use excessive lumbar rather than hip motion during a racket swing. A runner may brace the spine with excessive muscle co-contraction, and limit shock absorption and load transfer through the trunk. There may be a change in threshold, where a strategy normally reserved for a high load task is used at low load. All of these can lead to excessive tissue loading which is problematic for function, not only in terms of suboptimal lumbopelvic control, but also for the broader functions of the trunk. For instance, balance in standing is compromised if the trunk is stiffened.<sup>14</sup>

On this basis it would seem inappropriate to apply exercise universally to enhance stiffness (e.g. bracing co-contraction of abdominal and extensor muscles) for every patient or for every functional context. Such strategies should be reserved to enhance stiffness for moments of high demand. Other exercise is required to train appropriate movement.

#### Optimal lumbopelvic control involves three main neural strategies

The nervous system employs three basic strategies to optimise lumbopelvic control. The first is reactive control in which the nervous system activates a pattern of muscle activation in response to sensory input.<sup>15</sup> This class of

response is involved in formulating the response when the system is unexpectedly disturbed (e.g. trip, slip, push) or to fine tune muscle activation.

The second is preparatory control when the muscle activation required to control the lumbopelvic region can be initiated in advance of a disturbance.<sup>16</sup> This type of adjustment can only be used when demands can be predicted (e.g. voluntary initiated stepping, catching a watched ball).

As reactions take time and not all disturbances can be predicted, the system relies on a third strategy of ongoing tonic muscle activation at a low percentage of contraction to maintain a state of preparedness, just in case the spine is perturbed.<sup>17</sup>

All muscles of the trunk can contribute to these three classes of motor control strategy. Dysfunctions may present in each and it may be necessary to consider all three in a treatment program (e.g. train reactive control through challenging the system with balance tasks; train preparatory control by pre-activating muscles in advance of a task; train sustained gentle tonic activation).

### **Optimal motor control requires a whole system, not a single muscle**

A single muscle cannot be responsible for optimal motor control and core stability, and dysfunction would be unlikely to involve a single muscle. Instead control must depend on the integrated function of a whole system of muscles, and the muscles cannot be considered independently of the alignment of the spine and pelvis, and the pattern of movement.

All muscles of the lumbopelvic region contribute to optimal control of the region and this is influenced by muscles of adjacent regions (e.g. hip/thorax). But this does not mean that all muscles serve the same role. As a general principle, deeper muscles with attachments to individual vertebra and limited moment arms for torque generation can play a primary role in controlling intersegmental motion. The larger more superficial muscles with a greater moment arm for torque generation are more critical for stiffening the spine when co-contracting in antagonist muscle pairs, and for generation and control of movement when acting asymmetrically or in specific patterns of activation that promote torque in a specific direction.

#### **PRACTICE PEARL**

Research evidence universally shows that the transversus abdominis and multifidus muscles are not the only muscles required for lumbopelvic control and no function involves activation of these muscles in the absence of activation of other trunk muscles.

Both of these contributions are essential and deficits in either would lead to problems.

There has been considerable debate regarding the function and dysfunction of the transversus abdominis and multifidus muscles.<sup>18, 19</sup> Although always part of a more complex interplay of muscle activation, these muscles often act differently to other trunk muscles (e.g. less dependent on force direction, early and tonically),<sup>16, 20</sup> which is related to their distinct mechanical contribution to control.

Transversus abdominis acts primarily through generating intra-abdominal pressure and tension of fascial structures, both of which appear to control intersegmental and pelvic motion in multiple directions. Multifidus is situated close to the centre of rotation of the lumbar segments, suggesting limited role in torque generation. These muscles commonly have structural and functional changes in people with pain.<sup>21-24</sup>

Together these observations provide a foundation for detailed consideration of these muscles in the management of lumbopelvic dysfunction. Backed by biomechanical and modelling data of a contribution to optimal control, individuals with compromised activation of these muscles are likely to contribute to abnormal tissue loading. These patients would be likely to benefit from restoration of control as part of a comprehensive training program that includes considering other muscles, posture and movement.

### **Motor control training involves rehabilitation of whole system**

Considering the breadth of features of motor function that can underpin suboptimal tissue loading, it is clear that a motor control training program must address multiple features, including muscle activation, posture, or alignment and movement (Fig. 11.3). The exact features addressed and the combination depends on the individual's presentation and function. Thus, to optimise core stability, planning a training program to optimise motor control requires detailed assessment to identify features related to abnormal loading.

In terms of muscle activation, motor control of core stability would be suboptimal if muscle activity was insufficient, excessive or lacked coordination in terms of timing, amplitude or pattern of activation. Insufficient activation (e.g. delayed activation of transversus abdominis<sup>21</sup>) may allow excessive motion or poor quality of motion within the normal range of motion, both of which would lead to increased tissue load.

Excessive activation (e.g. augmented activation of obliquus externus abdominis) could restrict motion (limiting shock absorption and compromising function); increase joint load; and reduce variation (reduce sharing of load between structures). Poor coordination of muscle

**Figure 11.3** Suboptimal motor control generally involves features of posture or alignment, movement and muscle activation. The combination of features differs between individuals and each needs to be addressed, although there will be some interaction between them with exercise that targets one aspect having an effect on others

activation (e.g. *en bloc* activation of back muscles rather than differential activation) could change the location and amount of tissue load. None of these observations is universal and it would be illogical to target any change universally with exercise. The exercise program would involve the selection of techniques and strategies to change the pattern of activation.

A common clinical strategy that requires additional explanation is the common objective to isolate the activation of deeper muscles with specific exercises. It is important to clarify that this strategy does not aim to encourage a patient to activate *only* these muscles in function, but to train the *skill* of activating the muscles so that a patient can then integrate their activation into function, along with correcting any other suboptimal feature of motor control that is identified in the patient's presentation.

Like all elements of core stability, it is necessary to find a balance, and more muscle activity is not necessarily better. Although some degree of muscle activity, intra-abdominal pressure and fascial tension improves control,<sup>25</sup> if these are in excess of demands, this will lead to additional load or restriction of movement. It is necessary to tune muscle activity to meet, but not exceed, demands and to reduce it if the muscle is overactive.

Alignment or posture is also important. Although there is not one posture of the lumbopelvic region that is ideal for every patient, there is a range of features

that clearly increase load on the lumbopelvic region.<sup>5</sup> Examples include resting at the end of range (e.g. sitting with posterior pelvic tilt with lumbar flexion); hanging on passive tissues (e.g. resting on an adducted hip in standing to tense the iliotibial band); and active holding of a posture by excessive muscle activation or asymmetrical postures. Changes to alignment or posture to reduce the resulting tissue loading may be necessary to optimise loading. This could be achieved with multiple techniques such as instruction, feedback, taping and manual therapy (see below).

It is critical to consider the pattern of movement. Like posture, there are features of movement that are likely to be suboptimal.<sup>26</sup> Every movement involves more or less ideal solutions and there are many ways that it can be suboptimal. Some examples include too little movement of a region or segment; too much movement; too little variation; and poor relationship between adjacent regions or segments. Again, selecting the strategy to change movement strategy in order to optimise load is required.

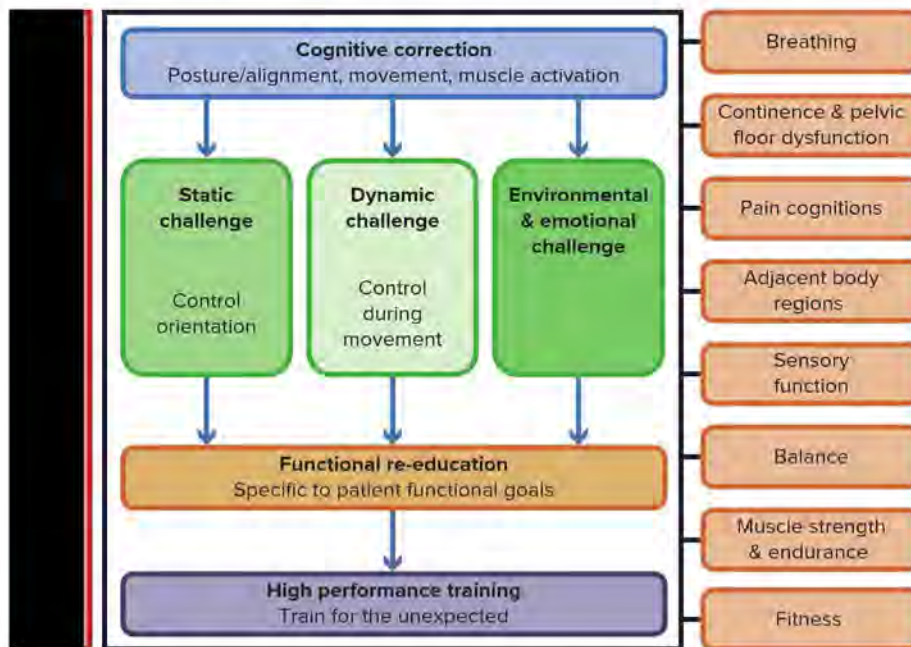

It is clear that motor control training for core stability requires an individualised approach. This is based on clinical and experimental data. When outcomes of randomised clinical trials are considered, there is a tendency for greater clinical effect size in trials that involve individualised training of specific subgroups of patients.<sup>27</sup> The least impressive outcomes are from trials that apply a generic treatment to a group of patients with non-specific back pain.

From an experimental perspective, there is clear evidence that exposure to pain induces adaptations that vary between individuals. For instance, if healthy individuals are provoked by a noxious stimulus to the back, all adapt to protect the spine, but no two participants achieve this with identical patterns of muscle activation.<sup>28</sup> Further, not all patients present with deficits in activation of the deep trunk muscles (transversus abdominis and multifidus muscles), and those that do have a deficit in these muscles have a better response to training that includes training of these components than do patients who do not have a deficit to start with.<sup>9</sup> Individualisation of training requires detailed assessment.

### Motor control training involves a motor learning approach

When the objective of training is to modify specific features of motor control to optimise core stability, this can be targeted with a motor learning approach. Skill learning commences with identifying and then correcting the fault or suboptimal feature of a task. Once the modified skill is learnt, this can then be integrated into functions of increasing complexity. This applies to the learning of many skills.<sup>29</sup>

**Figure 11.4 Motor control training for core stability.** Training begins with detailed training of features of posture or alignment, movement and muscle activation that are considered to contribute to suboptimal tissue loading. Once these skills are learnt it is necessary to introduce static and dynamic challenges to encourage refinement and diversification of the skill. Functional training is necessary to ensure modified motor control strategies are introduced into functional tasks. Training then progresses to high performance for the unexpected. A range of issues, highlighted in boxes to the right, can be barriers to recovery and require consideration for individual patients if they are present

When applied to motor control training for core stability (Fig. 11.4), the initial stage would involve modifying and tuning the features of muscle activation, posture or alignment, and movement that are identified in the assessment. This can be achieved by conscious, cognitive correction of the feature, with feedback (visual, ultrasound imaging, palpation, electromyography), or the use of techniques such as taping and manual guidance (see below).

Skill learning can be enhanced by simplifying the task (e.g. non weight-bearing positions, slower speed) and segmenting a complex task into component parts (e.g. practice of correction of a muscle activation, practice of a specific alignment) prior to practice of a complete task. The selection of which features to address first depends on the individual. It is perhaps best guided by the features that are likely to achieve the greatest change in pain provocation or most able to be achieved by the patient.

As with any skill training, once the skill is learnt the patient can be progressed by challenging the patient with more complex tasks (e.g. increased load, more challenging postures and movements). This can involve progressive levels of increased demand and it is generally necessary

to consider static control (of a specific alignment of the spine and pelvis) or dynamic control (of the lumbopelvic region as it moves) or control of the lumbopelvic region during whole body movement. Finally, the functions that a patient indicates are problematic can be practised with correction of the features of motor control.

### Interplay between motor control and biology of pain

Motor control training would be expected to have a greater effect for patients with a nociceptive component. As highlighted above, but critical to reiterate, motor control training aims to optimise the load on the tissues and this is most likely to impact an individual's symptoms if they continue to have a nociceptive contribution to their symptoms (Fig. 11.2). Patients whose pain is maintained by central sensitisation may derive benefit from education of healthy movement, but this will impact their function through mechanisms other than reduction of peripheral nociceptive input, such as experience with healthy movement as a step towards fear-deconditioning.

It must be remembered that pain is not 'in' the tissues and is a result of interplay between nociceptive input,

biological processes in the periphery and the nervous system that both inhibit and facilitate the pain experience, and cognitive and emotional aspects such as distress or fear (Fig. 11.2). Pain is a construct of the nervous system on the basis of each of those inputs and processes. Pain can be maintained by ongoing nociceptive input from the tissues and in its absence.

As highlighted above, the role of optimisation of tissue loading (through training of core stability) in the management of pain will be likely to be greatest in individuals with ongoing nociceptive contribution to pain. This type of pain is considered to have recognisable features such as a clear relationship with movement that is predictable and proportional, localised to an area, has clear aggravating and easing factors, and is localised on palpation.<sup>30</sup>

A recent clinical trial showed that motor control training and a graded activity general exercise approach were equally effective when the whole group of non-specific low back pain patients were considered together; however, motor control exercise was more effective for those who responded to a questionnaire that, although developed to identify instability (which may be considered too narrow a view of suboptimal motor control), also identifies characteristics that are consistent with nociceptive-type pain.<sup>31</sup>

Many patients also present with a host of biological changes (in addition to those that relate to suboptimal loading, such as modified inflammatory system activity<sup>32</sup>), and psychosocial features that also impact their pain presentation.<sup>33</sup> When present, these are likely to impact the efficacy of an exercise approach focused on motor control. For some, those processes are dominant and should be the primary target of intervention, for others, a combined approach may be helpful—restoration of function, but with attention to how people move.

An important consideration is that behavioural, psychologically informed treatments often encourage a patient to ignore pain, yet correction of motor control may demand consideration of when a movement is performed in a non-provocative manner. Care is required in selecting language to ensure the patient does not develop the belief that their spine is at risk and must be protected, which are concepts likely to reinforce unhealthy pain cognitions.

### **Implications of the role of trunk muscles in respiration and bladder and bowel function**

In addition to their role in controlling the spine, trunk muscles, particularly those that surround the abdominal cavity, have critical roles in breathing and bladder and

bowel function. These functions must be coordinated with the contribution of these muscles to lumbopelvic control. Yet in the present of disorders of continence (e.g. stress urinary incontinence), breathing (e.g. asthma) and back pain, the contribution to any or all of these functions may be disrupted.<sup>34</sup> Coordination of these functions is particularly critical for application to sport and more demanding physical activity.

Breathing requires modulation of pressure in the thorax—alternating activation of the diaphragm and other chest wall muscles in inspiration, and abdominal and internal intercostal muscles in expiration. These modulations of activity are coordinated with breathing in healthy individuals, but modified in those with respiratory disease and some with low back pain. Training to coordinate functions is likely to be required.

In terms of bladder and bowel function, continence is maintained if the pressure in the urethra or rectum exceeds that in the bladder/colon. Abdominal and diaphragm muscle activity increase intra-abdominal pressure, which concomitantly raises bladder and bowel pressure. Pelvic floor muscle activation is necessary to elevate intra-abdominal pressure. Thus, coordination between spine control and continence functions of the whole lumbopelvic system, including the abdominal wall, back, diaphragm and pelvic floor, requires consideration. This is particularly the case in the presence of pelvic floor muscle dysfunction, which may present as compromised or excessive muscle activation, both of which would have consequences for optimal control of the spine.

### **Is motor control training effective for everyone or is it more effective when targeted to specific individuals?**

As highlighted above, there is emerging evidence that motor control training for core stability is more effective for some individuals, and more effective when tailored to the individual patient. Hypothetically, motor control training would be more effective for patients and athletes presenting with symptoms that are related to modified loading (including an ongoing nociceptive component). As highlighted above, recent work highlights that the treatment is most effective for patients with a high score on a questionnaire which purports to indicate signs of instability.<sup>31</sup> Further work is required to determine whether this questionnaire instead reflects signs of ongoing nociceptive contribution to pain. Further, training is more effective for patients who are identified to have a deficit in control of the deep trunk muscles at baseline.<sup>8, 9</sup> It seems logical that this is not a treatment that can be applied in a blanket manner, but applied to the right patients and in a tailored manner.

## PRINCIPLES OF THE CLINICAL APPLICATION OF MOTOR CONTROL TRAINING

As highlighted above, the basis of a motor control approach for core stability is to optimise the manner in which a person loads the tissue of the spine and pelvis by addressing any suboptimal features of muscle activation, posture or alignment, and movement. It follows then that the application of motor control training requires careful assessment to identify the suboptimal features, and then design a treatment or exercise program to target these features, before progressing into functions of increasing complexity. The basic stages of a program to optimise motor control of core stability are presented in

Figure 11.4. A brief overview is provided below (for a detailed review see Hodges et al.<sup>3</sup>).

### Assessment of motor control for core stability

Assessment involves a series of screening tests to identify key features of muscle activation, posture and movement that could imply suboptimal loading, combined with more detailed analysis to identify the specific nature of the loading issue (Fig. 11.5). Subjective assessment is essential to provide initial guidance of key functional demands and provocative or relieving postures, movements or functions. Physical tests of motor control are based on the premise that it is possible to identify features of posture, movement or muscle

**Figure 11.5** Assessment of motor control of core stability requires detailed assessment of posture or alignment, muscle activation and movement. Posture or alignment is compared against an ideal which is refined for consideration of the individual patient. Muscle activation involves assessment of underactivity, overactivity, threshold and asymmetry of the whole trunk muscle system. Assessment can be informed by evaluating the capacity to activate the deeper trunk muscles and concurrent substitution by the more superficial or global muscles. Movement assessment involves assessing the pattern of movement against an optimal strategy during physiological movements (e.g. trunk flexion), functional movements (e.g. sit-to-stand) and specific clinical movement tests (e.g. hip rotation in prone)

activation that deviate from a predicted ideal and, in many cases, provoke symptoms. Provocation or relief of symptoms does not always provide a perfect indicator of the relevance of a motor feature for a patient's presentation.

In some cases a clear relationship will be identified. But in others a highly inconsistent, unrepeatable relationship with motor features and disproportionate (area or intensity) pain provocation may be present. This may indicate a dominant central sensitisation, which might not be ideally managed with a motor control approach. For prevention of future symptoms of a patient in remission or for primary prevention, pain cannot be used as a guide, and the assessment depends on the clinician's understanding of ideal control.

### Assessment of muscle activation

Assessment of muscle activation aims to identify evidence of overactivity or underactivity of any muscle(s). Observation of posture and movements can provide some indication of muscle activation (e.g. sitting with posterior tilt and extension at the thoracolumbar junction may suggest low activation of the multifidus and excessive activation of the thoracolumbar erector spinae).

A variety of clinical tests is available to analyse muscle activation. Some examples are described here. The common clinical tests of independent activation of the transversus abdominis and multifidus aim to assess both (i) the function of these deeper muscles (e.g. poor ability to activate the transversus abdominis independently is related to delayed activation in function<sup>35</sup>), and (ii) evidence of substitution or overactivity of the more superficial muscles. Clinical tools, observation, palpation, ultrasound imaging and electromyography can be used for the assessment. The capacity of the more superficial trunk muscles to control the lumbopelvic region can be derived from static tests that assess the capacity to control alignment when force is applied (e.g. load-applied limb movement). The threshold load that can be controlled, asymmetry in control and excessive bracing are assessed.

### Assessment of posture or alignment

Assessment of posture or alignment begins with the identification of features that differ from the predicted optimal posture. Although not optimal for all, a starting point for evaluating sitting or standing posture is to identify features that differ from an ideal that includes a level or slightly anteriorly tilted pelvis, gentle lumbar lordosis with a smooth transition to a gentle thoracic kyphosis, cervical lordosis, symmetry in frontal plane and no rotation in the transverse plane. For many, this posture optimises load sharing and requires only gentle muscle activation to maintain.<sup>36</sup> This goal needs to be modified or refined when considering the individual patient as the same posture is not ideal for all.

Assessment involves identifying features that deviate from this ideal with confirmation of the relevance for the patient's presentation by evaluating the response of pain or discomfort and muscle activation. The ideal may feel unusual to the patient, but it should not be painful or require high muscle activation to hold. Analysis of alignment is generally necessary in a range of relevant functional postures to identify suboptimal features using a similar approach.

### Assessment of movement

Assessment of movement involves a similar process to assessment of posture except that every movement pattern has its own ideal pattern of motion and muscle activation. For instance, forward flexion involves sharing motion between the hips, pelvis and spine with a specific sequence. Clear understanding of the requirements of movement is required. Movement tests typically involve assessment of physiological movements (e.g. trunk flexion), standardised functional movements (e.g. sit-to-stand) and specific movement tests (e.g. control of the spine and pelvis during hip rotation in prone). Several clinical approaches have been developed that include specific tests of movement to assist in identifying relevant features of movement (e.g. movement systems impairment<sup>26</sup>). In the case of the management of athletes, it is essential for the clinician to have a clear understanding of the features of optimal performance of the typical motor functions involved.

### Consider subgrouping patients

Assessment can be facilitated by consideration of patient subgroups. Subgrouping based on motor control features has been developed by several groups and can help to simplify the process of identifying the cluster of features that may require attention with training.<sup>26, 37</sup> Subgrouping using this approach is based on the premise that there are groups of patients who present with a similar combination of motor control features that are related to their symptoms. When a clinician can identify the subgroup into which a patient belongs, then the task of selecting the combination of features that need to be prioritised and targeted with treatment can be simplified. For instance, if a patient is identified with a 'flexion' motor control impairment,<sup>37</sup> then the therapist can predict that relevant motor control features may include control of the lumbar lordosis, poor dissociation of motion of the pelvis and lumbar spine from the thoracolumbar junction, and compromised activation of the multifidus muscles. In this way subgrouping simplifies the clinical reasoning process by aiding the pattern recognition.

### Training of motor control for core stability

At the conclusion of the assessment, a clinical hypothesis is formulated regarding the likelihood that suboptimal tissue loading is relevant for the patient's condition,

**Table 11.1 Application of motor learning to skill training to lumbopelvic pain****1. Cognitive phase of learning**

Learn and optimise features of basic motor skill, high degree of attention to:

- pattern of muscle activation
- alignment or posture
- movement strategy

**2. Associative phase of learning**

- challenge control with increasing demand
- diversify skill to different contexts
- refine skill:
  - static and dynamic challenges
  - different physical and mental contexts
  - enhance capacity for physical performance—endurance training or strength training for high-intensity control

**2. Associative phase of learning**

- attention demand reduced
- enhance versatility of skill:
  - integrate learned features into function
  - high performance training for the unexpected

and the relationship between specific features of motor control and symptoms or potential symptoms. On this basis, an exercise program is tailored to modify the specific features of posture or alignment, movement and muscle activation to optimise tissue loading, with a plan for progression of exercise towards improved function.

Training applies the same principles of motor learning used to develop any new skill, and involves a sequence of steps from initial learning of the movement components followed by progressions of increasing complexity and load. The initial step involves modifying the target features of motor control that have been identified in the assessment to be relevant for the patient's symptoms. This is generally achieved with cognitive training using the principles of motor learning (see Table 11.1).<sup>29</sup> This process progresses from initial optimisation of the target features of motor control using a combination of exercise and clinical strategies that are tailored to the individual, followed by increasing the challenge to consolidate and diversify the control, and finally, integration into function.

There is substantial evidence that the initial step of training should be specific to the identified problem (e.g. control of a specific alignment or muscle activation) and that cognitive training with attention to the task (feedback and understanding of the goal) leads to greater cortical changes than unskilled practice with load. The principles of segmentation (practice of the specific elements of a task that require change prior to integration into the complete task) and simplification (practice with reduced load, demand or complexity to enable high-quality performance of the trained element) are applied. A range of clinical techniques can be

tailored to the individual to achieve the required change in motor performance (Table 11.2). The basic objective of the first phase is to identify a strategy the patient or athlete can employ to modify the feature of motor control that requires improvement, followed by practice.

Once the patient or athlete has learnt to change the feature of motor control that underpins the suboptimal loading, it is then necessary to progress the individual to be able to control these features with progressively challenging tasks. This associative phase of motor learning<sup>29</sup> aims to *refine* the skill, *diversify* the skill and increase the physical capacity.

Progression should include both static and dynamic exercises. Static progressions are very common and there are many examples of exercise approaches that fit this domain. The basic premise is that the alignment of the pelvis and spine is optimised and then maintained statically while load is applied through either the limbs or an external force. Threshold loads and asymmetries are identified and targeted with training. Typical examples are pilates exercises (e.g. reformer exercise with the pelvis and spine maintained statically as the limbs move to slide the body), leg loading tasks in supine, side-bridging, etc. Exercise difficulty is progressed by increasing the load, speed or task instability (e.g. less stable surfaces), and the ability to maintain control of the alignment is the cue to determining the task difficulty that can be tolerated.

Dynamic progressions are less commonly applied in typical exercise programs, but they are no less critical for learning optimal control of the spine and pelvis. Dynamic training involves loading the corrected motor control

**Table 11.2 Clinical techniques to aid motor learning**

Technique	Purpose	Examples
Instructions	Verbal instructions to highlight how a task is to be performed differently	'Roll forwards on tailbone'; 'gently flatten the lower abdomen'
Imagery	Mental image to help a patient understand the modification that is required	'Lengthen spine'
Manual guidance	Therapist's hands on the patient to guide performance for patient to experience optimal performance	Therapist's hands on superior edge of sacrum to guide anterior rotation of pelvis
Manual cues	Patient's hands placed on specific landmarks to provide feedback of optimal alignment or movement	Patient's hands on manubriosternal junction and pubic symphysis to guide upright trunk alignment
Dissociation tasks	Change relative motion between adjacent regions of body	Separate motion of the lumbar spine and pelvis from the thorax
Feedback	Provide information regarding accurate or inaccurate performance of task. Used to provide information of movement strategy, alignment and muscle activation	Visual—mirror; ultrasound imaging (muscle activation) Kinaesthetic—tactile/palpation (finger and thumb on xiphoid and navel to provide feedback of thoracolumbar alignment), tape (applied to the lumbar spine for feedback of alignment) Auditory/visual—EMG biofeedback of obliquus externus abdominis to reduce overactivity
Muscle activation	Modification of muscle activity to enable change in posture or movement	Palpation, observation, EMG biofeedback
Cues/reminders	Technique to remind a patient to modify performance	Tape applied to the lumbar spine that provides input to skin when the lumbar spine flexes
Manual therapy and connective tissue techniques	Modification of joint mobility, muscle activation, muscle tension	Manual therapy to the thoracic spine to reduce thoracic paraspinal muscle activity

feature during movement. As for static training, load is applied while the patient maintains some objective, which in this case is a specific feature of movement. Dynamic training can involve control of the spine as it moves, control of the spine as the whole body moves, or control of spine while the patient is supported on an unstable surface. Examples might include control of the lumbar lordosis during rotation of the spine, and maintaining spine alignment while using movement to balance on a balance board.

Progression to functional exercise and functional tasks is essential. Transfer of improved motor control strategies to the patient's function is best achieved the closer to the function the person practices. This may require segmenting and simplifying a complex function initially to enable correct or optimal performance of the improved skill as a component of the complex task, but should progress to practice of the complete task. It is also necessary to provide challenges—physical (load,

endurance), emotional (stress, fatigue) and environmental (e.g. predictable, unpredictable) to ensure the skill is diversified to address all contexts (Fig. 11.4). Functional training requires that the patient or athlete has learnt to perceive (proprioceptive awareness) the correct performance in order to correct errors. A final phase is to challenge patients to prepare them for high performance with higher load and unexpected challenges.

All patients need to progress through the basic sequence from initial correction of the relevant features of motor control to function, but some also require consideration of other issues to ensure optimal performance is achieved and to overcome potential barriers. For an individual patient this might include management of issues of control of adjacent joints (e.g. foot control problems that modify leg, pelvis, spine movement; scapulothoracic control), continence, breathing, balance, muscle strength and endurance, cardiovascular fitness, unhealthy beliefs and cognitions about pain and injury

and so on. Identification of these issues may be apparent from subjective questioning, observation of movement and specific tests or questionnaires. Treatments may need to be tailored for these aspects and draw on the expertise of other professionals.

Motor learning requires permanence of the learnt motor function. Through practice and diversification, it is a key objective for the improved motor control strategy to be automatically applied in function. In situations of high demand, reinforcement through additional cognitive attention to the correction may be necessary. Development of a versatile and robust motor strategy requires practice and challenge.

### Training of motor control for core stability for prevention of pain and injury

Although there is not yet sufficient high-quality evidence to support the assumption that applying the principles of motor control training can prevent pain and injury, it is plausible that identifying suboptimal features of posture or alignment, muscle activation and movement in an individual, and modifying those features with training, will help to prevent future development of pain. This is a topic of considerable interest and programs have been developed and applied with this in mind. The challenge is to identify suboptimal features that may be relevant for future development of pain or injury when provocation of symptoms is not available for confirmation that relevant features are identified. This approach depends on theoretical models that predict which features may be relevant and how they can be recognised. For athletic and sports performance this requires detailed understanding of optimal motor control for the specific sporting tasks. The approach of screening motor control for risk is strongly advocated by some.<sup>26</sup>

### Considerations for training of motor control for core stability in athletes

Motor control of core stability is particularly relevant for athletes at all levels. The major issues that require specific consideration are:

1. the features of motor control required to complete the task (e.g. the specific combination of movements, postures and muscle activation), which may be highly refined for the completion of the sport-specific function
2. the features of the task that may promote suboptimal control
3. training load and demands required to maintain sporting or athletic performance. This demands that the clinician has expert knowledge of the sport being considered.

Running is an ideal example to illustrate the breadth of goals that are inherent in optimal core stability for an athlete. When running, it is essential to maintain upright posture relative to gravity, to maintain the relative alignment between adjacent segments, both large (body regions—thorax relative to lumbar spine relative to pelvis) and small (intervertebral segments); while moving the spine to transfer load between body regions, absorb reactive moments from foot contact, minimise energy expenditure, achieve progression of the body through space; and maintaining respiration, continence, balance and cardiovascular function.

Any perturbation to this system can disrupt the stability of the system (e.g. landing on the outside of the foot, an unexpected increase in respiratory demand, a modified muscle activation or movement strategy to avoid pain) and lead to interference with other elements in this delicate balance. A holistic view that considers the interaction between elements is necessary. For instance, a runner with low back pain may have augmented co-contraction of trunk muscles to protect the spine from provocation of pain, but this may then compromise the efficiency of the spine for shock absorption, load transfer and use of the chest wall motion to breathe. Detailed understanding of the mechanics of running (Chapter 8) is critical to identifying features that are suboptimal.

### CONCLUSION

This chapter aimed to discuss the rationale for motor control training for core stability, to dispel some common myths and to provide an overview of the comprehensive program required to optimise motor control. It is critical to remember that core stability does not imply stiffness with a sole objective to restrict motion. Optimal control depends on a balance between movement and stiffness that is matched to the demands of the task. Motor control training must be matched to the presentation of the patient and to his or her functional demands.

# Preventing injury

with ROALD BAHR, BEN CLARSEN and GRETHE MYKLEBUST

*An ounce of prevention is worth a pound of cure.*

Benjamin Franklin (1706–1790)

An important role for the sports medicine clinician is to minimise activity-related injury, that is, to improve the benefit:risk ratio associated with physical activity and sport. The 2000s saw a remarkable acceleration in the focus on sports injury prevention. Fortunately, athletes can now benefit from the knowledge that interventions can prevent many major injuries, such as acute knee, ankle and hamstring injuries.

Sports injury prevention can be characterised as being 'primary', 'secondary' or 'tertiary'. In this book, we use the term 'prevention' synonymously with what is technically known as 'primary prevention'.<sup>1</sup> Examples of primary prevention include health promotion and injury prevention (e.g. ankle braces being worn by an entire team, even those without previous ankle sprain). Secondary prevention can be defined as early diagnosis and intervention to limit the development of disability or reduce the risk of re-injury. We refer to this as 'treatment' in this book (e.g. early treatment of an ankle sprain; see Chapter 17). Finally, tertiary prevention is the focus on rehabilitation to reduce and/or correct an existing disability attributed to an underlying disease. We refer to this as 'rehabilitation' (Chapter 18); in the case of a patient who has had an ankle sprain, this would refer to balance exercises and graduated return to sport after the initial treatment for the sprain.

The proactive clinician will give prevention advice during consultations where treatment is being sought. Health professionals working with teams will initiate injury prevention strategies, whether engaged in a traditional team sport like football, or working with a team of individual athletes such as in athletics or swimming. To guide this process, this chapter will introduce the concept

of risk management,<sup>2</sup> which includes systematic injury surveillance, pre- and in-season strategy planning sessions with coaches, regular screening of athletes (see also Chapter 46), and the development of specific prevention programs for the team and for the individual athlete.

From there, this chapter will cover specific topics in injury prevention, including:

- prevention of hamstring strains, ankle sprains and acute knee injuries
- prevention of overuse injuries
- managing load to prevent injury
- protective equipment
- appropriate surfaces.

## A CONCEPTUAL APPROACH TO INJURY PREVENTION

Willem van Mechelen et al. introduced the now classic conceptual model for research on sports injury prevention (Fig. 12.1).<sup>3</sup> This model can be successfully applied by sports medicine clinicians as well. First, identify the magnitude of the problem and describe it in terms of the incidence and severity of sports injuries. If you are responsible for a team, this involves recording all injuries within the squad, as well as training and match exposure. Second, identify the risk factors and injury mechanisms that play a part in causing these sports injuries. For the clinician, this involves systematic steps to examine the athletes, and their training and competition program (see below). The third step is to introduce measures that are likely to reduce the future risk and/or severity of sports injuries, based on the aetiologic factors and injury mechanisms identified in the second step. Finally, the

**Figure 12.1** A conceptual model of injury causation<sup>3</sup>  
FROM VAN MECHELEN ET AL

effect of the measures must be evaluated by repeating the first step. In the research setting, preventive programs are best evaluated using a randomised controlled trial design. For the clinician responsible for a team, continuous surveillance of the injury pattern within the team will reveal whether changes occur in the injury rate.

Clinicians wishing to prevent injuries in a systematic way could base their approach on the updated model by Meeuwisse et al. to describe the potential causative factors for injury.<sup>4, 5</sup> This conceptual model was also expanded by Bahr and Holme<sup>6</sup> and Bahr and Krosshaug<sup>7</sup> (Fig. 12.2). The model illustrates the multifactorial nature of sports injuries, emphasising the relationship of intrinsic and extrinsic risk factors to injury mechanisms.

First, it considers the intrinsic risk factors—factors which may predispose or protect the athlete from injury. This includes athlete characteristics such as age, maturation, gender, body composition and fitness level. One factor that consistently has been documented to be a significant predictor almost regardless of the injury type studied is previous injury. Intrinsic factors such as these interact to predispose to or protect from injury.

Intrinsic risk factors can be modifiable and non-modifiable, and both are important from a prevention point of view. Modifiable risk factors may be targeted for change (e.g. through specific training methods). Non-modifiable factors (such as sex) can be used to target intervention measures to those athletes who are at increased risk. An example of the clinical relevance of sex as a non-modifiable risk factor in sports injury prevention is the higher risk of injury to the anterior cruciate ligament (ACL) in female athletes compared with males. Female athletes are at up to six times greater risk for sustaining an ACL tear than their male counterparts in comparable team sports.<sup>8</sup>

The second group of risk factors is the extrinsic factors athletes are exposed to; for example, floor friction in indoor team sports, snow conditions in alpine skiing, a slippery

surface (running track), very cold weather, or footwear. In the same way as intrinsic factors, extrinsic factors may increase risk (e.g. inappropriate footwear) or protect from injury (appropriate footwear). Exposure to such extrinsic risk factors may interact with the intrinsic factors to make the athlete more or less susceptible to injury.

When intrinsic and extrinsic risk factors act simultaneously, the athlete may be at far greater risk of injury than when risk factors are present in isolation. Note that risk factors—intrinsic (e.g. muscle strength) and extrinsic (e.g. weather conditions)—are usually not static, but change with time, and can even change during one training session (e.g. due to fatigue).

### The inciting event

The final component in injury causation is the inciting event, which is usually referred to as the injury mechanism—what we see when watching an injury situation. Again, it may be helpful to use a comprehensive model to describe the inciting event, which accounts for the events leading to the injury situation (playing situation, player and opponent behaviour), as well as to include a description of whole body and joint biomechanics at the time of injury (Chapter 8).<sup>7</sup> Each injury type and each sport have their typical patterns, and for team medical staff it is important to consult the literature to reveal the typical injuries and their mechanisms for the sport in question. However, one limitation of the model is that it is not obvious how the team's training routine and competitive schedule can be taken into consideration as potential causes, and the model has therefore traditionally mainly been used to describe the causes of acute injuries. For overuse injuries, the inciting event is usually distant from the outcome. For example, for a stress fracture in a long-distance runner, the inciting event is not usually the single training session when pain became evident, but the training and competition program he or she has followed over the previous weeks or months.

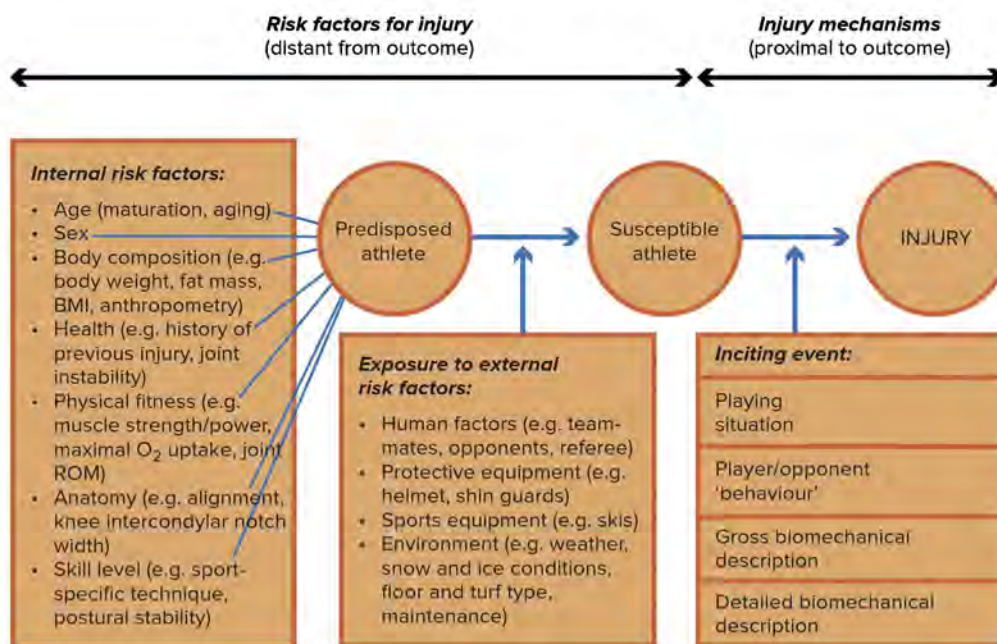

### RISK MANAGEMENT: APPLYING PREVENTION MODELS TO YOUR TEAM

For clinicians, the conceptual models can be adapted to identify potential causes of injury and develop a targeted prevention program. The key questions to ask are: What are the typical injuries? Who is at increased risk? Why? And how do injuries typically occur?

When caring for a defined group of athletes such as a football team or an alpine skiing team, this can be done using a systematic risk management approach.<sup>2</sup> This includes:

- reviewing the literature—what are the typical injuries patterns in the sport?

**Figure 12.2** A comprehensive injury causation model based on the epidemiological model of Meeuwisse et al.<sup>4</sup> and modified by Bahr & Krosshaug.<sup>7</sup> BMI = body mass index; ROM = range of motion

- developing an injury surveillance program within the team—recording injury and participation data
- season analysis—risk profiling the training and competition program
- performing a periodic medical assessment—mapping current problems and intrinsic risk factors
- developing and initiating a targeted prevention program.

### Reviewing the literature—risk identification and assessment

Each sport has its typical injury pattern. Just think of the names of some sports injuries: tennis elbow, runner's knee, jumper's knee. For most sports, there is ample data in the literature to identify and assess the risks. Note that injury risk is not just a question of injury frequency—the severity of injury must also be taken into account.

Injury data can be illustrated by a risk matrix that highlights risks in terms of likelihood and consequences. A risk matrix is a powerful tool for risk assessment. We derive the example shown in Figure 12.3 from soccer. It suggests that injury reductions in the areas of ACL, hamstring and ankle injuries are priorities. By further examining which factors contribute to the causation of these, we can formulate strategies to reduce injury rates. Therefore, in soccer it makes sense to target training programs to prevent ACL tears towards female athletes,

**Figure 12.3** Qualitative risk matrix in elite soccer, illustrating the relationship between injury severity (consequence) and injury incidence (likelihood). The darker the colour, the greater the cross-product of severity and incidence, and the greater the priority should be given to prevention. The matrix also illustrates that risk differs between males and females. (SCD = sudden cardiac death)

while the lower risk among males may not justify such interventions. In contrast, a prevention program for male players should definitely focus on preventing hamstring strains.

## Developing an injury surveillance program within the team

Although basing the risk assessment on data from the literature is valuable, it is necessary to establish a system to monitor injuries and exposure to assess risk within your own team. For medical staff, recording injuries is one of the easiest tasks in risk management as we are required to keep accurate records of all assessments and treatment provided to our patients. Thus, establishing a surveillance system simply involves analysing information that is already there. To make this task even easier, excellent electronic tools are available, with the necessary statistical tools integrated in software used to keep routine patient records.

Another task is to establish a system to record individual training and competition exposure within the team. This is a challenge for the medical team, since they are not always present during practices or on road trips. Therefore this task is often done by the coaching/fitness staff. Many of the injury-recording software programs also have the capability of recording exposure data, which can then be entered based on the coaching records. Exposure data is necessary to be able to calculate risk.

The standard method for calculating injury incidence typically used in team sports is the number of time-loss injuries per 1000 hours of exposure. For some sports and specific player positions (e.g. a baseball pitcher), injuries per pitch may be a more appropriate measure when identifying relationships between injury and exposure. It may also be relevant to record exposure in relation to extrinsic risk factors, such as turf type (e.g. training on grass, gravel, artificial turf), use of personal protective

equipment, and whether the exposure is during competition or training.

Interpretation of injury data is difficult unless exposure data are collected. Consider the example where there is an increase of 30% in the number of match injuries from one season to the next. If the number of matches also increased by 30%, then there would be no increase in injury incidence.

A limitation with the standard methods for injury registration is that they substantially underestimate the true burden of overuse injuries due to a reliance on time-loss injury definitions. Overuse injuries represent the predominant injury type in sports that involve long, monotonous training sessions (e.g. cycling, swimming and long-distance running), as well as in technical sports that involve the repetition of similar movement patterns such as throwing or jumping. Symptoms such as pain or functional limitation most often appear gradually and may be transient in nature. Therefore it is likely that athletes will continue to train and compete despite the presence of overuse conditions, at least in the early phase. The same is the case for minor illness, such as the common cold.

Thus many health problems, especially overuse problems, do not lead to time loss from sport and are therefore not recorded in standard injury surveillance systems.<sup>9</sup> To address this limitation, Clarsen et al.<sup>10, 11</sup> have developed the Oslo Sports Trauma Research Center (OSTRC) Questionnaire on Health Problems for prospective monitoring of all illness and injury, not just those leading to time loss from sports participation. This approach may be more appropriate for sports where overuse injuries and illnesses are expected to dominate.

### Oslo Sports Trauma Research Center Questionnaire on Health Problems

The OSTRC Questionnaire on Health Problems is distributed to athletes once a week to record and monitor the consequences of any illnesses and injuries they have incurred, including those that do not lead to time loss from sport.<sup>10</sup> Ideally, it is delivered as an electronic questionnaire that directs athletes only to relevant questions, based on their responses.

The questionnaire begins with **four key questions** that all athletes should answer (Table 12.1). If they indicate a health problem in any of the questions (i.e. any response except the minimum value), they are then asked:

- whether they are referring to an illness or an injury
- to provide the location (for injuries) or the symptoms (for illnesses)
- to indicate the number of days of time loss the problem has caused in the past week
- whether they have received medical attention for the problem
- whether they have any more problems (in which case the questionnaire starts again).

In some teams and organisations, this weekly questionnaire can act as an important communication platform between athletes and sports medicine clinicians, particularly when athletes are geographically dispersed and/or have inconsistent contact with their team's medical staff. In these cases, it may be useful to add extra questions to the questionnaire such as 'who knows about this problem?' and 'do you have any comments for your team medical staff?'

The severity of each reported problem is rated using the scoring system shown in Table 12.1. By adding the scores for Questions 1 to 4, a severity score out of 100 can be calculated. This score is tracked over time to give a reflection

of the overall impact of the problem and of fluctuations in its severity (Fig. 12.4a). Summary data for the entire team can be collected (Fig. 12.4b).

**Table 12.1 Oslo Sports Trauma Research Center Questionnaire on Health Problems**

Participation	Severity score
<b>Q1. Have you had any difficulties participating in normal training or competition due to injury, illness or other health problems during the past week?</b>	
• Full participation without health problems	0
• Full participation, but with injury/illness	8
• Reduced participation due to injury/illness	17
• Cannot participate due to injury/illness	25
<b>Training volume</b>	
<b>Q2. To what extent have you reduced your training volume due to injury, illness or other health problems during the past week?</b>	
• No reduction	0
• To a minor extent	6
• To a moderate extent	13
• To a major extent	19
• Cannot participate at all	25
<b>Training volume</b>	
<b>Q3. To what extent has injury, illness or other health problems affected your sports performance during the past week?</b>	
• No effect	0
• To a minor extent	6
• To a moderate extent	13
• To a major extent	19
• Cannot participate at all	25
<b>Training volume</b>	
<b>Q4. To what extent have you experienced symptoms/health complaints (e.g. pain, coughing, fever) during the past week?</b>	
• No symptoms/health complaints	0
• To a minor extent	8
• To a moderate extent	17
• To a severe extent	25

### Season analysis—risk profiling the training and competition program

One helpful method to manage risk in sports is a pre-season review of the planned training and competition program to identify risks. The method of season analysis therefore is fundamentally different from injury

surveillance, where data on injuries are collected as they happen. Season analysis represents an attempt to identify risks before they occur. Risks in the program can be related to the competition schedule, the training program, the possibilities for athlete recovery, travel or other issues.

**Figure 12.5** Risk profile. Examples of periods of season when a college basketball team may be at particular risk of injury. The comments below concern the risk periods that are circled.

1. Change of time zone, off-court training surface, climate and altitude during training camp in Colorado. Emphasis on defensive stance training and quick lateral movements could lead to several groin injuries (Chapters 31 and 32). Athletes should not increase the amount or intensity of training too much.
2. Transition to greater amount of on-court training and intensity, combined with several practice games. Floor surface quite hard. Risk of lower limb injuries such as Achilles tendinopathy, medial tibial stress syndrome.
3. New training camp to fine-tune players before beginning the competitive season; practice games on unusually slippery courts. Competition to avoid being cut from the squad leads to increased intensity during training and competition.
4. The beginning of the competitive season. A higher tempo and a packed competitive schedule to which the athlete is unaccustomed. Risk of overuse injury (e.g. patellar tendinopathy, tibial stress fracture) compounded by heavy academic program leads to additional fatigue.
5. High risk of acute injuries during the competitive season, and a tough competition schedule at full intensity.
6. Interposed period of hard basic training, with strength exercises to which the athlete is not accustomed, and plyometric training increases risk of tendinopathy and muscle strain.
7. The end of the competitive season. Worn out and tired players? This is an important time to treat low-level 'grumbling' injuries aggressively. Waiting for the injury to heal with 'rest' alone is not recommended.
8. Transition to basic training period with running on trails.

The analysis is based on the idea that the risk of injuries is greater during transitional periods and that each stage has certain characteristics that may increase risk. Examples are when athletes switch from one training surface to another (e.g. from grass to gravel) or to new types of training (e.g. at the start of a strength training period). Figure 12.5 illustrates how a team may be at particular risk for different injury types at different stages of the season. Other examples of key events which could be correlated with increased injury risk include:

- poor sleep due to tight schedule or time differences
- changeover from heavy pre-season training to competition
- return to play after mid-season pause
- beginning of final rounds
- increased training and competition load associated with representative duties
- change of coach/manager with different training methods
- change in training volume
- change of climate (e.g. move from a training camp in a warm climate to a colder climate)
- selection time for important matches (e.g. representative schedule—a player may hide early symptoms of an injury, thinking this may prevent selection).

Although medical personnel responsible for teams or training groups may have to initiate this type of analysis,

it is strongly recommended that the process be done in collaboration with the coaching team and, if at all possible, the athletes. Their inclusion will enable them to draw on their past experiences with the team, which is especially important if there are no injury surveillance data available from the past. If injury surveillance data are available, the season analysis is an opportunity to review past experiences formally, and discuss whether the injury patterns seen may be related to the training and competition program. For example, a surge in stress fractures in a soccer team may be attributed to a simultaneous increase in the volume of running and a change from a soft to a hard running surface. This type of analysis is an important basis for planning preventive measures, particularly to avoid overuse injuries. The risk profile usually varies from sport to sport, which underlines how important it is that medical staff be intimately familiar with the characteristics of the sport they cover.

### The periodic medical assessment—mapping current problems and intrinsic risk factors

Periodic medical assessments (PMAs) are routinely performed on hundreds of thousands of athletes around the world every year, in some cases required by sports regulations or even by law.

**PRACTICE PEARL**

The value of doing routine physical exams on athletes is questionable. If done properly, they can represent a key ingredient in the risk management program. If they are done simply to clear athletes for participation, their value in injury prevention is limited. Unfortunately, this is commonly the case.

Chapter 46 provides a detailed discussion of the many potential objectives of performing a PMA. In a prevention context, two of these are particularly relevant:

1. to identify current illnesses, injuries and chronic medical conditions
2. to identify factors that increase risk of future injury or illness.

While a PMA is often referred to as a pre-participation or pre-season examination, it is better performed at the end of the season, when there is still sufficient time for optimal treatment and rehabilitation of ongoing illness or injury and time to work on correcting any risk factors identified.

The factors included in the PMA should be tailored to the sport in question, by focusing on conditions known to be particularly prevalent (e.g. low back problems in rowers, eating disorders among female gymnasts, reduced pulmonary function among cross-country skiers), or where the physical requirements of the sport imply a higher risk of certain conditions (e.g. Marfan syndrome among basketball or volleyball players). However, if the purpose is to identify risk factors to predict future injury, the value of doing routine examinations alone is limited. For screening exams to serve a purpose in risk management, there are some additional requirements. First, the exam must be designed to identify athletes with risk factors relevant to the sport in question. Second, there must be a plan to follow up athletes with measures intended to reduce risk, if risk factors are identified. Third, the screening exam and follow-up must be planned and led by the medical and coaching staff of the team. Let us consider each of these requirements in turn.

### 1. Identify athletes with risk factors

The first requirement, that the exam be designed to identify athletes with risk factors relevant to the sport in question, is rarely met in current practice. In fact, in most cases the same screening exam is used across sports. This is inappropriate. There can be no single recipe for all sports, as injury patterns and risk factors differ significantly. To design a screening program for one particular sport, it is therefore necessary to define the key injury types (based on data from the literature on incidence and severity, and preferably also surveillance data as described earlier),

and then to define the key risk factors (for these injuries). Based on this information, the screening exam can be tailored to the sport.

Even if the key risk factors have been defined, a key task remains—to select appropriate methods to screen for these risk factors. Screening methods should be valid, accurate, sensitive and specific. Valid means that the testing method measures the factor you wish to measure. For example, if low hamstring strength is a risk factor for muscle strains, what method should be used to measure this best? That the test is accurate (reliable), means that it will yield the same result each time. Finding valid and accurate tests to measure relevant risk factors is difficult.

However, to predict who may be at increased risk for injury is nearly impossible. A testing method with high sensitivity will identify all players with increased risk. A test with high specificity will identify only players with increased risk. Few, if any, tests exist which can clearly distinguish between athletes with high and low risk for a sports injury.<sup>12</sup> In fact, no tests exist which have high sensitivity *and* high specificity to predict future injury. Therefore, screening tests should be interpreted with caution.

### 2. Plan to follow up risk factors

The second requirement is that if the presence of a known injury risk factor is identified, an appropriate course of action can be taken to control the risk. If strength is inadequate, it should be followed up with a strength training program. If balance is poor, a training program should be designed and implemented to rectify this. This might be on an individual level, but in the absence of predictive screening tests, a team approach is probably more appropriate.

### 3. Medical and coaching staff of the team must be involved in screening and follow-up

In community-level sport, it may be tempting for a club or school to enlist the assistance of local sports medicine personnel to screen their athletes. This is only advisable if they can establish a mechanism to communicate the results to the team, and there are resources to follow up athletes with health problems or risk factors. Also, the specialist must be up to date with screening methods for the sport in question and their interpretation.

## Developing and initiating a targeted prevention program

The final step in the risk management process is to assess the risks to the team and the individual athlete. The injuries (and illnesses) to be targeted are identified from the risk matrix (Fig. 12.3), the scientific literature and team injury surveillance data from past seasons. The season analysis may have identified specific risks associated with the training and

competition program. Finally, the specific injury and risk profile for the individual athlete is mapped through the PMA. Based on this assessment, a prevention program targeting these risks should be developed for the team and for the individual athlete. The next sections provide examples of prevention programs targeting three acute sports injuries—hamstring strains, ankle sprains and acute knee injuries.

## PREVENTING HAMSTRING STRAINS

Hamstring strains are frequent in sports involving maximal sprints and acceleration. Among sprinters, hamstring strains represent approximately one-third of all acute injuries.<sup>13</sup> In studies from professional sports, hamstring strains rank as the first or second most common injury in soccer,<sup>14–17</sup> Australian rules football,<sup>18, 19</sup> rugby union and league,<sup>20, 21</sup> and American football,<sup>22, 23</sup> accounting for one in every five to six injuries in most studies. There also seems to be a trend with a gradual increase in the proportion of hamstring strains compared to other injury types.<sup>24, 25</sup> Hamstring strain injuries are also common in dancing and waterskiing.<sup>26</sup>

### Injury mechanisms

Hamstring strains most often occur during maximal sprints. It is difficult to document exactly at what time during the running cycle injuries occur.<sup>27</sup> However, since the net moment developed by the hamstrings is thought to be maximal in the late swing phase right before heel strike, this is thought to be a vulnerable position.<sup>28, 29</sup> In this instance, the hamstring muscles work eccentrically. Another suggestion is at push-off.

### Risk factors

A number of risk factors have been proposed for hamstring strains, the most prominent being the following four intrinsic factors: age; previous injury; reduced hip range of motion (ROM); and poor hamstring strength.<sup>6, 30</sup> In theory, limited ROM for hip flexion could mean that muscle tension is at its maximum when the muscle is vulnerable close to maximum length. However, this hypothesis has yet to be confirmed, since there are several studies on soccer players suggesting that hamstring flexibility is not a risk factor for strains.<sup>31, 32</sup>

Low hamstring strength would mean that the forces necessary to resist knee flexion and initiate hip extension during maximal sprints could surpass the tolerance of the muscle-tendon unit. Hamstring strength is often expressed relative to quadriceps strength as the hamstrings:quadriceps ratio, since it is the relationship between the ability of the quadriceps to generate speed and the capacity of the hamstrings to resist the resulting forces that is believed to be critical. Several studies show that players with low hamstring strength or low hamstrings:quadriceps strength ratio or side-to-side strength imbalances may be at increased risk of injury.<sup>6</sup>

A history of previous hamstring strain greatly increases injury risk, as documented in numerous studies.<sup>6, 33, 34</sup> Injury can cause scar tissue to form in the musculature, resulting in a less compliant area with increased risk of injury. A previous injury can also lead to reduced ROM or reduced strength, thereby indirectly affecting injury risk. Soccer players with a history of previous hamstring injury have a 5–7 times higher risk of injury.

Older players are at increased risk for hamstring strains, and although older players will be more likely to have a previous injury, increased age is also an independent risk factor for injury.<sup>32, 34</sup>

Short fascicle length in the long head of the biceps femoris is an independent risk factor, especially when combined with low levels of eccentric knee flexor strength.<sup>35</sup> Notably, the greater risk of a future strain injury in older players or those with a previous hamstring injury is reduced when they have longer fascicles and high levels of eccentric strength.

It has been suggested that an indicator of susceptibility for the damage from eccentric exercise is the optimum angle for torque.<sup>36</sup> When this is at a short muscle length, the muscle is thought to be more prone to eccentric damage, but this theory has been challenged.<sup>37</sup>

Other risk factors, which have been suggested but are less well studied include race, sex, level of play, player position, improper running technique, superior running speed (peak performance), low back pain, increases or changes in the training program (particularly intense periods of training), insufficient warm-up and muscle fatigue. Players of African or Australian Aboriginal origin sustain significantly more hamstring strains than Caucasian players,<sup>34</sup> and it has been suggested that these players may be faster runners when compared to their Caucasian counterparts, possibly because of a higher proportion of type II muscle fibres. A faster running speed will generate higher hamstring torques, which may explain the increased injury risk.

### Prevention programs

There are no intervention studies on elite athletes on the preventive effect of flexibility training on hamstring strains. However, one study on military basic trainees indicates a reduced number of lower limb overuse injuries after a period of hamstring stretching,<sup>38</sup> while another military-based study found no effect of stretching.<sup>39</sup> However, it should be noted that these studies were designed to examine the effect of general stretching on lower limb injuries in general, not a specific hamstring program on hamstring strain risk.

Questionnaire-based data on flexibility training methods collected from 30 English professional football clubs, where the stretching practices of the teams were correlated to their hamstring strain rates, indicate that using a standard stretching protocol reduces injury risk.<sup>40</sup> A study from Australian rules football has observed a

reduction in the incidence of hamstring strains with a three-component prevention program, where stretching while fatigued was one of the components.<sup>41</sup> The other factors in the program were sport-specific training drills and high-intensity anaerobic interval training. Thus, it is not possible to determine which of these factors are responsible for the observed effect.

The best evidence for injury prevention is available for programs designed to increase hamstring strength, particularly eccentric hamstring strength. Some studies indicate that low hamstring strength may be a risk factor for sustaining hamstring strains,<sup>31, 42, 43</sup> particularly eccentric strength.<sup>44, 45</sup> EMG studies have shown that activity is highest late in the swing phase and during heel strike, when the hamstrings work eccentrically or transfer from eccentric to concentric muscle action.<sup>29, 46</sup> It is assumed that most hamstring strains occur during eccentric muscle actions, when the muscle activity is highest.<sup>34, 35</sup> It is well documented that strength training is mode specific.<sup>47, 48</sup> Based on this it may be argued that, to be specific, strength training for the hamstring muscles should be eccentric.

Recent studies from Scandinavia have shown that replacing the traditional hamstrings strength exercise used by teams—hamstring curls—with exercises to develop eccentric strength reduces the risk of hamstring strains.<sup>14, 49</sup> Traditional hamstring curls were ineffective in increasing eccentric hamstring strength among elite athletes.<sup>50</sup> In contrast, a simple partner exercise—the Nordic hamstring lower (Fig. 12.6)—improved eccentric strength.<sup>50</sup> A pilot study has also shown that using a special apparatus—the Yo-Yo™ flywheel ergometer—also increases eccentric hamstring strength.<sup>51</sup> Both of these methods prevented hamstring strains in studies on soccer players<sup>14, 49–52</sup> and rugby union players.<sup>20</sup>

Because it is easy to implement Nordic hamstring exercises in a team setting, we recommend this exercise as a specific tool to prevent hamstring injuries. However, to avoid delayed onset muscle soreness it is important to follow the recommended exercise prescription with

**Figure 12.6** The Nordic hamstrings exercise. Subjects are instructed to let themselves fall forwards, and then resist the fall against the ground as long as possible by using their hamstrings

a gradual increase in training load when introducing a program of Nordic hamstring lowers (Table 12.2). By the end of a 10-week training period, many players are able to stop the downward motion completely before touching the ground (i.e. at about 30° of knee flexion), even after being pushed by their partners at a considerable speed. When a player can reach this stage, the characteristics of the Nordic hamstring lower exercise appear to resemble the typical injury situation: eccentric muscle action, high forces and near full-knee extension. The program has been implemented in several different sports and younger age groups, and injuries from the exercise itself have not been recorded.

## PREVENTING ANKLE SPRAINS

with EVERT VERHAGEN

Ankle sprains are the most common injuries seen in sports and recreational activities. Nearly every fifth patient seen in the emergency room after sports-related injuries has

**Table 12.2** Training protocol for Nordic hamstring exercises (see Fig. 12.6).<sup>50</sup> Load is increased as subject can withstand the forward fall longer. When managing to withstand the whole ROM for 12 reps, increase load by adding speed to the starting phase of the motion. The partner can also increase loading further by pushing at the back of shoulders

Week	Sessions per week	Sets and repetitions
1	1	2 × 5
2	2	2 × 6
3	3	3 × 6–8
4	3	3 × 8–10
5–10	3	3 × 12/10/8 reps

sustained an ankle sprain.<sup>53</sup> It has been estimated that there is one ankle sprain per 10 000 persons each day, which translates to approximately 10 million sprains every year in the United States alone.<sup>54</sup> It has been estimated that about 25% of all injuries across all sports are ankle injuries, and even more in some sports like volleyball, basketball and orienteering.<sup>55-60</sup>

### Injury mechanisms

The typical injury mechanism is landing or stepping with the foot in an inverted position (i.e. plantarflexed, internally rotated and supinated). With the foot in this position, the ankle joint is inherently unstable. The posterior talar plafond is more narrow than the anterior portion, thereby reducing the bony stability of the ankle mortise when the foot is plantar flexed. Unless the dynamic musculotendinous ankle stabilisers can compensate for this reduced structural stability when the ankle joint is perturbed, the ligaments that statically stabilise the lateral ankle are acutely overloaded when the athlete puts weight on the inverted foot. In soccer, such perturbations often result from tackles, where the player receives a laterally directed hit on the medial side of the ankle or lower leg, whereupon landing in a supinated position leads to an inversion sprain.<sup>55, 56</sup> In volleyball and basketball, injuries often result from landing on the foot of an opponent or teammate.<sup>57-59</sup>

### Risk factors

The most important risk factor that has been identified for ankle sprains is a previous ankle injury in the past 12-24 months. In fact, research has shown that among adult athletes, four out of five ankle sprains occur in previously injured ankles.<sup>59, 61, 62</sup> Compared to an ankle with no prior injury, the risk of injury is fourfold greater for an ankle that has been sprained one or more times.<sup>57</sup> Furthermore, the more recent the injury, the higher the risk. The injury rate during the first 6-12 months after an ankle sprain is nearly tenfold higher than for an ankle without previous injury. Following an ankle sprain, the proprioceptive system of the ankle is affected, hampering the stability and sense of movement of the ankle joint. This subsequently leads to more inverted positions upon landing from a jump or stride, as well as lesser control over the dynamic musculotendinous ankle stabilisers to counteract perturbations, leading up to a higher chance of subsequent injury in equal situations.<sup>63, 64</sup>

Postural sway is closely linked to a previous ankle sprain occurrence.<sup>65</sup> Postural sway is generally characterised in a practical approach that involves measurements of the duration of time that a subject can maintain a single-leg stance without touching down to recover balance. Athletes who are able to maintain a single-leg stance for

at least 15 seconds are considered to have normal posture, while those that touchdown to regain balance within the 15-second test are considered to have abnormal posture. Athletes with abnormal posture are more likely to suffer ankle sprains.

A number of other risk factors have been suggested to be associated with an increased injury risk, such as sex, height and weight, limb dominance, foot type, foot size, anatomic alignment of the lower extremity, ankle ROM, ankle and generalised joint laxity, and muscle strength. However, the relationship between these factors and injury risk appears to be weak.<sup>65</sup>

### Prevention programs

There is strong evidence that taping or bracing should be recommended for a period of up to 12 months after an ankle sprain, when risk of injury is increased several times.<sup>66</sup> The mechanism by which such ankle orthoses are thought to work is not known with certainty, but may involve simply enhancing the athlete's proprioceptive awareness of the ankle joint. This view is corroborated by the fact that the preventive effect of braces is limited to players with previous injury, where proprioceptive function is reduced.<sup>67-70</sup> In addition, orthoses do not seem to restrict ankle inversion enough to explain their prophylactic effect on ankle sprain incidence. If the protective effect were purely mechanical, one would expect an effect in healthy, previously uninjured ankles as well. The latter has been shown in basketball, but this finding remains to be confirmed in additional research.<sup>71</sup> Many different ankle supports are commercially available.

Ankle taping restricts inversion motion, although it appears that ankle supports are superior to ankle taping since ankle supports do not lose their ability to restrict inversion, while tape does 'loosen up' after several repeated cycles of vertical jumping. Unlike semi-rigid orthoses, the effectiveness of ankle taping has not been tested in randomised controlled trials, but if the effect is mainly through enhancement of proprioception, there is no reason to expect taping has less preventive effect than orthoses. Other factors, such as cost and skin care, should also be considered in the choice between tape and orthoses. Finally, there is no evidence that wearing an ankle orthosis increases the incidence of knee injuries, and most studies suggest that semi-rigid orthoses do not significantly impair athletic performance.<sup>72</sup>

Tropp et al.<sup>68</sup> and others<sup>69, 70</sup> have shown that proprioceptive function is reduced in athletes who complain of a feeling of persistent instability following an ankle sprain. Sensorimotor control of the affected ankle joint is impaired in the immediate recovery period following an acute sprain,<sup>63, 64</sup> but studies have shown that this function can

**Figure 12.7** Balance board training

be restored through a balance board training program.<sup>73–75</sup> In these studies, proprioceptive function was quantified by measuring the reaction time to a sudden inversion strain, or the degree of postural sway during a one-legged balance test. It should be noted that the use of the term proprioceptive function, which is defined as the function of the afferent components only, may be inappropriate in this context. The ability to react to a sudden inversion stimulus or balance on one leg clearly depends on both sensory and motor function, and should perhaps therefore be termed sensorimotor control.

The preventive effect of balance and sensorimotor exercise has been well described in the literature.<sup>66, 76</sup> A balance board training program has been shown to reduce the risk of re-injury in functionally unstable ankles in soccer players.<sup>68</sup> This basic program consists of balance exercises on one leg on a disc (Fig. 12.7). Over the years, this basic program has evolved into a variety of sports-specific multifaceted sensorimotor training programs that involve more types of exercises than one-legged balance exercises alone. In a one-season randomised trial, for example, balance exercises were introduced as part of the regular warm-up

for high-level recreational volleyball players.<sup>77</sup> Ankle sprain incidence was reduced by 60% among players who reported a history of previous injury. Other effective examples can be found for other sports including soccer,<sup>78</sup> handball,<sup>79</sup> basketball<sup>80</sup> and American football.<sup>81</sup>

The specific preventive effect of sensorimotor training has also been studied as part of the rehabilitation process after an initial ankle sprain. This yielded positive results not only for the prevention of secondary injury,<sup>82</sup> but also for other complaints that may persist or develop after the initial ankle injury, such as pain and instability.<sup>74</sup> Consequently, clinical care guidelines advocate the application of sensorimotor training within or straight after the rehabilitation phase after an ankle sprain.<sup>83</sup>

The exact intensity and duration of the program depends on the individual patient and the severity of the initial ankle sprain.

#### PRACTICE PEARL

It appears reasonable to recommend a program of 10–20 minutes of balance board training five times a week over 10–12 weeks for all athletes with a history of ankle sprain (Fig. 12.7).

In other words, taping, bracing and neuromuscular training are all effective for the prevention of ankle sprain recurrences. Although preventive effects have been reported in a general athletic population, evidence suggests this overall effect is due to a strong preventive effect in previously injured athletes (tertiary prevention) and that any effect on fresh ankle sprains (primary prevention) is either non-existent or very low.

The next question is then: which measure should be preferred for the prevention of ankle sprain recurrences? Naturally, the answer is that the method the athlete prefers will achieve the best results. After all, this is the measure that the athlete is most likely to use. However, a combination of an extrinsic prophylactic measure (tape or brace) with neuromuscular training will probably achieve the best preventive outcomes with minimal burden for the athlete (Fig. 12.8).

The preventive potential of combining bracing/taping with balance training lies in the different pathways through which these measures achieve their preventive effect. Extrinsic measures provide immediate protection, but only when worn, as they only provide support for a previously injured ankle and do not target the underlying neuromuscular impairment. Neuromuscular training targets the underlying risk-increasing pathology, but it takes some time before a preventive effect is established. When extrinsic measures are employed during the period of neuromuscular training, the patient benefits

**Figure 12.8** Conceptual illustration of optimal ankle re-injury prevention program<sup>66</sup>

from an immediate risk-reducing effect while targeting the underlying causes of an increased recurrence risk.

## PREVENTING ACUTE KNEE INJURIES

Preventing major knee injuries such as ACL ruptures should be a priority in many sports, especially those characterised by pivoting movements, sudden changes of direction, and accelerations and decelerations. ACL ruptures are one of the most common types of serious sports injury. For example, a typical elite-level female soccer team can expect one ACL injury every season.<sup>84</sup> Due to the costly treatment, long rehabilitation time and increased risk of osteoarthritis associated with ACL injuries, they have received a great deal of attention in sports injury prevention research. Much of the research is also relevant to other types of traumatic knee injuries.

### Injury mechanisms

Approximately 70% of ACL injuries occur in non-contact situations, often during a cutting manoeuvre or a single-leg landing after a jump.<sup>85</sup> Cutting or sidestep manoeuvres are associated with dramatic increases in the varus-valgus and internal rotation moments, as well as deceleration.

The typical ACL injury occurs with the knee externally rotated and in 10–30° of flexion when the knee is placed in a valgus position as the athlete takes off from the planted foot and rotates their upper body with the aim of suddenly changing direction. ACL injury mechanisms are discussed in detail in Chapter 35.

### Risk factors

The most important intrinsic risk factor for ACL injury is sex, with studies in soccer, basketball, handball and wrestling showing that females have a 2–4 times increased risk compared to their male counterparts.<sup>86, 87</sup> The reasons

for this are not completely clear. Various researchers have suggested differences in anatomy, and in hormonal and neuromuscular function as potential reasons for the higher injury risk in females. To date, however, there is little evidence linking all these potential intrinsic risk factors to non-contact ACL injuries, and a great deal of controversy exists on the relative importance of the different factors.<sup>88</sup> Recent studies also suggest that a history of knee ligament injury is a predominant risk factor for a subsequent injury, such as a re-rupture of the ACL graft, an ACL rupture to the contralateral knee, or another severe knee injury.<sup>33, 89</sup>

An extrinsic risk factor for ACL injury in handball and Australian rules football is high friction between shoes and the playing surface. This can cause the foot to stop abruptly during a cutting or turning manoeuvre, increasing stress on the knee.<sup>90, 91</sup> The relationship between playing surfaces and injury risk is discussed at the end of this chapter.

## Prevention programs

There is strong evidence that acute knee injuries can be reduced by 25–50% using structured exercise programs targeting strength, balance and neuromuscular control.<sup>92–96</sup> A number of prevention programs are available, all of which are designed to be performed as a structured warm-up prior to training and matches aiming to:

- alter the quality of the movement in the lower limb
- increase core and lower limb stability
- raise awareness of knee position in relation to the foot
- emphasise alignment of the hip, knee and foot in all exercises.

The primary goal of this strategy is to engrain 'safe' movement patterns and discourage those believed to place the knee at high risk of injury (such as hip adduction/knee valgus).

A recent meta-analysis of nine randomised controlled trials investigating injury prevention programs in soccer players demonstrated an overall positive effect in reducing knee injuries in general (26% reduced risk) and a non-significant trend in reducing ACL injuries in particular.<sup>97</sup> Another meta-analysis, which included randomised and non-randomised trials in a range of sports, found a significant effect of prevention programs in reducing ACL injuries (17% reduced risk). This meta-analysis recommended that for best effect, programs should be aimed at younger athletes, performed for longer than 20 minutes duration, a minimum of twice per week, and include exercise variations and verbal feedback.<sup>98</sup>

Although the International Federation of Association Football (FIFA) 11+ was developed for soccer players, similar multifaceted warm-up programs exist for other sports such as floorball and handball and the same concept can be applied to other sports settings as well.<sup>93, 100</sup>

# 11+ A complete warm-up program

with MARIO BIZZINI, ASTRID JUNGE and JIRI DVOŘÁK

The '11+' injury prevention program was developed by an international group of experts for the International Federation of Association Football (FIFA). It is a good example of a multifaceted 20-minute warm-up program that includes core stability, balance, strength and running exercises (Fig. 12.9). Youth football teams using 11+ as a standard warm-up had

a significantly lower risk of injuries than teams who warmed up as usual. Teams that performed the 11+ at least twice per week had 37% fewer training injuries and 29% fewer match injuries.<sup>95,99</sup>

The FIFA 11+ has three parts: Part 1 consists of running exercises at a slow speed combined with active stretching,

## The 11+

### PART 1 RUNNING EXERCISES - 8 MINUTES

**1 RUNNING STRAIGHT AHEAD**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**2 RUNNING HIP OUT**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**3 RUNNING HIP IN**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**4 RUNNING CIRCILING PARTNER**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**5 RUNNING SHOULDER CONTACT**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**6 RUNNING QUICK FORWARDS & BACKWARDS**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

### PART 2 STRENGTH - PLYOMETRICS - BALANCE - 10 MINUTES

**7 THE BENCH STATIC**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**8 THE BENCH ALTERNATE LEGS**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**9 THE BENCH ONE LEG LIFT AND HOLD**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**10 SIDEWAYS BENCH STATIC**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**11 SIDEWAYS BENCH RAISE & LOWER HIP**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**12 SIDEWAYS BENCH WITH LEG LIFT**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**13 HAMSTRINGS BEGINNER**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**14 HAMSTRINGS INTERMEDIATE**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**15 HAMSTRINGS ADVANCED**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**16 SINGLE-LEG STANCE HOLD THE BALL**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**17 SINGLE-LEG STANCE THROWING BALL WITH PARTNER**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**18 SINGLE-LEG STANCE TEST YOUR PARTNER**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**19 SQUATS WITH TOE RAISE**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**20 SQUATS WALKING LUNGES**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**21 SQUATS ONE-LEG SQUATS**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**22 JUMPING VERTICAL JUMPS**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**23 JUMPING LATERAL JUMPS**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**24 JUMPING BOX JUMPS**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

### PART 3 RUNNING EXERCISES - 2 MINUTES

**25 RUNNING ACROSS THE PITCH**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**26 RUNNING BOUNDING**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**27 RUNNING PLANT & CUT**  
The player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km. In the last 5 minutes, the player is asked to do 10-15 minutes of straight running, 5-6 km.

**KNEE POSITION CORRECT**

178

and controlled partner contacts; Part 2 consists of six sets of exercises, focusing on core and leg strength, balance and plyometrics/agility, each with three levels of increasing difficulty; and Part 3 consists of running exercises at moderate/high speed combined with planting/cutting movements.

The field set-up course is made up of six pairs of parallel cones, approximately 5–6 m apart. Two players start at the same time from the first pair of cones, jog along the inside of the cones and do the various exercises on the way. After the last cone, they run back along the outside. On the way back, speed can be increased progressively as players warm up.

## PART 1: RUNNING EXERCISES

### 1 RUNNING—STRAIGHT AHEAD

Jog straight to the last cone. Make sure you keep your upper body straight and your hip, knee and foot aligned. Do not let your knee buckle inwards. Run slightly more quickly on the way back. 2 sets.

### 2 RUNNING—HIP OUT

Jog to the first cone, stop and lift your knee forwards. Rotate your knee to the side and put your foot down. At the next cone repeat the exercise on the other leg. Repeat until you reach the other side of the pitch. 2 sets.

### 3 RUNNING—HIP IN

Jog to the first cone, stop and lift your knee to the side. Rotate your knee forwards and put your foot down. At the next cone repeat the exercise on the other leg. Repeat until you reach the other side of the pitch. 2 sets.

### 4 RUNNING—CIRCLING PARTNER

Jog to the first cone. Shuffle sideways towards your partner, shuffle an entire circle around one another (without changing the direction you are looking in), then shuffle back to the first cone. Repeat until you reach the other side of the pitch. 2 sets.

### 5 RUNNING—JUMPING WITH SHOULDER CONTACT

Jog to the first cone. Shuffle sideways towards your partner. In the middle, jump sideways towards each other to make shoulder-to-shoulder contact. Land on both feet with your hips and knees bent. Shuffle back to the first cone. Repeat until you reach the other side of the pitch. 2 sets.

### 6 RUNNING—QUICK FORWARD AND BACKWARD SPRINTS

Run quickly to the second cone then run backwards quickly to the first cone, keeping your hips and knees slightly bent. Repeat, running two cones forwards and one cone backwards until you reach the other side of the pitch. 2 sets.

## PART 2: STRENGTH, PLYOMETRICS, BALANCE

All exercises have three levels of increasing difficulty.

Players should begin with level 1, which is presented here. Levels 2 and 3 of exercises 7–12 are presented on [www.fifa.com/medical](http://www.fifa.com/medical) and videos are available in the free mobile application GET SET—Train Smarter.

Only when an exercise can be performed without difficulty for the specified duration and number of repetitions should the player progress to the next level.

### 7.1 THE BENCH—STATIC

**Starting position:** Lie on your front, support your upper body with your forearms, elbows directly under your shoulders.

**Exercise:** Lift up your upper body, pelvis and legs until your

body is in a straight line from head to foot. Pull in stomach and gluteal muscles and hold the position for 20–30 seconds. 3 sets. **Important:** Do not sway or arch your back. Do not move your buttocks upwards.

### 7.2 ALTERNATE LEGS

### 7.3 ONE LEG LIFT AND HOLD

*continued*

**8.1 SIDEWAYS BENCH—STATIC**

**Starting position:** Lie on your side with the knee of your lowermost leg bent to 90°. Support yourself on your forearm and lowermost leg, elbow of supporting arm directly under shoulder. **Exercise:** Lift pelvis and uppermost leg until they form a straight line with your shoulder and hold the position for 20–30 seconds. Repeat on other side. 3 sets. **Important:** Keep pelvis stable and do not let it tilt downwards. Do not tilt shoulders, pelvis or leg forwards or backwards.

**8.2 RAISE AND LOWER HIP****8.3 WITH LEG LIFT****9.1 HAMSTRINGS—BEGINNER**

**Starting position:** Kneel with knees hip-width apart; partner pins your ankles firmly to the ground with both hands.

**Exercise:** Slowly lean forwards, while keeping your body straight from the head to the knees. When you can no longer hold the position, gently take your weight on your hands, falling into a press-up position. 3–5 repetitions. **Important:** Do exercise slowly at first, but speed up once you feel more comfortable.

**9.2 INTERMEDIATE****9.3 ADVANCED****10.1 SINGLE-LEG STANCE—HOLD THE BALL**

**Starting position:** Stand on one leg, knee and hip slightly bent and hold the ball in both hands. **Exercise:** Hold balance and keep body weight on the ball of your foot. Hold for 30 seconds, repeat on the other leg. Exercise can be made more difficult by lifting the heel from the ground slightly or passing the ball around your waist and/or under your other knee. 2 sets on each leg. **Important:** Do not let your knee buckle inwards. Keep your pelvis horizontal and do not let it tilt to the side.

**10.2 THROWING BALL WITH PARTNER****10.3 TEST YOUR PARTNER****11.1 SQUATS WITH TOE RAISE**

**Starting position:** Stand with feet hip-width apart, hands on your hips. **Exercise:** Slowly bend hips, knees and ankles until your knees are flexed to 90°. Lean upper body forwards. Straighten upper body, hips and knees and stand up on your toes. Slowly lower down again, and straighten up slightly more quickly. Repeat for 30 seconds. 2 sets. **Important:** Do not let your knee buckle inwards. Lean upper body forwards with a straight back.

**11.2 WALKING LUNGES****11.3 LEG SQUATS**

**12.1 JUMPING—VERTICAL JUMPS**

**Starting position:** Stand with your feet hip-width apart, hands on your hips. **Exercise:** Slowly bend hips, knees and ankles until your knees are flexed to 90°. Lean upper body forwards. Hold this position for 1 second, then jump as high as you can, and straighten whole body. Land softly on the balls of your feet. Repeat for 30 seconds. 2 sets. **Important:** Jump off both feet. Land gently on the balls of both feet with your knees bent.

**12.2 LATERAL JUMPS****12.3 BOX JUMPS****PART 3: RUNNING EXERCISES****13 RUNNING—ACROSS THE PITCH**

Run approximately 40 m across the pitch at 75–80% of maximum pace, then jog the rest of the way. Keep your upper body straight. Your hip, knee and foot are aligned. Do not let your knees buckle inwards. Jog easily back. 2 sets.

**14 RUNNING—BOUNDING**

Take a few warm-up steps then take 6–8 high bounding steps with a high knee lift and then jog the rest of the way. Lift the knee of the leading leg as high as possible and swing the opposite arm across the body. Keep your upper body straight. Land on the ball of the foot with the knee bent and spring. Do not let your knee buckle inwards. Jog back easily to recover. 2 sets.

**15 RUNNING—PLANT AND CUT**

Jog 4–5 steps straight ahead. Then plant on the right leg and cut to change direction to the left and accelerate again. Sprint 5–7 steps (80–90% of maximum pace) before you

decelerate and plant on the left foot and cut to change direction to the right. Do not let your knee buckle inwards. Repeat the exercise until you reach the other side of the pitch, then jog back. 2 sets.

**PRACTICE PEARL**

The key point of the program is to use the proper technique during all exercises. Pay close attention to correct posture and body control, including straight-leg alignment, knee-over-toe position and soft landings. The FIFA 11+ should be completed as a complete warm-up at least 2–3 times per week; it should take approximately 20 minutes to complete.

See the instructional video of each exercise on <http://f-marc.com/fifa-11-plus/>. The FIFA 11+ poster can be downloaded for free. It is available in nine languages and is provided to clubs free of charge.

**PREVENTING OVERUSE INJURIES**

Overuse injuries are the predominant injury type in sports involving long, monotonous training sessions such as cycling, swimming and running, as well as in technical sports that involve the repetition of similar movement patterns such as throwing, jumping and kicking.<sup>11</sup> They occur among athletes of all levels, particularly in elite athletes and young, dedicated athletes whose total training and competition load increases rapidly.<sup>101</sup>

Although a majority of sports injury prevention research has focused on acute injuries, evidence for overuse injury prevention is increasing.<sup>102</sup> Similar to acute injuries, prevention strategies for overuse injuries can target modifiable intrinsic risk factors such as

flexibility, strength and neuromuscular control, as well as extrinsic risk factors such as shoes or sports equipment. As the 'inciting event' for overuse injuries is cumulative tissue overload that occurs over time, close monitoring of athletes' training and competition loads may be a particularly effective prevention strategy. There is also an opportunity for secondary prevention of overuse injuries via early identification and rapid initiation of appropriate treatment.

**Stretching**

Although stretching has long been promoted as an injury prevention method, recent systematic reviews conclude that there is no evidence to support its efficacy.<sup>103–105</sup> However, targeted stretching of glenohumeral joint

internal rotation remains a popular prevention strategy in throwing athletes, and formed one part of a multimodal training program shown to reduce the rate of overuse shoulder injuries in elite handball players.<sup>106</sup>

### Structured training programs

As discussed previously in this chapter, there is strong evidence that structured multimodal training programs targeting muscle strength and neuromuscular control (such as the FIFA 11+) are effective in preventing acute lower limb injuries in team sports. This approach has also been shown to be effective in preventing lower limb overuse injuries,<sup>93, 95, 107</sup> particularly among adolescent athletes whose risk of overuse injury is almost halved by completing injury prevention programs.<sup>103</sup>

#### PRACTICE PEARL

Structured warm-up programs consisting of strength and neuromuscular control exercises have been shown to halve the rate of lower limb overuse injuries among adolescent athletes.

These promising results have not been consistently replicated in adult populations. A number of studies have failed to show an effect of general or targeted prevention training on lower limb overuse injuries among amateur athletes, professional athletes and military recruits.<sup>78, 108-112</sup> For example, a study of 209 professional soccer players found that eccentric training programs commonly used to treat Achilles and patellar tendinopathy were ineffective when used as an across-the-board prevention strategy.<sup>112</sup> However, one randomised controlled trial found that patellofemoral pain could be prevented among military recruits using a daily exercise program consisting of gluteal and quadriceps strengthening exercises and lower limb stretching exercises.<sup>113</sup> Similarly, a recent randomised trial found that a 10-minute warm-up program consisting of glenohumeral internal rotation stretching, rotator cuff strengthening and scapular stability exercises reduced the prevalence of shoulder injuries among elite-level handball players.<sup>106</sup> Research in this field is ongoing.

### Technique modification

Ensuring optimal sporting technique is likely to be an effective way of preventing overuse injuries, particularly in sports involving repetitive loading patterns. For example, runners should avoid excessive contralateral hip drop to prevent lower limb injuries and lower back pain (Chapter 8), and tennis players should aim for double-handed backhand shots to prevent 'tennis elbow'

(Chapter 9). Further examples of sport-specific technique errors linked to injury are covered in Chapter 9.

### Nutritional strategies to prevent stress fractures

Inadequate levels of calcium and vitamin D, which play an essential role in bone mineralisation, homeostasis and remodelling, are thought to be risk factors for stress fractures (Chapter 4).<sup>114</sup> This may be a particular problem in individuals with inadequate dietary intake or with limited sunlight exposure (due to geographical or cultural reasons), dark skin, or medical conditions that interfere with fat absorption (such as Crohn's disease).<sup>115</sup>

A randomised controlled trial involving female military recruits found that daily supplementation with 100 mg calcium and 800 IU vitamin D reduced the incidence of stress fractures by 20%.<sup>116</sup> This finding is supported by cohort studies of athletes which have shown that high dietary intake of calcium and of vitamin D are associated with lower stress fracture risk.<sup>117, 118</sup> For example, one study of female endurance runners found that for every cup of skim milk consumed per day, the risk of stress fractures was reduced by 63%.<sup>117</sup>

According to current recommendations, 1000 to 1200 mg of calcium per day is required for optimising bone health. Although there is debate regarding optimal vitamin D status, serum 25-hydroxy vitamin D levels should be at least 50 nmol/mL and should ideally be between 90 and 100 nmol/mL.<sup>115</sup> The current recommended daily intake of vitamin D is 600 to 800 IU; however, individual needs may vary according to many factors including sun exposure, and some suggest that up to 2000 IU is indicated in high-risk groups.<sup>115</sup>

It should be noted that bisphosphonates (osteoclast inhibitors), which are commonly used in the treatment of osteoporosis and which may be useful in the treatment of stress fractures,<sup>114, 119</sup> are not effective in preventing bone stress injuries.<sup>120</sup>

### Modifying extrinsic risk factors

In certain sports, injuries are commonly attributed to extrinsic factors such as shoes, insoles and sporting equipment. The extent to which these factors play a role in injury prevention remains a source of much debate.

#### Shoe selection

Individual prescription of different shoe types (such as cushioning, motion control and stability shoes) based on static foot alignment is commonly promoted as an injury prevention method, particularly among shoe retailers.<sup>121</sup> However, a recent meta-analysis of randomised controlled trials suggests that this approach does little to prevent

injuries.<sup>122</sup> In several large trials conducted on military recruits, individualised prescription of shoe type was compared to all subjects receiving a stability shoe.<sup>123-125</sup> No studies were able to demonstrate a difference in the incidence of overuse injuries between groups.

### Barefoot/minimalist running

It has been proposed that running barefoot or in 'minimalist' shoes designed to replicate barefoot running may prevent lower limb overuse injuries.<sup>126, 127</sup> This is because several of the common biomechanical differences seen in barefoot running, such as reduced peak ground reaction forces and increased ankle plantarflexion and knee flexion at foot strike (Chapter 8),<sup>128</sup> are theoretically protective against some injury types. However, this may be an over-simplification of a complex relationship. Although the loads on some structures such as the knee and hip joints may be reduced in barefoot running, other structures such as the forefoot, ankle, Achilles tendon and calf muscles experience increased loading and may be at greater risk of injury. Also, certain individuals fail to adapt their running technique and experience *increased* vertical ground reaction forces when barefoot running.

There is currently no evidence that barefoot or minimalist-shoe running is an effective prevention intervention.<sup>129</sup> In fact, one study which randomly assigned normal (neutral), partial-minimalist and full-minimalist shoes to 103 runners found that the groups using minimalist shoes had injury rates up to three times higher than those in normal neutral shoes.<sup>130</sup> The use of barefoot or minimalist shoes is therefore likely to have more value as a targeted strategy in the management of certain types of running injuries (as discussed in Chapter 8) than as a generalised injury prevention intervention.

### Orthotic insoles

The preventive effects of prefabricated and custom-made orthotic insoles have been investigated in 10 different studies of military personnel, including a total of 4788 subjects.<sup>105</sup> Seven studies found that insoles had a significant preventive effect for a range of lower limb overuse conditions, such as stress fractures, medial tibial stress syndrome, patellofemoral pain and Achilles tendinopathy. Based on these findings, several high-quality meta-analyses have supported the use of orthotic insoles for injury prevention.<sup>104, 105, 131</sup> However, the effects of orthotic insoles in athletes remain unknown, and the exact mechanism by which they prevent injury remains contentious.<sup>131</sup>

### Sports equipment

Careful selection of sports equipment may play an important role in overuse injury prevention. Specific

examples of equipment-related factors related to injury are discussed in Chapter 9.

## MANAGING LOAD TO PREVENT INJURY

with TIM GABBETT

The concept of load management was introduced in Chapter 10 with a focus on athletic performance enhancement. Here, we revisit load management with greater focus on its increasingly recognised role in injury prevention. Of course, this is an artificial separation. In reality, injury prevention and performance enhancement are intimately linked.

### The relationship between load and injury

High training and competition loads have been linked to increased injury risk in a wide variety of sports, including Australian rules football, baseball, basketball, cricket, rugby league, rugby union, rowing, soccer, swimming, volleyball and water polo.<sup>132</sup> This may not only be due to an increased rate of overuse injuries, but also of acute injuries, as overloaded athletes can have impaired neuromuscular control, reaction time and decision-making ability.

In some studies, high absolute loads have been shown to increase injury risk, which has led to certain sport-specific recommendations or regulations on the total amount of training and competition that athletes should perform. For example, in little league baseball there are specific age-based rules on the maximum number of pitches that players can perform per day and the minimum amount of rest required between matches.<sup>133</sup> The effects of these regulations remain undocumented. However, they have been well accepted by the sport and are often credited as having reduced the rate of injury among young baseball pitchers. Similar recommendations have been published by the English Cricket Board in an effort to prevent injuries in fast bowlers.

Although limiting the total amount of training and competition is likely to reduce injuries in many sports, that approach is unlikely to be accepted by elite-level athletes and coaches, whose primary concern is to train hard to maximise performance. The approach also fails to account for the large individual variation in load tolerance between athletes. Any given team will contain 'fragile' athletes as well as 'robust' ones who can tolerate very high loads. In fact, some studies have shown that high training loads may indeed be protective against injury, most probably due to enhanced physical resilience. This is the 'training-injury prevention paradox'.<sup>134</sup>

Rather than limiting the absolute amount of training and competition that athletes can perform, recent attention has focused on developing ways by which

athletes can safely achieve and maintain high loads while minimising injury risk. These include:

1. managing the rate of load increase
2. managing the acute:chronic load ratio, and
3. adjusting training based on athletes' responses to external loads.

In order to monitor the loads athletes are subjected to, they must be quantified. The term 'external load' is often used to refer to loads placed upon the athlete, such as their training volume and intensity, the number of repetitions of certain movements (e.g. throws or jumps) or the number of impacts they are subjected to. Recent technological advances such as GPS, power monitors and wearable microsensors have greatly improved the ability to quantify external loads.<sup>135</sup>

The term 'internal load' is used to refer to the athlete's response to an external training or competition load. It can be measured using subjective measures such as the rate of perceived exertion (RPE) or standardised wellness questionnaires,<sup>136, 137</sup> or using objective measures such as heart rate, physical performance tests, blood markers and heart rate variability.<sup>137</sup>

Both external and internal loads, or indeed a combination of the two (e.g. training duration  $\times$  RPE), can be used to monitor the rate of load increase and the acute:chronic load ratio.

### Monitoring the rate of load increase

A number of studies have shown that large week-to-week differences in training load increase injury risk, irrespective of the total training load.<sup>138-140</sup> For example, a study of Australian Football League players by Piggott et al. showed that 40% of injuries were associated with a change in weekly training load of greater than 10%, compared to the preceding week.<sup>138</sup> Similarly, Gabbett found that when rugby league players' weekly training loads increased by less than 10%, their risk of injury was under 10%. However, when training load was increased by 15% or more, players' injury risk escalated to between 21% and 49% (Fig. 12.10).<sup>134</sup>

Of course, the rate at which week-to-week changes in load can be tolerated will vary between individual athletes and across sports. For example, Nielsen et al. found that novice runners could tolerate a weekly progression in training volume of between 20% and 25% in the first 10 weeks of a running program, without a dramatic increase in injury risk.<sup>140</sup> Nevertheless, based on the current evidence, limiting week-to-week training load increases to 10% seems to be a good rule of thumb.

### Monitoring the acute:chronic load ratio

The acute:chronic load ratio reflects an athlete's training status at a given point in time, taking into account

**Figure 12.10** Likelihood of injury among professional rugby league players with different weekly changes in training load. Note the dramatic increase in risk when week-to-week loading increases by  $\geq 15\%$ . FIGURE ADAPTED FROM GABBETT<sup>134</sup>

their training completed over the previous week (their acute load, synonymous with 'fatigue') and their training completed over the previous 4 weeks (their chronic load, synonymous with 'fitness').

#### PRACTICE PEARL

The acute:chronic load ratio has been linked to both performance and injury risk. An athlete with a high chronic and low acute load will be fit, well rested and ready to perform. Conversely, an athlete with a low chronic and high acute load will be fatigued and have an increased risk of injury.

Studies in rugby league,<sup>141, 142</sup> cricket,<sup>143</sup> Australian rules football,<sup>144</sup> Gaelic football<sup>145</sup> and soccer<sup>146</sup> have demonstrated that athletes with high acute:chronic load ratios have an increased risk of injury. Modelling data from several of these studies, Gabbett showed that ratios exceeding 1.5 represented a 'danger zone' where injury risk was substantially increased.<sup>134</sup> In contrast, ratios between 0.8 and 1.3 represented a 'sweet spot' where injury risk was minimised (Fig. 12.11).

Although the exact thresholds may vary in other sports, the underlying concept is likely to remain the same. In order to minimise their injury risk, athletes should build up training loads gradually, closely monitoring their acute:chronic load ratio. This is especially relevant after a period of reduced training (e.g. due to illness or injury) or when resuming training after an off-season break.<sup>147</sup>

**Figure 12.11** The relationship between the acute:chronic ratio and injury, modelled of using data from cricket, Australian rules football and rugby league  
REPRODUCED WITH PERMISSION FROM *BRITISH JOURNAL OF SPORTS MEDICINE*<sup>134</sup>

The acute:chronic load ratio helps us understand how two athletes performing the same training session may have completely different injury risk, depending on the amount and consistency of training they have performed over the past month. Similarly, it provides athletes and coaches with a guide to what is an acceptable level of training progression to minimise injury risk.

### Monitoring athletes' response to load—the traffic-light approach

Continuous monitoring of athletes' response to training is common practice in many high-level team sports, and may be useful in preventing overtraining, illness and injury. In this context, the goal of daily monitoring is to identify early signs of deleterious overtraining such that appropriate adjustments can be made to the athletes'

## Calculating the acute:chronic load ratio

The acute:chronic load ratio can be calculated using a wide range of load measures, such as GPS and accelerometer-derived metrics,<sup>146</sup> throw counts,<sup>143</sup> and session RPE (training session duration multiplied by the athlete's rate of perceived exertion; see Chapter 10).

Table 12.3 shows an athlete's training data over 12 weeks. In this example, the acute load represents the

cumulative session-RPE data for all training sessions completed by the athlete each week. The chronic load represents the rolling average of the previous 4 weeks' acute loads (i.e. in week 4, the chronic load is the average of weeks 1, 2, 3 and 4. In week 5, it is the average of weeks 2, 3, 4 and 5, and so on). The acute:chronic load ratio is calculated each week by dividing the acute load by the chronic load.

**Table 12.3** An example of calculating the acute:chronic load ratio based on an athlete's session-RPE data over 12 weeks. Note that 4 weeks of data are necessary to calculate the chronic loads and acute:chronic load ratio

Week	Acute load (current week)	Chronic load (average of previous 4 weeks)	Acute:chronic load ratio
1	2750		
2	2250		
3	2500		
4	2750	2562.5	1.07
5	800	2075	0.39
6	1000	1762.5	0.57
7	1200	1437.5	0.83
8	2750	1437.5	1.91
9	2250	1800	1.25
10	2500	2175	1.15
11	2750	2562.5	1.07
12	2250	2437.5	0.92

*continued*

In this example, the athlete had a period of reduced training in weeks 5, 6 and 7—perhaps due to a minor injury. The rapid resumption of normal training in week 8 leads to a spike in the acute:chronic load ratio into the 'danger zone' above 1.5 (Fig. 12.12), indicating an increased risk of subsequent injury.

**Figure 12.12** Monitoring an athlete's acute:chronic load ratio, based on data presented in Table 12.3

training program. We refer to this as the 'traffic light approach' as, based on their daily monitoring results, athletes are often categorised as: able to complete full training (green light); needing reduced training (orange light); or needing complete rest (red light).

Measures that have been used in efforts to detect overtraining can be broadly classified into objective and subjective measures (Table 12.4).

It is not easy for clinicians to decide on the best method of athlete monitoring. Each approach has its own strengths and limitations, and despite an increasing number of commercial claims to the contrary, there is no magic formula to predict which athletes will get sick or injured.

A recent systematic review found that subjective and objective measures generally did not correlate, with subjective measures being more responsive to changes in acute and chronic training loads.<sup>136</sup> As shown in Table 12.4, a number of validated questionnaires can be used to monitor athletes for signs of overtraining. However, these consist of 22–76 questions, making them too time consuming for daily administration.<sup>158</sup> Therefore, teams often use short questionnaires consisting of 5–7 Likert-scale questions for

daily monitoring, with more comprehensive questionnaires administered less frequently.<sup>159</sup> The content of these short questionnaires varies; however, the following subscales have recently been identified as being responsive to acute changes in load:<sup>136</sup>

- non-training stress
- fatigue
- physical recovery
- general health/wellbeing
- being in shape.

Irrespective of the monitoring measures used, the main challenges facing the clinician include:

- establishing each athlete's baseline: their normal training response needs to be known before abnormal responses can be identified
- differentiating between intended and deleterious overtraining: coaches will often schedule hard training sessions to stimulate a training response (Chapter 10).

Due to these challenges, monitoring for overtraining remains as much art as science, and necessitates a close communication with athletes and coaching staff.

**Table 12.4** Examples of measures used to monitor athletes for signs of deleterious overtraining

Objective measures	
Heart rate (HR) measures (e.g. HR versus RPE, <sup>148</sup> HR recovery <sup>149</sup> and HR variability <sup>150</sup> )	
Biochemical, hormonal and immunological markers (from blood or saliva) <sup>137, 151</sup>	
Physical performance tests (e.g. vertical jump height <sup>152</sup> )	
Psychomotor speed <sup>153</sup>	
Subjective measures	
Profile of mood states (POMS) <sup>154, 155</sup>	
Recovery stress questionnaire for athletes (RESTQ-S) <sup>156</sup>	
Daily analyses of life demands of athletes (DALDA) <sup>157</sup>	

## PROTECTIVE EQUIPMENT

Protective equipment has been designed to shield various parts of the body against injury without interfering with sporting activity. Protective equipment can also be used on return to activity after injury in situations where direct contact may aggravate the injury.

Helmets are mandatory in certain sports such as motor racing, motor cycling, cycling, ice hockey, horse-riding and American football. In other sports, the use of helmets is not universally accepted, such as in rugby and skateboarding.

Other protective equipment commonly worn includes: mouth guards in most collision sports; shoulder pads in American football and rugby; chest, forearm and groin protectors in ice hockey; knee pads when playing on artificial surfaces or while rollerblading; wrist guards in rollerblading and snowboarding; and shin pads in soccer and hockey. It is important that protective equipment fits correctly.

The use of protective equipment may increase an athlete's confidence. This may help prevent injuries, but may also lead the athlete to take bigger risks or play more aggressively.

## APPROPRIATE SURFACES

with JOHN ORCHARD

Playing surfaces remain under the injury prevention spotlight, as differing traction and shock absorption properties have long been linked to injury risk. The association between playing surface and injury risk was first proposed in handball as early as 1990.<sup>160</sup> Later, a

large epidemiological study compared the ACL injury rate between two different floor types—wooden floors (parquet, generally having lower friction) and artificial floors (generally having higher friction).<sup>161</sup> The results indicated that the risk of ACL injury among female handball players is higher on high-friction artificial floors than on wooden floors. However, other factors also play a significant role for shoe surface friction, principally shoe type and floor maintenance.

In Australian rules football, Orchard and colleagues noted the greater rate of ACL injuries in the northern (warmer) climates.<sup>162</sup> Although it was tempting to attribute this to drier weather, and thus ground hardness, that hypothesis was not supported by data from American football teams where games were played on natural grass.<sup>163</sup> Further analysis of both the Australian and US data suggested that the type of grass, and thus, the tightness of the thatch, may influence ACL risk; the more northern Australian rules football venues had grass types that permitted excessive shoe-surface traction (Fig. 12.13a-d).

According to turf authority McNitt, perennial rye grass is associated with lower shoe-surface traction than Kentucky blue grass or Bermuda grass because it creates less thatch.<sup>164</sup> These studies suggest that rye grass generally offers a safer surface with respect to ACL injuries for football than some other grasses.

### Natural grass versus artificial turf

The link between artificial turf and injury risk has long been controversial. Early generations of turf, introduced in the 1960s, were linked to an increased risk due to their

(a)

(b)

**Figure 12.13** Four different types of grasses that provide the surface for Australian rules football and have been associated with different rates of ACL injury (a) Bermuda ('couch') grass surface, showing a thick thatch layer between grass leaves and soil (b) Kikuyu grass, also showing a thick thatch layer

(c)

(d)

**Figure 12.13 (cont.)** (c) Rye grass surface, showing a minimal thatch layer. This is probably a safer surface than the others, as the blades or cleats of the football boot are less likely to be 'gripped' by the surface (d) Annual blue grass surface, showing a moderate thatch layer

REPRODUCED WITH PERMISSION FROM *BRITISH JOURNAL OF SPORTS MEDICINE*<sup>162</sup>

having minimal padding and high friction coefficients.<sup>165</sup> However, new turf types are continuously being developed, with newer types (third and fourth generation) having properties closer to natural grass.<sup>166</sup> Research into the injury risk of third- and fourth-generation turf

is conflicting, and in some cases may have been biased by industry funding. Nevertheless, recent systematic reviews have concluded that there is little evidence of any difference in overall injury risk between natural and artificial turf.<sup>165, 167</sup>

# Recovery

with SHONA HALSON and PHIL GLASGOW

*Paul Quantrill will never forget the feeling of pure exhaustion at the most important moment of his career. It was the fourth game of the 2004 American League Championship Series, at Fenway Park, with the Yankees trying to finish a sweep of the Boston Red Sox. The teams were tied, 4-4, heading into the bottom of the 12th. It was Quantrill's 100th relief inning of the season. 'We were done,' Quantrill said. 'We were wrecked. We battled, but we just weren't where we needed to be.'*

www.nytimes.com, 31 March 2016

The concept of mechanotransduction (Chapter 17) recognises that when the body is exposed to mechanical stress, it adapts. In sport, careful manipulation of training parameters induces specific adaptations to enhance performance. Training-induced adaptations include improvements in strength, endurance, neuromuscular control and flexibility. Training to promote adaptation requires a delicate balance of overload and recovery. Strategies to expedite recovery are central to training and competition plans.

Effective recovery can permit greater levels and quality of training and thereby enhance performance. Conversely, inadequate recovery from training and competition impair performance and may eventually result in injury, illness or burnout. How performance changes in response to exercise depends on a complex interplay of factors that include peripheral muscle changes,<sup>1</sup> central neural drive<sup>2</sup> and psychological responses.<sup>3</sup> Effective recovery should seek to address the physiological, structural, neural and psychological limitations of performance.

A range of modalities have been purported to facilitate various aspects of recovery; the evidence for many of these modalities is scant and at times conflicting.

### PRACTICE PEARL

As with many aspects of sports medicine, the most appropriate blend of recovery strategies depends on a detailed understanding of the sport and the athlete as well as the relative benefits of the choice of recovery modality.

## ASSESSING RECOVERY

The traditional way to assess the effectiveness of interventions has been to test the athlete and investigate markers of the 'damage' associated with the test. The primary test models are (i) eccentric contraction induced delayed onset muscle soreness (DOMS); and (ii) sports-related training sessions. The variable nature of the exercise regimens used to induce damage and/or physiological stress make effective generalisation of findings challenging in some cases.

Following such a test, a typical test battery would include analysis of:

- general muscle function (peak torque maximum voluntary contractions: isometric and isokinetic)
- specific performance tasks (counter-movement jump (CMJ), squat jump, repeated sprint ability) which may be more meaningful in terms of direct impact on performance
- extent of tissue damage (creatine kinase, CK)
- level of metabolite removal (blood flow, blood lactate) and perception of soreness (pain on visual analogue scale, VAS)
- athlete's self-perception of recovery as well as psychological measures (e.g. profile of mood states, POMS).

## ACTIVE RECOVERY

Active recovery refers to low-intensity work performed after exercise to facilitate better performance in a subsequent exercise bout. This is a common part of training; 81% of French professional soccer teams carry out some form of cool

down after training.<sup>4</sup> Active recovery is therefore often the first form of recovery performed after exercise.

The type of active recovery performed will be heavily influenced by the duration, intensity and nature of the exercise from which the athlete is recovering. For example, the goals of recovery after a short maximal bout of exercise such as sprinting will be different to those following prolonged endurance events.

### After high-intensity short-duration exercise

For recovery after short-duration high-intensity exercise, passive recovery appears to better promote resynthesis of phosphocreatine (PCr)—a rapidly mobilised reserve of high-energy phosphates in skeletal muscle—than does active recovery. Time to exhaustion was longer when intermittent exercise alternated with passive recovery (15s work: 15s rest) than with active recovery.<sup>5,6</sup> Similar observations were reported for short cycle sprints (4s duration) when followed by passive recovery of 21 seconds when compared to low-intensity active recovery (32%  $\dot{V}O_{2\max}$ ).<sup>7</sup> Since recovery following repeated sprint activities involving the PCr system relies almost exclusively on aerobic factors,<sup>8</sup> the better outcomes with passive recovery may be due to greater availability of oxygen for PCr resynthesis in resting muscles than when muscles are still being contracted (active).<sup>7,9,10</sup> Passive rather than active recovery is therefore recommended following high-intensity short-duration exercise.

### After longer-duration exercise—active recovery and metabolite clearance

Active recovery may have a greater role to play following longer duration activities. It may provide a benefit by increased removal of metabolites, particularly blood lactate. Muscle performance is impaired in the presence of high blood lactate levels,<sup>11</sup> so lactate level is widely considered to be important in determining the extent of recovery after high-intensity exercise. While the role of lactate in sports performance is still a subject of much debate, most studies consider it to be a useful indirect marker of cell and metabolic acidosis.<sup>12</sup>

Active recovery is the most effective way to increase blood flow and facilitate removal of metabolites following exercise.<sup>13–15</sup> Exercise intensity levels close to the anaerobic threshold have been identified as most effective for lactate clearance.<sup>15–17</sup> In a study of 10 moderately trained males, lactate levels were reduced most rapidly when participants ran at 80–100% of their lactate threshold.<sup>17</sup> Runners who self-regulated their speed tended to run at around 80% of threshold and experience comparable reductions in blood lactate. This suggests that moderately trained individuals may self-select the

most appropriate exercise intensity. The physiological mechanism underpinning this observation is unclear.

Active recovery may be of greatest benefit in sports that involve a significant anaerobic contribution. It appears that active recovery is particularly effective if subsequent bouts of exercise are carried out within 10–20 minutes.<sup>15,18</sup> Given that blood lactate levels return to baseline within one hour of passive recovery (Fig. 13.1),<sup>16,19</sup> there is less convincing evidence for active recovery carried out several hours or days after exercise. In a series of studies investigating the effects of active recovery between games separated by 3 days in female soccer players, there was no influence on a wide range of measures of recovery including perceived muscle soreness, neuromuscular fatigue (CMJ), sprint performance, maximal isokinetic knee flexion and extension) or biochemical markers (inflammatory plasma cytokine response, plasma endogenous antioxidants, dietary antioxidants, oxidative stress markers, CK, urea).<sup>20,21</sup>

Similarly, in a study investigating self-selected recovery modalities in Australian Football League (AFL) players over a season, fewer players chose active recovery (pool or cycle) compared with cold-water immersion (CWI), compression garments or passive stretching.<sup>22</sup> There were no benefits on performance measures during a season for any of the recovery modalities. However, those players who used CWI, compression and floor stretching reported

**Figure 13.1** Blood lactate concentrations following exercise. Mean blood lactate (La) concentration during passive (Pass) and active recoveries at: (1) 50% of the difference (50%DT) between individual anaerobic threshold and individual ventilatory threshold (IVT) above the IVT (IVT+50%DT), (2) IVT recovery intensity and (3) 50%DT below the IVT (IVT-50%DT). Comparison between recovery conditions within each time point for soccer players. \*Significant difference versus IVT+50%DT recovery intensity (FROM BALDARI ET AL. 2004<sup>16</sup>)

greater perceived recovery. These findings highlight that players view recovery as an important part of their training and that AFL players tend not to select active recovery. The authors suggested that this may be due to players not wanting to expend further energy.

### Psychological effects of active recovery

While metabolite elimination has been the primary focus of many studies, some authors have reported positive psychological effects of active recovery. Le Meur and Hausswirth have suggested that stimulation of metabosensitive type III and IV afferent nerves may facilitate better mental recovery.<sup>23</sup> In a study investigating the effect of active recovery following rugby matches, there were reductions in a measure of mental wellbeing, the POMS scores, in players who performed low-intensity water-based exercise when compared to passive recovery.<sup>24</sup> We cannot generalise these findings as the study measured only 15 players after one match.

In summary, active recovery most effectively reduces blood lactate levels at exercise intensity close to the lactate threshold; such reductions may improve performance for a subsequent exercise bout within 10–20 minutes. There is no strong evidence for the use of active recovery for exercise bouts that are several hours or days after the initial session. Note that active recovery has never been reported to impair performance.

### MASSAGE

Massage has become ubiquitous in sports recovery. The effectiveness of massage has been attributed to increases in blood flow, mechanical effects on muscle tissue, reduced pain and psychological benefits.

### Massage and blood flow

One of the postulated mechanisms by which massage may speed recovery is through increased local blood flow to remove metabolites and mobilise inflammatory markers. Studies that investigated the influence of massage on muscle blood flow and blood lactate removal reported no improvement in blood flow or blood lactate levels following either superficial or deep massage of the quadriceps after high-intensity cycling. They did, however, observe improved blood flow following active recovery.<sup>12</sup>

In the study by Wiltshire et al. of the effect of massage of the forearm after a fatiguing isometric grip protocol, massage *reduced* blood flow.<sup>25</sup> This may have been due to mechanical pressure on blood vessels. While no other studies have reported blood flow reductions with massage, many studies failed to detect any effect on either blood flow or lactate levels.<sup>26–28</sup> There is strong evidence that, when compared to active recovery, massage is no more effective in reducing blood lactate than passive

control activity. As discussed earlier in this chapter, active recovery is well established as an effective way to facilitate blood flow. Therefore, if the goal of the recovery is to increase local blood flow, active recovery should be the modality of choice. Although some might argue that the lack of effect of massage on blood flow means massage does not assist recovery, massage may address other aspects of recovery.

### Massage, muscle tone and viscoelasticity

Many recovery interventions, particularly the manual therapies, aim to influence the mechanical properties of soft tissues. Athletes and clinicians report reduced muscle tone and spasm following massage. The assumption is that this will reduce soreness, permit force production and enhance quality of movement. However, the influence of soft tissue mechanical properties on performance and recovery has not been well characterised. Massage may reduce tissue stiffness.<sup>29, 30</sup> Although a number of studies have considered the effect of compression on muscle viscoelastic behaviour, there are limited studies investigating the effects of massage on these factors.<sup>30</sup> Thus, the effect of massage on these factors following exercise and the potential performance benefits are not clear.

### Massage and delayed onset muscle soreness (DOMS)

Massage in post-exercise recovery is often assessed using a delayed onset muscle soreness (DOMS) model to determine effects on soreness and measures of muscle performance. While there are challenges extrapolating findings from these studies due to the diverse exercise regimens and massage protocols employed, a few important trends emerge. A number of studies report that massage is effective in reducing post-exercise soreness; however, its effectiveness in improving measures of muscle function is less positive. Smith et al. observed significant reductions in soreness of the elbow flexors following eccentric exercise in participants who received a 30-minute massage 2 hours after exercise; reductions in pain were apparent from 24 to 96 hours post-exercise.<sup>31</sup> Similarly, Zainuddin et al. reported that massage applied for 10 minutes at 3 hours after exercise reduced pain, swelling and serum CK levels when compared to controls.<sup>32</sup> No such improvements were observed for recovery of muscle performance (maximum voluntary contraction). A positive effect on soreness but not muscle function was also observed for 20 minutes of massage administered to the hamstrings 2 hours after eccentric exercise when compared to sham massage.<sup>33</sup>

Positive effects for both muscle performance and soreness have been reported when massage is combined with other modalities. Jakeman, Byrne and Eston compared

a control group with a combination of compression garments and a 30-minute massage administered immediately after exercise.<sup>34</sup> Athletes who received massage and wore compression garments reported less pain as well as improved CMJ, squat jump and isokinetic muscle strength, compared to control athletes. A further study in basketball players using a post-match recovery strategy of combined stretches and massage reported reduced soreness and increased CMJ in male players, while female players demonstrated improvements in sprint performance only.<sup>35</sup>

#### PRACTICE PEARL

The beneficial effects of massage on muscle recovery appear to be greatest when treatment is administered within two hours of exercise; there is no evidence to support the use of massage for recovery 24 hours after exercise has ceased.<sup>36</sup> This makes clinical sense: most recovery modalities discussed in this chapter should be administered as soon as possible after exercise.

### Cellular and structural effects of massage

There is some evidence that massage may influence key cellular mediators. Rapaport et al. reported increases in circulating phenotypic lymphocyte markers and decreased mitogen-stimulated cytokine production following massage.<sup>37</sup> Similarly, Crane et al. observed a downregulation of pro-inflammatory cytokine expression following massage after eccentric exercise.<sup>38</sup> The authors also reported increased activity of mechanically sensitive proteins (FAK and ERK1/2). These observations suggest that the mechanical stimulus provided by massage may be capable of influencing mechanotransduction in the muscle (see Chapter 17). In a series of studies using a rabbit model, researchers from Ohio State University investigating the effects of massage-like compressive loading following eccentric exercise have demonstrated accelerated recovery of isometric torque production,<sup>39</sup> altered viscoelastic properties,<sup>30</sup> decreased number of torn muscle fibres and enhanced restoration of muscle function.<sup>40</sup> They have also identified a number of key variables that may be important to the use of massage in recovery. These have included timing,<sup>41</sup> magnitude and frequency of the applied force, and treatment duration.<sup>39</sup>

These findings provide a conceptual framework for some of the effects of massage; however, further studies are required to determine their clinical significance.

### Psychological effects of massage

Consistent psychological benefits of massage are reported in the literature with positive effects reported for salivary IgA, POMS and perceived recovery of fatigue from exercise. Moraska observed that massage in non-athletic populations reduces psychological measures including anxiety, tension, stress and depression, while increasing mood and quality-of-life measures.<sup>42</sup> Arroyo-Morales et al. suggest that massage restores autonomic nervous system balance via its effects on the parasympathetic nervous system.<sup>43</sup> They observed that a 40-minute massage applied after three 30-second Wingate tests restored or maintained pre-exercise heart rate variability values when compared to sham ultrasound treatment. Massage also facilitates relaxation and has been demonstrated to improve scores on the General Wellbeing Scale (an 18-item scale with subscales measuring anxiety, depression, positive wellbeing, self-control, vitality and general health) and the Perceived Stress Scale in healthy adults.<sup>44</sup>

The type of massage used can influence the degree of relaxation. In one study comparing light, moderate and vibratory stimulation, moderate massage was demonstrated to offer greater reduction in stress with a concomitant decrease in heart rate and EEG.<sup>45</sup> Interestingly, the light and vibratory stimulation groups showed increased arousal as evidenced by increased heart rate and EEG activity. It is therefore important to consider the type of massage intervention used.

Massage is highly valued by athletes. Studies in both athletic and non-athletic populations have highlighted that one of the main reasons for using massage therapy is that it provides a personalised approach to care that enhances relaxation and creates a positive client-therapist relationship.<sup>46</sup> The 'culture' of a massage experience (how professional the setting, the relationship with the clinician) influences the athlete's perception of the massage. There is strong evidence that massage does not increase blood flow or aid metabolite removal, but it may influence various inflammatory and cellular responses. There is no evidence that massage is detrimental to recovery.

#### PRACTICE PEARL

Massage effectively modifies both perception of recovery and soreness. The effect of massage on correlates of performance is less clear and may be strongly influenced by the inclusion of other recovery strategies.

## NEUROMUSCULAR ELECTRICAL STIMULATION

Neuromuscular electrical stimulation (NMES) is a modality commonly used to promote recovery in athletes. A review of NMES in post-exercise performance recovery highlighted the challenges associated with determining its effectiveness due to the wide variety of exercise types as well as stimulation protocols used.<sup>47</sup> In general, the application of electrical stimulation following exercise is proposed to have two primary effects:

1. increased blood flow and metabolite removal through muscle pump action
2. reduction in pain through stimulation of sensory nerve endings.

While attractive in its assumptions, the evidence regarding the ability of NMES to effectively increase local blood flow and reduce blood lactate levels is less convincing.

### NMES and blood flow

The importance of the muscle pump to facilitate blood flow in the lower limb is well established. The calf muscle has been described as the second heart<sup>48</sup> and the effectiveness of low-level calf muscle activity to improve local blood flow has been identified.<sup>49, 50</sup> A number of studies have compared the effect of NMES with active recovery and have consistently shown that active recovery is more effective in increasing blood flow and reducing blood lactate levels. In a study comparing the effects of four modalities (active recovery, passive recovery, NMES and CWI) on the recovery of grip strength following a fatiguing rock-climbing protocol, Heyman et al. reported no difference in blood lactate levels between NMES and passive recovery while observing a significant increase in blood flow and a concomitant reduction in blood lactate following 20 minutes of gentle cycling.<sup>18</sup>

Some positive effects on lower limb blood flow for NMES have recently been reported using devices that focus on peroneal nerve stimulation. These studies derive from the use of electrical stimulation in angiology and highlight the importance of deep calf muscle activity. In two studies investigating peroneal nerve stimulation following a 90-minute shuttle test and a Yo-Yo intermittent recovery test,<sup>51, 52</sup> increases in local blood flow were reported. These observations suggest that NMES of this nature may enhance metabolite clearance following exercise when compared to passive recovery. However, it is not clear how these interventions compare with an active recovery protocol and whether they correspond to improvements in performance.

## NMES and performance

The effect of NMES on correlates of sports performance such as strength, endurance and jump performance has been assessed following various types of exercise. While isolated studies have indicated that NMES may be slightly more effective than passive recovery for restoration of strength<sup>53</sup> and running performance,<sup>52</sup> the majority of authors conclude that NMES is no more effective than passive recovery for these parameters. Although the lack of consistent positive effects of NMES may be due to the wide range of methods of stimulation used following different exercise protocols, it is not possible to state whether NMES effectively restores performance following exercise.<sup>47</sup>

### NMES and muscle soreness

As outlined above, reducing muscle soreness is a common aspect of sports recovery. A number of studies have investigated the effect of NMES on DOMS. Most studies have failed to observe any positive effect of NMES on soreness when compared to active or passive recovery.<sup>47</sup> A few studies have suggested that NMES may temporarily reduce pain,<sup>54, 55</sup> but these effects do not correlate with improved performance. Maffiuletti and DuPont make an interesting observation that NMES can effectively improve the subjective perception of recovery in athletes.<sup>56</sup> The authors highlight that athletes consistently report that they feel better recovered or have greater levels of perceived energy than those who do not use NMES despite displaying no associated improvements in sports performance. The role of altered pain perception and other psychological factors in this regard is unclear; however, as discussed below, the perception of recovery may have beneficial effects for performance.

In summary, there is some limited evidence that NMES can enhance blood flow and metabolite removal with certain types of electrical current applied over the peroneal nerve. There is no evidence that NMES can effectively enhance recovery of correlates of performance, but it may effectively enhance the perception of recovery through neuropsychological means. A pragmatic approach to the use of NMES in recovery is shown in Table 13.1.

## STRETCHING

Athletes often stretch after exercise in an attempt to improve range of motion and reduce the perception of musculotendinous stiffness. While it is a regular component of post-exercise regimens, there is limited evidence of the effect of stretching on various aspects of recovery.

**Table 13.1 A pragmatic approach to the use of neuromuscular electrical stimulation (NMES) in recovery<sup>56</sup>**

- NMES should be combined with submaximal voluntary dynamic contractions (such as toe curls) whenever possible, in order to maximise blood flow increase.
- NMES should be applied distally (to the calf or foot muscles and eventually to the common peroneal nerve) rather than proximally (to the quadriceps muscle belly) to maximise the muscle pump effect.
- NMES is most effective in weight-bearing and contact sports to reduce signs and symptoms of muscle damage.
- NMES should be delivered with low doses but for long durations (such as overnight), during travel or by means of electrostatically charged self-adhesive membranes.

Maffiuletti N, Dupont G. Electrostimulation-related recovery strategies. *Aspetar Sports Medicine Journal* 2015;4:64–70. Reproduced with permission.

Lund et al. suggested that stretching following bouts of eccentric exercise may delay recovery.<sup>57</sup> In a study investigating the effect of static stretching on DOMS following eccentric exercise in the quadriceps of seven untrained females, they reported that recovery of strength was impaired in the group who stretched their quadriceps for three repetitions of 30 seconds each day after exercise. The authors proposed that stretching after eccentric exercise caused further mechanical disruption and exacerbated muscle damage. In contrast, Torres et al. reported no effect of daily stretching on maximum voluntary contraction of the quadriceps following eccentric exercise in healthy untrained men.<sup>58</sup> They also reported no effect of static stretching on CK levels or soreness, but did observe improvements in muscle stiffness when compared to passive recovery. The authors suggest that the changes in muscle stiffness may have functional benefits in terms of normalising muscle tone and enhancing quality of movement. This is an interesting postulation and merits further research.

A few studies have reported positive effects of stretching on cycling performance; Dawson et al. noted improvements in a 6-second cycle sprint test 15 hours after an Australian rules football match with stretching when compared to a control.<sup>59</sup> Dynamic stretching also improved performance during a second exhaustive bout of cycling.<sup>11</sup> Given the isolated nature of these findings and the fact that they were only observed during cycling, it is not possible to state that stretching positively influences recovery of performance in other sport settings.

Most studies report no effect of stretching on recovery. A comparison of static stretching, CWI and passive recovery following strenuous stair climbing in rowers reported no differences between each of the interventions for strength or CK levels.<sup>60</sup> Similarly, no differences were observed for systemic markers of stress and inflammation, blood lactate, anaerobic performance or psychological mood states after an exhaustive bout of endurance exercise for static stretching or for active recovery using either an anti-gravity treadmill or cycle ergometer.<sup>61</sup> Reviews have consistently failed to detect any positive effect of stretching on correlates of recovery after exercise despite testing various different stretching protocols.<sup>62</sup> It

is important to note that post-exercise stretching does not appear to have any detrimental effects on performance.

## SLEEP

Optimal sleep quality and quantity is the single best recovery strategy available to athletes. In studies of performance following partial sleep deprivation, sustained exercise was more affected than single maximal efforts.<sup>63</sup> Thus, longer submaximal exercise tasks such as long-distance running may be affected following sleep deprivation.

Suboptimal sleep may have a range of consequences for athletes beyond reduced performance, such as impaired immunity and endocrine function. This can affect the recovery process and adaptations to training.<sup>64</sup> Sleep deprivation can also result in reduced cognitive function, increased pain perception, mood changes, altered metabolism and changes in inflammatory indicators.<sup>64</sup>

Athletes often rank sleep deprivation and poor sleep quality as prominent causes of fatigue and tiredness.<sup>65</sup> Many athletes often have difficulties sleeping prior to important competitions.<sup>66, 67</sup> Juliff et al. questioned 283 elite Australian athletes and found that 64.0% of athletes indicated worse sleep on at least one occasion in the nights prior to an important competition over the past 12 months.<sup>67</sup> Athletes complained of difficulty falling asleep (82.1%) particularly because of thoughts about the competition (83.5%) and general nervousness (43.8%).

Activity monitors have recently been utilised to measure sleep in British<sup>68</sup> and Australian<sup>69</sup> athletes with quite similar results. The 47 elite British athletes spent a total of  $8:40 \pm 0:50$  hours:minutes in bed, compared with  $8:10 \pm 0:20$  in the control group. The athlete group had a longer sleep latency (time taken to fall asleep) ( $18 \pm 17$  vs.  $5 \pm 3$  min) and a lower sleep efficiency (estimate of sleep quality) than controls ( $81 \pm 6$  vs  $89 \pm 4\%$ ), resulting in a similar time asleep ( $6:55 \pm 0:43$  vs  $7:11 \pm 0:25$  hours:minutes; mean  $\pm$  SD). Thus, athletes had a comparable quantity of sleep to controls, but inferior quality of sleep.

On average, the 124 Australian individual and team sport athletes went to bed at  $23:59 \pm 1.3$ , woke up at  $07:15 \pm 1.2$  and obtained  $6.8 \pm 1.1$  hours of sleep per night. Athletes from individual sports went to bed earlier,

**Table 13.2 Sleep hygiene strategies. Adapted from Halson<sup>64</sup>**

Bedroom	<ul style="list-style-type: none"> <li>• The bedroom should be cool (19–21°C is best), dark and quiet.</li> <li>• A comfortable bed and pillows is important.</li> </ul>
Electronics	<ul style="list-style-type: none"> <li>• Avoid watching television in bed and using the computer or smartphone in bed. These can steal sleep time and form bad habits.</li> </ul>
Food and fluid	<ul style="list-style-type: none"> <li>• Avoid the use of caffeinated food and fluids later in the day.</li> <li>• Do not go to bed after consuming too much fluid; this may result in waking up to use the bathroom.</li> </ul>
Behaviour	<ul style="list-style-type: none"> <li>• Create a good sleep routine by going to bed at the same time and waking up at the same time.</li> <li>• Before bed routine can help the body prepare for sleep. The routine should start about 30 minutes before bedtime (i.e. clean teeth, read a book, etc.).</li> <li>• Avoid watching the clock. Many people who struggle with sleep tend to watch the clock too much. Frequently checking the clock during the night can wake you up (especially if you turn on the light to read the time) and may reinforce negative thoughts.</li> <li>• Be organised. Utilise a 'to-do' list or diary to ensure organisation and avoid unnecessary over-thinking while trying to sleep.</li> <li>• Investigate relaxation/breathing techniques.</li> <li>• If you haven't been able to get to sleep after about 20 minutes or more, get up and do something calming or boring until you feel sleepy, then return to bed and try again. Sit quietly on the couch with the lights off (bright light will tell your brain that it's time to wake up).</li> </ul>

woke up earlier and obtained less sleep (individual vs team; 6.5 vs 7.0 h) than athletes from team sports.<sup>69</sup>

Given the effects of sleep deprivation on performance and other important aspects of elite athlete physiology and psychology, athletes should be appropriately educated regarding the importance of sleep and potential strategies to enhance sleep. Sleep hygiene practices that may enhance sleep quantity and quality are outlined in Table 13.2.

## WATER IMMERSION

Post-exercise water immersion of various types has become popular with elite athletes to accelerate recovery from training and competition. Three main forms of water immersion exist: cold water immersion (CWI), hot water immersion (HWI) and contrast water therapy (CWT). Several authors have conducted meta-analyses to help clarify and explore the effects of these modalities on performance. Poppendieck et al. examined effect sizes for a range of performance measures following various cooling strategies.<sup>70</sup> The largest average effect size was for sprint performance (2.6%,  $g=0.69$ ), followed by endurance parameters (2.6%,  $g=0.19$ ), jump performance (3.0%,  $g=0.15$ ) and strength (1.8%,  $g=0.10$ ). Similarly, Bieuzen et al. examined the effects of CWT on exercise-induced muscle damage and reported significantly greater improvements in CWT when compared to passive recovery.<sup>71</sup> Further, CWT reduced muscle strength loss compared to passive recovery. Studies that compare the different forms of water immersion typically report that CWI and CWT enhance recovery more than HWI when used appropriately following cycling<sup>72, 73</sup> and

resistance training.<sup>74</sup> Studies report accelerated performance recovery following CWI and CWT compared to HWI.<sup>75</sup>

### PRACTICE PEARL

The results of recent meta-analyses suggest that on average CWI and CWT recovery interventions are beneficial for recovery of performance and perceptual parameters.

As a result, recent research has focused on possible underlying mechanisms to explain these improvements.

Cold water immersion and other forms of cryotherapy have traditionally been utilised to minimise inflammatory responses, and decrease oedema and pain. Physiologically, this has been shown to occur through reductions in limb blood flow, and reductions in skin, muscle and core temperature.<sup>76</sup> Further, hydrostatic pressure can limit swelling and fluid accumulation, increase central blood volume and facilitate removal of metabolic waste.<sup>77</sup> Positive cardiovascular effects have also been observed with CWI, including lower heart rate, increased cardiac output and/or stroke volume.<sup>77</sup>

The effects of CWI on both the brain and pacing strategies have also been examined as possible contributors to improved performance findings. De Pauw et al. used brain mapping via electroencephalography to demonstrate changes in brain electrical activity indicative of decreased arousal and increased somatosensory information processing.<sup>78</sup> The same research group also

demonstrated different cycling time trial pacing strategies in the heat,<sup>79</sup> likely the result of decreased thermal strain.

For recovery techniques to be beneficial following training, they must not only accelerate recovery, but also allow adaptations to training to occur. Based on the improvements in performance observed in acute CWI studies, two adaptation theories have been proposed. The first is that hydrotherapy allows athletes to perform subsequent training sessions with a greater training load or quality, thus resulting in an enhanced stimulus for adaptation. Conversely, the second theory suggests that CWI may decrease adaptations to training due to minimisation of fatigue and inflammation occurring following training. Thus, some practitioners are questioning the use of chronic hydrotherapy treatment in elite athletes with respect to a potential negative influence on training adaptation.

Yamane et al. report that regular CWI resulted in an attenuation of cycling performance improvements when compared to a control condition over a training period of 4–6 weeks.<sup>80</sup> Similar findings were reported by Higgins et al. whereby repeat sprint test performance decreased with CWI when compared with control in amateur rugby union players.<sup>81</sup> Further, Frohlich et al. reported a small reduction in single-leg adaptation to strength training in trained male students when compared to cases where the leg was not immersed.<sup>82</sup>

In contrast, recent research using elite cyclists found that CWI had no effect on adaptation during 6 weeks of training.<sup>83</sup> CWI has also been shown to better maintain cycling performance over 5 days.<sup>84, 85</sup> When examining submaximal performance, two recent studies have demonstrated an increase in submaximal cycling<sup>86</sup> and submaximal resistance exercise<sup>87</sup> suggesting that an athlete may be able to train at higher workloads, thereby increasing long-term training adaptation. This is an important new line of investigation as previous studies have focused almost entirely on maximal performance and not on the ability to enhance daily training.

Increasing evidence exists to support the use of CWI and CWT, particularly in acute settings such as that of a competition or event. Further research is needed to fully elucidate the longer-term effects of water immersion on adaptation to training.

## COMPRESSION

Many recovery strategies for elite athletes are based on medical equipment or therapies originally used on patients. Compression clothing is one of these strategies as it has traditionally been used to treat various lymphatic and circulatory conditions.<sup>88</sup> Compression garments are thought to improve return of blood to the heart through application of graduated compression to the limbs from the ankle upwards. The external pressure created by

compression garments may reduce swelling, inflammation and muscle soreness, and thereby enhance recovery.<sup>89</sup>

Research investigating compression in athletes typically focuses on wearing compression either during exercise or during recovery. Research examining performance while wearing compression is conflicting, mainly due to the heterogeneity in subjects, study design and type of compression worn. In a recent meta-analysis, Born et al. reported small effect sizes for the application of compression clothing during exercise for short-duration sprints (10–60 m), vertical-jump height, extending time to exhaustion (such as running at  $\dot{V}O_{2\max}$  or during incremental tests) and time trial performance (3–60 min).<sup>90</sup>

From a specific recovery perspective, compression has been shown to improve performance between two 40 km time trials performed 24 hours apart.<sup>91</sup> In this case, the compression was worn for the full 24 hours, which may not be practical or comfortable for many athletes. Compression has also been shown to improve sprint performance, with a shorter recovery period. Maximal sprint performance was enhanced when using compression for 20 minutes between sprints.<sup>92</sup> Results of a meta-analysis suggest that when compression clothing was applied for recovery purposes after exercise, small to moderate effect sizes were observed in recovery of maximal strength and power, especially vertical-jump exercise; reductions in muscle swelling and perceived muscle pain; blood lactate removal; and increases in body temperature.<sup>88</sup> Research investigating a multifaceted approach to recovery (including the use of full-body compression garments, CWI and sleep) was shown to assist subsequent tennis performance as well as resulting in favourable physiological outcomes such as reduced blood lactate, heart rate and perceived muscle and joint soreness.<sup>93</sup>

From the research available, it appears that compression garments may be beneficial and do not appear to be harmful in any way. We recommend that compression garments be worn for at least 60 minutes after training or competition to maximise the recovery process.

## NUTRITION

with GRAEME CLOSE

Nutrition is essential for complete recovery. Recovery eating and drinking should help meet the athlete's total nutritional goals in terms of energy needs, desire to manipulate physique and overall requirements for nutrients. It must also be manageable within the practical constraints that govern the athlete's food intake; for example, to be affordable, to fit in with the daily timetable and social commitments, and to involve foods and drinks that are acceptable and readily available. Three primary concerns are fluid replacement, restoring fuels (largely carbohydrate in competitive sport today) and repair (largely protein).

## Replacing fluids

Substantial fluid loss should be replaced. The simplest way to determine the amount of fluid lost is by weighing the athlete pre- and post-event. Every 1 kilogram of weight loss equates to 1 litre of fluid loss. The athlete should consume (i.e. via drinks and meals) water and sodium at a modest rate that minimises diuresis/urinary losses.<sup>94</sup> Because sweat losses and obligatory urine losses continue during the post-exercise phase, effective rehydration requires the intake of about 125–150% of the final fluid deficit (e.g. 1.25–1.5 L fluid for every 1 kg of body weight lost).<sup>95</sup>

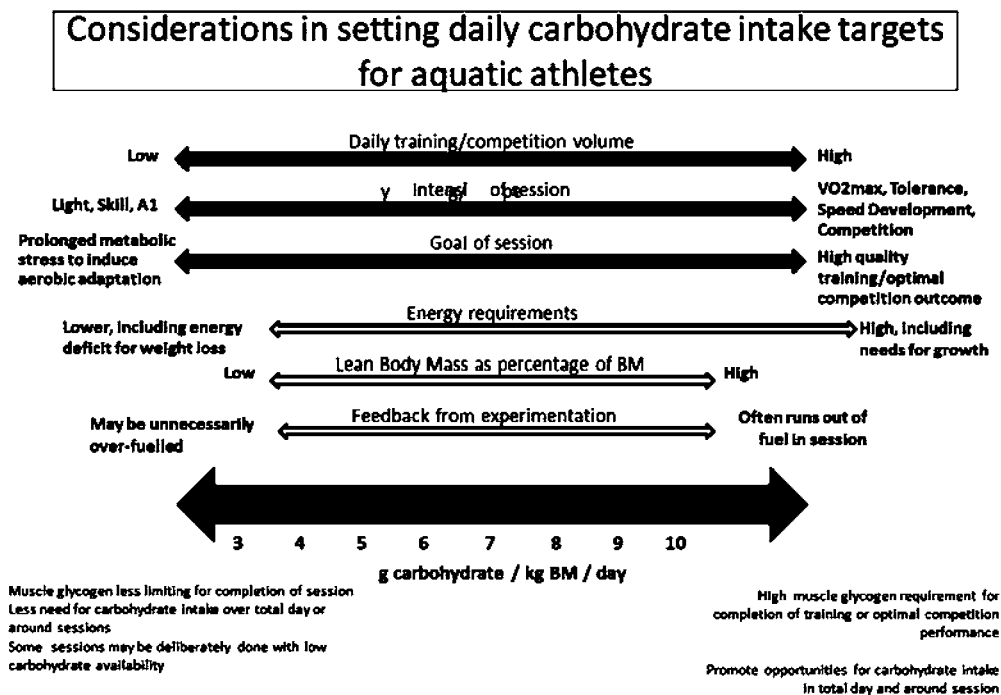

Dietary sodium/sodium chloride (from foods or fluids) helps to retain ingested fluids, especially extracellular fluids, including plasma volume. Therefore, athletes should include sodium in their post-exercise nutrition, particularly when large sodium losses have been incurred. The optimal sodium level in a rehydration drink appears to be close to the sodium content of sweat<sup>96</sup> and thus may be as high as 50–80 mmol/L; this is higher than the sodium concentration of typical sports drinks and is close to the level found in oral rehydration solutions manufactured for the treatment of diarrhoea. Fluid can be consumed with meals or snacks that include salt-rich foods (e.g. breads, breakfast cereals, crackers, cheese, preserved meats) or have been seasoned with added salt. Milk is a better sport drink for rehydration than many commercial products because of its sodium content as well as the protein and fat in it which may aid fluid retention.<sup>97</sup>

Alcohol, particularly strong beers and shots, is a diuretic and is thus discouraged in the recovery period. However, the previous warnings about caffeine as a diuretic appear to be overstated when it is habitually consumed in moderate amounts (e.g. <180 mg = 1–2 standard brewed cups).<sup>95</sup>

The athlete should start to consume fluids on finishing and aim to consume the target volume over the next 2–4 hours. Spreading fluid intake over a period of time promotes gastrointestinal comfort and maximises retention via smaller urine losses.<sup>98</sup> When the athlete's total energy needs are low, low-energy fluids such as water, low-energy soft drinks and mineral waters are recommended. When energy needs are higher, fluids can be combined with energy sources.

## Replacing fuel

As most athletes use carbohydrates as their major fuel supply, glycogen restoration is one of the goals of post-exercise recovery, particularly between bouts of carbohydrate-dependent exercise where there is a priority on performance in the second session. Refuelling requires adequate carbohydrate intake and time. Provided that total energy intake is adequate,<sup>99</sup> increasing carbohydrate intake increases muscle glycogen storage until an upper limit for glycogen synthesis is reached.<sup>100</sup> The most recent guidelines for post-exercise glycogen storage recognise a scaling of requirements according to the fuel cost of training or competition and the athlete's body size.<sup>101</sup> (Figure 13.2)

**Figure 13.2** Considerations in setting daily carbohydrate intake targets for aquatic athletes<sup>98</sup>

REPRINTED WITH PERMISSION FROM L M BURKE AND I MUJIK, 2014, 'NUTRITION FOR RECOVERY IN AQUATIC SPORTS', *INT J SPORTS NUTR EXERC METAB*

**Table 13.3 Carbohydrate-rich recovery snacks (50 g CHO portions)<sup>104</sup>**

- 700–800 mL sports drink
- 2 sports gels
- 500 mL fruit juice or soft drink
- 300 mL carbohydrate loader drink
- 2 slices toast/bread with jam or honey or banana topping
- 2 cereal bars
- 1 cup thick vegetable soup + large bread roll
- 115 g (1 large or 2 small) cake-style muffins, fruit buns or scones
- 250 g baked potato with salsa filling
- 100 g pancakes (2 stack) + 30 g syrup

The mean hourly rate of glycogen restoration is about 2% of the total glycogen capacity per hour; the maximum rate is around 5%. Thus, it can take approximately 24 hours to normalise stores after substantial levels of depletion.<sup>98</sup> During the 2–4 hour period after exercise, there is a potential for high rates of muscle glycogen storage as a result of the depletion-activated stimulation of the glycogen synthase enzyme and exercise-induced increases in muscle membrane permeability and insulin sensitivity.<sup>102</sup> This potential can be realised only if carbohydrates are consumed during this period; if not, refuelling rates are very low.<sup>103</sup>

Meals and snacks can be chosen from a variety of foods and fluids according to personal preferences of type and timing of intake.<sup>100, 101</sup> The athlete should aim for recovery drinks, snacks or meals providing carbohydrate equal to approximately 1 g/kg/hour body mass for the first 4 hours post-exercise. Appropriate carbohydrate-rich foods are shown in Table 13.3.

## Repair

The Australian Institute of Sport (AIS) provides the following information in its factsheet on recovery nutrition:

*Prolonged and high-intensity exercise causes a substantial breakdown of muscle protein. During the recovery phase there is a reduction in catabolic (breakdown) processes and a gradual increase in anabolic (building) processes, which continues for at least 24 hours after exercise. Early intake after exercise (within the first hour) of essential amino acids from good quality protein foods helps to promote the increase in protein rebuilding. Consuming food sources of protein in meals and snacks after this 'window of opportunity' will further promote protein synthesis, though the rate at which it occurs is less.<sup>104</sup>*

The maximal protein synthetic response to a resistance exercise bout is achieved with the intake of approximately 20–25 g of high-quality protein<sup>105</sup> or 0.3 g/kg body mass.

Protein consumed in excess of this threshold stimulates increased rates of irreversible protein oxidation and may be considered wasteful.<sup>105</sup> The pattern of intake over the rest of the day should probably involve a series of meals or snacks every 3–5 hours providing about 20–25 g of protein rather than frequent feedings of smaller protein doses or infrequent meals with larger protein doses.<sup>106</sup> Consuming protein just before bed may also be valuable because it can increase muscle protein synthesis at a time when it would otherwise be low.<sup>107</sup>

The important characteristics of protein-rich foods appear to be the digestibility of the food and its content of essential amino acids, especially leucine. High-quality protein-rich foods such as milk (or whey), eggs and meat are all associated with significant increases in muscle protein synthesis after exercise.<sup>108</sup> In the period immediately after exercise, at least, there is superior muscle protein synthesis with the intake of proteins that are rapidly digested to provide a rapid rise in plasma leucine concentrations; this includes whey protein (a rapidly digested, or 'fast', protein) and liquid protein forms.<sup>109</sup>

Adding a source of carbohydrate to the post-exercise protein will further enhance the training adaptation by reducing the degree of muscle protein breakdown. Chocolate milk is an excellent recovery drink combining carbohydrate and protein.<sup>110</sup> Table 13.4 provides a list of carbohydrate rich snacks that also provide at least 10 g of protein, while Table 13.5 lists a number of everyday foods that provide approximately 10 g of protein.<sup>104</sup>

According to the Australian Institute of Sport (AIS):

*Some athletes finish sessions with a good appetite, so most foods are appealing to eat. On the other hand, a fatigued athlete may only feel like eating something that is compact and easy to chew. When snacks need to be kept or eaten at the training venue itself, foods and drinks that require minimal storage and preparation are useful. At other times, valuable features of recovery foods include being portable and able to travel interstate or overseas. Situations and challenges in sport change from day to day and between athletes, so recovery snacks need to be carefully chosen to meet these needs.<sup>104</sup>*

Increasing numbers of athletes, especially endurance and ultra-endurance, are using fat rather than carbohydrate as their preferred primary fuel source.<sup>111</sup> Others are adopting the 'train low, compete high' regime which involves low carbohydrate intake during training with the aim of optimising use of fat as a fuel source, then using carbohydrates on the day of competition.<sup>112, 113</sup>

In those athletes using the low-carbohydrate high-fat method of fuelling, glycogen stores are not significantly depleted so restoration with a high-carbohydrate meal following exercise is not required. Most athletes on this

**Table 13.4 Carbohydrate-protein recovery snacks (contain 50 g CHO plus valuable source of protein and micronutrients)<sup>104</sup>**

- 250–300 mL liquid meal supplement
- 300 g creamed rice
- 250–300 mL milkshake or fruit smoothie
- 600 mL low-fat flavoured milk
- 1–2 sports bars (check labels for carbohydrate and protein content)
- 1 large bowl (2 cups) breakfast cereal with milk
- 1 large or 2 small cereal bars + 200 g fruit-flavoured yoghurt
- 220 g baked beans on 2 slices of toast
- 1 bread roll with cheese/meat filling + large banana
- 300 g (bowl) fruit salad with 200 g fruit-flavoured yoghurt
- 2 crumpets with thick spread peanut butter + 250 mL glass of milk
- 250 g baked potato + cottage cheese filling + glass of milk

**Table 13.5 Foods providing approximately 10 g of protein<sup>104</sup>**

- Animal foods
  - 40 g of cooked lean beef/pork/lamb
  - 40 g skinless cooked chicken
  - 50 g of canned tuna/salmon or cooked fish
  - 300 mL of milk/glass of Milo
  - 200 g tub of yoghurt
  - 300 mL flavoured milk
  - 1.5 slices (30 g) of cheese
  - 2 eggs
- Plant-based foods
  - 120 g of tofu
  - 4 slices of bread
  - 200 g of baked beans
  - 60 g of nuts
  - 2 cups of pasta/3 cups of rice
  - ¾ cup cooked lentils/kidney beans

regime find that simply having their normal meals is sufficient for nutritional recovery.

Before leaving the topic of fuel, we remind you that research funding influences which elements of sports medicine are addressed. Food companies have openly contributed to the advancement of science with research grant funding to quality scientists. Such funding helps to leverage national health research grants; for example, the National Institutes of Health (NIH) in the United States, the Medical Research Council (MRC) in the UK and the National Health and Medical Research Council (NHMRC) in Australia. Many of these grants were used to study the effects of carbohydrate on recovery and performance. Other industries, such as the dairy industry and the meat

industry, contributed to scientific research but their funding has not matched that of companies whose profits derive largely from carbohydrate products.

## PULLING THE DIFFERENT THREADS TOGETHER—PRACTICAL CONSIDERATIONS FOR THE CLINICIAN

As stated above, recovery modalities for athletes must not only accelerate recovery but also allow training adaptation. Different types of activities place different demands upon the system and as such may require distinct approaches. A sound understanding of the nature of the activity from which the athlete seeks to recover and the associated metabolic, neural, psychological and mechanical load is necessary to ensure that each aspect of recovery is maximised. Table 13.6 summarises some of the factors that influence decision making.

For example, reduced-impact or non weight-bearing exercise may be preferable following high-intensity exercise that involves lower limb mechanical loading. It is reasonable to consider that the tissue damage incurred during sports such as rugby may repair best with reduced mechanical loading; therefore, such strategies including cycling or water-based recovery may be more appropriate.

The perception of recovery appears to be important and has the potential to influence sports performance. Investigating the effect of the perception of soreness on vertical jump in male soccer players, Smith and Jackson reported an inverse relationship between perception of soreness and vertical jump performance.<sup>114</sup> This poses the interesting suggestion that performance during many of the tasks associated with recovery literature may be positively influenced by perception which, one would postulate, is related to central neuropsychological mechanisms rather than to local physiological effects. Given that many of the modalities commonly used as part of recovery have the potential to provide a strong psychological response, the positive effects reported by authors may include a large central effect. This should not be underestimated and specific strategies that maximise the complex interaction between perception, arousal and sports performance should be considered.

This is not without its challenges, as the ability to extrapolate these principles is limited and highly context-specific. For example, the increased stress associated with important matches or during a period of particularly high training load may have significant effects on the perception of fatigue and subsequent performance. It is reasonable to suggest that during periods such as these, various modalities that facilitate enhanced feelings of wellbeing and reduced pain may be preferable; such modalities may include massage, NMES and compression garments.

**Table 13.6 Summary of the various recovery modalities**

Modality	Systems influenced	Key recommendations
Active recovery	<ul style="list-style-type: none"> <li>• Metabolic</li> <li>• Psychological</li> </ul>	<ul style="list-style-type: none"> <li>• Most effective when subsequent exercise bout is within 20 min</li> <li>• Exercise intensity close to lactate threshold</li> </ul>
Massage	<ul style="list-style-type: none"> <li>• Neural</li> <li>• Structural</li> <li>• Psychological</li> </ul>	<ul style="list-style-type: none"> <li>• Within 2 hours after exercise</li> <li>• Minimum 10 min duration</li> <li>• Moderate intensity</li> </ul>
Neuromuscular electrical stimulation	<ul style="list-style-type: none"> <li>• Neural</li> <li>• Psychological</li> </ul>	<ul style="list-style-type: none"> <li>• To increase blood flow, use distal application to initiate calf muscle pump</li> <li>• As soon as possible after exercise</li> </ul>
Stretching	<ul style="list-style-type: none"> <li>• Structural (muscle tone)</li> <li>• Psychological</li> </ul>	<ul style="list-style-type: none"> <li>• Static stretching immediately after exercise</li> <li>• Mild–moderate intensity</li> </ul>
Cold-water immersion	<ul style="list-style-type: none"> <li>• Psychological</li> <li>• Neural</li> <li>• Metabolic</li> </ul>	<ul style="list-style-type: none"> <li>• As soon as possible after exercise</li> <li>• A total duration of 10–15 min</li> <li>• Temperature range 10–15°C</li> </ul>
Contrast water therapy	<ul style="list-style-type: none"> <li>• Psychological</li> <li>• Neural</li> <li>• Metabolic</li> </ul>	<ul style="list-style-type: none"> <li>• As soon as possible after exercise</li> <li>• Cold: 10–15°C</li> <li>• Hot: 38–40°C</li> <li>• 5–7 rotations of 1–2 min</li> </ul>
Compression	<ul style="list-style-type: none"> <li>• Psychological</li> <li>• Neural</li> </ul>	<ul style="list-style-type: none"> <li>• Apply immediately after exercise for minimum of 60 min</li> </ul>
Sleep	<ul style="list-style-type: none"> <li>• All systems</li> </ul>	<ul style="list-style-type: none"> <li>• Use strategies outlined in Table 13.2 to enhance sleep quality</li> </ul>
Nutrition	<ul style="list-style-type: none"> <li>• Metabolic</li> <li>• Structural</li> <li>• Psychological</li> </ul>	<ul style="list-style-type: none"> <li>• Rehydrate to 1.5x the weighed fluid loss (to account for ongoing losses)</li> <li>• Refuel with appropriate carbohydrate (Tables 13.3 and 13.4)</li> <li>• Repair with protein (Tables 13.4 and 13.5)</li> </ul>

Key considerations to aid decision making include the period of the annual training program (e.g. pre-season vs mid-season, high volume vs low volume), as well as the previous experience of the athlete and the culture of the specific sport. For example, CWI has become part of normal practice of many team sports and is now a usual part of the post-match recovery routine. Many such practices become embedded in preparation and scheduling; a recovery strategy that involves an alteration in the use of CWI has the potential to influence the perception of recovery as well as any associated psychological or physiological effects. Similarly, a decision to include specific interventions that are unfamiliar may place additional stress on the athlete. As such any changes (whether introduction or removal

of specific practices) should be carried out at a time that minimises any secondary effects on the athlete.

## SUMMARY

Sleep and good nutritional practices are the cornerstone of recovery and every effort should be made to maximise the benefits of these interventions. As outlined above, additional modalities may be used to augment recovery through the complex interaction of psychological, metabolic, structural and neurophysiological factors. The ability to influence recovery in the sporting environment relies on the intelligent application of these principles to meet the specific needs of the athlete.

# Clinical assessment: moving from rote to rigorous

by CHAD COOK

*Listen: the patient is telling you the diagnosis.*

Sir William Osler, Canadian physician (1849–1919)

Clinical assessment is every top clinician's foundation stone and it is a complex skill. Its three goals are to:

1. determine the diagnosis of the patient
2. identify appropriate treatment mechanisms specific to that condition, and
3. build a professional, interpersonal relationship with the patient to guide efficient management.

Differential diagnosis is used to identify the pertinent diagnosis (condition) of the patient and is the focus of this chapter. This chapter should be read together with Chapter 15.

Differential diagnosis is a systematic process used to identify the proper diagnosis from a competing set of possible diagnoses. The diagnostic process involves identifying or determining the aetiology of a disease or condition through evaluation of patient history, physical examination, and review of laboratory data or diagnostic imaging; and the subsequent descriptive title of that finding.<sup>1</sup>

### WHY IS DIFFERENTIAL DIAGNOSIS IMPORTANT?

Failure to correctly identify an appropriate diagnosis can lead to negative patient-reported outcomes,<sup>2</sup> delays in appropriate treatment,<sup>1</sup> and unnecessary healthcare costs.<sup>3</sup>

What makes diagnostic tests inaccurate?

- failure to order appropriate tests (58% of instances)
- inadequate history/physical examination (42% of instances)
- incorrect test interpretations (37% of instances).<sup>4</sup>

With respect to medical errors, diagnostic errors are the most commonly recorded type (29% of all errors) and account for the highest proportion of total payments (35%).<sup>5</sup>

#### PRACTICE PEARL

Differential diagnostic errors result in death or disability almost twice as often as other error categories.

Although the exact prevalence of diagnostic error remains unknown, data from autopsy series spanning several decades conservatively and consistently reveal error rates of 10–15%.<sup>6</sup>

### DIFFERENTIAL DIAGNOSIS: A THREE-STEP PROCESS

Regardless of treatment environment, most clinicians follow a three-step questioning process during diagnostic assessment.<sup>7</sup>

1. The first question of diagnosis involves the query of whether the patient's symptoms or emergent injury are reflective of a visceral disorder or a serious or potentially life-threatening illness. It is critical to be able to differentiate patients with symptoms that arise from a potentially life-threatening pathology or a non-mechanical disorder (i.e. referred pain).
2. The second question of diagnosis involves determining from where is the patient's pain arising? This step has three substeps that involve: a. ruling out a location; b. ruling in a location but not knowing the tissue-related structure; and c. confirming the tissue-related structure that is causal. Although it is assumed that one can make an accurate tissue-related diagnosis, it is well known that differentiating tissue in the low back, shoulder, abdomen and hip is very challenging and it is not uncommon to see clinicians treat these areas without full knowledge of the tissue of origin. We will discuss this further at the end of this chapter.

3. The third question of diagnosis involves determining what has gone wrong with this person as a whole that would cause the pain experience to develop and persist.<sup>7</sup> This stage involves careful exploration of the social, psychosocial and socioeconomic contextual elements. This element is outlined in Chapter 17 (treatment) and given more detailed attention in Chapters 23 (neck pain) and 29 (low back pain).

## HOW TO CALCULATE AN ACCURATE DIAGNOSIS

Diagnostic accuracy can be evaluated through a common set of metrics, metrics that are universally used regardless of testing type (e.g. imaging [Chapter 15], clinical testing, laboratory testing).

### PRACTICE PEARL

**Absolutely essential metrics that every clinician MUST understand include reliability, sensitivity and specificity, positive and negative predictive values, and positive and negative likelihood ratios (LR+ and LR–, respectively).**

## Reliability

In diagnostic terms, reliability involves the ability of a test to consistently identify a similar finding when retested (e.g. dynamometer testing for strength), or when used by a different clinician, or the level of consistent agreement among two or more clinicians when a particular test which requires interpretation is used (e.g. Lachman's test). Reliability is a required characteristic of diagnostic testing and is generally scored by 0–1 if one evaluates a numerically scored test such as a goniometer, or 0–1 if one assesses agreement among clinicians (higher scores reflecting greater agreement).

## Sensitivity and specificity

Sensitivity and specificity are internal measures (meaning they are relatively independent of the sample) that are used in two distinct populations: 1. the disease of interest or injured population (sensitivity); and 2. a competing disease or non-injured population (specificity). Sensitivity is the percentage of people who test positive for a specific disease among a group of people who have the disease and this value is generally scored from 0%–100%. Higher values have a greater ability to accurately identify those *who have the disease of interest*. Specificity is the percentage of people who test negative for a specific disease among a group of people who do not have the disease and this value is also scored from 0%–100%. Higher values are more accurate at identifying those *who do not have the disease of interest*.

To recap, sensitivity and specificity capture values from two distinct populations: 1. the disease of interest or injured population (sensitivity); and 2. a competing disease or non-injured population (specificity). Figure 14.1 represents the conditions of interest for calculating sensitivity and specificity. Sensitivity only reflects those who have a 'true positive' and a 'false negative' test finding. Specificity only represents those who have a 'true negative' and a 'false positive' test finding. As one can see, each value only represents (potentially) one-half of the diagnostic story, and using these values independently is a mistake commonly made among clinicians.

### PRACTICE PEARL

**The assumptions of SP in ('high specificity rules in') and SN out ('high sensitivity rules out') are erroneously based on these assumptions.**

Unfortunately, these outdated assumptions are misguided and cannot be advocated for clinical practice, primarily because routinely used tests have very high sensitivity and very low specificity (and vice versa), eliminating their capacity to discriminate conditions.

## Positive and negative predictive values

Predictive values reflect the clinical setting. They are relevant when one asks the clinical question, 'The clinical screening test is positive. What is the likelihood that this patient truly has the condition?' Positive predictive value

**Figure 14.1** Sensitivity is measured among those individuals who have the disease. A great number of true positives and few false negatives lead to a high sensitivity (left ovoid). Specificity is measured among those who do not have the disease. In this case, a low number of false positives and a high number of true negatives generate a high specificity. Each of these numbers only represents half the diagnostic story.

is the probability that subjects with a positive screening test truly have the disease. Negative predictive value is the probability that subjects with a negative screening test truly don't have the disease.

Like sensitivity and specificity, positive and negative predictive values only capture a portion of the population (Fig. 14.2) and should not be used exclusively in clinical practice because they fail to tell the full story of the test's utility. Positive predictive values include only true positives and false positives. Negative predictive values include only false and true negatives.

#### PRACTICE PEARL

Very importantly, positive and negative predictive values are markedly influenced by the prevalence of disease in the population that is being tested. If we test in a high-prevalence setting, it is more likely that persons who test positive truly have disease than if the test is performed in a population with low prevalence, thus artificially supporting the diagnostic value of a positive finding on a test.

### Likelihood ratio

A high positive likelihood ratio (LR+) influences post-test probability with a positive finding. A value of  $>1$  rules in a diagnosis. A low negative likelihood ratio (LR-) influences post-test probability with a negative finding. A value closer to 0 is best and rules out the condition. Although others have suggested thresholds for independent decision making, likelihood ratios should be evaluated within the context of pre-test prevalence and in each unique clinical setting.

**Figure 14.2** Positive and negative predictive values. These should be used when the clinician is trying to answer the question, 'The clinical screening test is positive. What is the likelihood that this patient truly has the condition?'

Both sensitivity and specificity are used to determine positive and negative likelihood ratios. LR+ is calculated using the formula  $(\text{sensitivity})/(100-\text{specificity})$ , whereas LR- is calculated using the formula  $(100-\text{sensitivity})/(\text{specificity})$ . In LR+ and LR- the full population of interest, including those with and without the disease of interest, is factored into the decision-making metrics.

This supports likelihood ratios as the most favourable metric for determining influence of post-test probability and for truly understanding the influence of a test on diagnosis accuracy. Likelihood ratios account for the prevalence, give further perspective, and allow for adjustments of test values in extreme cases of low or high prevalence. Some consistencies occur regardless of disease of interest. A higher pre-test probability will always improve the post-test probability. A lower pre-test probability will demand a strong LR+ (to rule in); conversely, a higher pre-test probability will require a lower LR- (to rule out) to notably alter the post-test probability.

### Clinical utility

Clinical utility is a term used when evaluating the ability of the metrics to influence post-test probability (either in ruling out the condition or ruling it in) or just improving your likelihood of being correct. A nomogram is a routinely used mechanism to identify post-test probability. A nomogram has three scoring mechanisms, mounted vertically, left to right (Fig. 14.3).<sup>8</sup>

**Figure 14.3** Fagan's nomogram<sup>8</sup>

REPRODUCED FROM FAGAN TJ. LETTER: NOMOGRAM FOR BAYES' THEOREM. N ENGL J MED. 1975;293(5):257

## Applying Fagan's nomogram to the clinical setting: this tool is a key and underrated instrument for your career

Nomograms are an important learning mechanism to understand the interplay of pre-test probability, test metrics and post-test probability when differentially diagnosing. Consider the case of a patient with an anterior cruciate ligament (ACL) injury (Fig. 14.4). Although ACL injuries are relatively uncommon per athlete exposure, the injuries make up a larger percentage of patients with knee problems in the sports medicine setting.<sup>9</sup>

If the percentage of individuals seen with an ACL injury in a busy sports medicine setting is 15%, one can assume that by chance, if the clinician 'guessed' ACL injury, he or she would be correct in 15% of cases. Since our goal is to improve post-test

probability, the clinician may use a Lachman's test to further evaluate the likelihood of the condition. In a meta-analysis, the Lachman's test had an LR+ of 4.5 and LR- of 0.2.<sup>10</sup> Using the pre-test probability of 15% (based on numbers from the busy sports medicine setting) a positive Lachman's test would increase the post-test probability to 44% (green arrow, Fig. 14.4). In contrast, a negative finding on the Lachman's would result in a post-test probability of 4% (red arrow, Fig. 14.4).

Similar calculations can be performed for all conditions in all settings, with an understanding that pre-test prevalence will vary in different settings. Note that likelihood ratios are only as good as the influence they provide on post-test probability.

The left column represents the pre-test probability of the disease of interest with either no testing, based on the probability of occurrence in the practice environment of

**Figure 14.4** This illustrates the case where the pre-test probability (left) was 15%, LR+ (middle line) was 4.5 and the post-test probability (derived from those points if the test was positive, green arrow) was 44%. In practice, this means the clinician has increased his/her confidence about a diagnosis from 'relatively unlikely' to 'relatively likely'. This will affect the treatment plan and the conversation with the patient as to the treatment plan (see 'shared decision making' in Chapters 2 and 15.)

REPRODUCED WITH PERMISSION OF NEW ENGLAND JOURNAL OF MEDICINE

the clinician (i.e. anterior cruciate ligament tears are more common in a sports medicine specialist's environment), or based on the data used to evaluate the sample. This value is scored 0% (low prevalence) to 99% (high prevalence). The middle column represents the inherent likelihood ratio (positive in the upper column, negative in the lower column) and is generally combined with the pre-test probability to determine post-test probability.

The final column (on the right of the nomogram) represents the post-test probability. This value is determined by running a line from the pre-test probability, through the middle column (test metric) to the post-test probability value (Fig. 14.4).

### PRACTICE PEARL

Differential diagnosis is case dependent and several rules of thumb are useful.

Tests will generally have high LR+ or a small LR- but rarely both. Consequently, the test metrics drive appropriate use: some should be used early to rule out a condition (those with small LR-) and some should be used later to confirm the presence of the condition (those with a large LR+). If the tests are used inappropriately, such as using a test with low LR- but also a low LR+, to rule in a condition, one is unlikely to accurately represent what the test is designed to do. Table 14.1 gives some examples of which tests are best for use early to 'rule out' a condition (small LR-) or late to 'rule in' a condition (large LR+).

For a comprehensive list of the best tests and measures, and each test's individual metrics, see the textbooks on physical examination by Professors Chad Cook and Eric Hegedus (Fig. 14.5)<sup>11</sup> and clinical assessment by Dr Michael Reiman (Fig. 14.5).<sup>12</sup> Both are essential resources.

**Table 14.1** Common tests and measures and the test's ability to 'rule in' or 'rule out' a condition<sup>11</sup>

Test	Dominant test metric	Best use in clinical practice
Straight-leg raise for lumbar radiculopathy	A (negative) test has a small LR– and reduces to the post-test probability of lumbar radiculopathy	The test should be used early in the examination to rule out lumbar radiculopathy only
The External Rotation Lag sign for infraspinatus tears of the shoulder	A (positive) test has a high LR+ and increases the post-test probability of an infraspinatus tear	The test should be used near the end of the examination to rule in an infraspinatus tear of the shoulder
The Hawkins–Kennedy test for impingement of the shoulder	A (negative) test has a low LR– and reduces the post-test probability of shoulder impingement	The test should be used early in the examination to rule out impingement of the shoulder
The patellar-pubic percussion test for the hip (fractured femur)	The test has both a low LR– and a high LR+ and influences post-test probability with a negative and a positive	The test is a rare one that can rule in or rule out a hip fracture and can be used at all time points, respecting safety for the patient
The anterior drawer test for an ACL tear	A (positive) test has a high LR+ and increases the post-test probability of an ACL tear	The test should be used near the end of the examination to rule in an ACL tear
The squeeze test for a syndesmosis injury at the ankle	The test does not exhibit a high LR+ or a small LR–, thus it does not influence post-test probability	The test should not be used to rule in or rule out

## THE FORMAL DIAGNOSTIC ASSESSMENT

Diagnosis relies on taking a careful history, performing a thorough physical examination and using appropriate investigations. There is a tendency for clinicians to rely too heavily on sophisticated investigations and to neglect their clinical skills.<sup>13</sup> The goal of the clinical assessment when considering differential diagnosis is to improve post-test probability, thus providing the most appropriately aligned care to the athlete. During clinical assessment, all test findings have the capacity to influence post-test probability, including: 1. patient history and intake information; 2. observation; 3. the dedicated clinical (movement and performance) examination; and 4. special triage or confirmatory testing.

It is imperative to recognise that key features such as training history, nutrition, general health, work and leisure habits, past injury, equipment use, sports-specific demands, involvement in other sports and psychological features can markedly influence the diagnosis of a patient. These features paint a comprehensive picture of the state of the athlete's condition and the external factors that may drive future care needs.

It is well known that clinicians place too great a value on single testing mechanisms during differential diagnosis, and the tests do not have the capacity to discriminate in absence of these other important considerations. This includes ALL forms of tests, such as imaging, laboratory testing and so on. In essence, a good clinician evaluates all the information and places the test finding in context.

### PRACTICE PEARL

Most clinicians overestimate the utility of special tests, assuming they provide more decision-making capacity than they do. Only use special tests in context to the rest of the clinical assessment.

## The role of bias in influencing diagnostic metrics

Can you rely on published reports of test accuracy? Unfortunately not, because the design of a study can markedly influence its reported diagnostic accuracy. Recognising this, Whiting and colleagues created the Quality Assessment of Diagnostic Accuracy Studies tool (QUADAS) and subsequently QUADAS II.<sup>14</sup> A number of researchers have recognised the influence of bias through use of QUADAS and its impact on elevating test metrics. Each study should be carefully analysed for risk of bias before considering the test's use in clinical practice. Some biases can elevate the value of accuracy metrics by four

### PRACTICE PEARL

Diagnostic metrics from diagnostic accuracy studies that exhibit high risk of bias, regardless of where these studies were published, should not be incorporated into clinical practice. Bias markedly influences test metrics.

times the realistic amount, suggesting far greater utility of a test that may provide very little in clinical practice.

## Challenges to making a diagnosis

Differential diagnosis is an imperfect science. For reasons beyond the limitations of testing, some diagnoses are extremely difficult to make. The following are examples of non-correctable challenges to diagnosis and deserve explanation.

- Verification bias occurs when the gold standard procedures (e.g. biopsy, surgery) are provided to only a select few (because of costs, effort and so on) and subsequently only reflect that select few. Unfortunately, the extra step needed to improve the accuracy limits the generalisability of the finding. Whether a more traditional population would yield the same result is unknown.<sup>15</sup>
- Syndromes refer only to the set of detectable (examination) characteristics (signs and symptoms) that are related to a defined diagnosis. Unlike diseases, which have hard imaging, clinical or laboratory findings, syndromes are purely based on numerous intangible features (e.g. thoracic outlet syndrome), increasing the likelihood that two individuals can be diagnosed with the same problem, despite exhibiting notably different clinical findings.
- Condition severity is a known mediator to diagnostic accuracy. For example, a superior labral anterior posterior (SLAP) lesion can be categorised into four distinct groups using Snyder's classification.<sup>16</sup> Type I and type II classifications exhibit clinical features that are strikingly similar to a rotator cuff tear, impingement, bursitis and so on, and these classifications are notably difficult to differentiate in clinical practice in comparison to the more severe classifications of type III and IV.
- Incorporation bias occurs when the test is part of the diagnosis. An example is patellofemoral pain syndrome which is a diagnosis based on anterior knee pain and challenges with functional activities. Often, the functional activities are testing for their predictability; despite that, these are part of the diagnosis itself. The main problem with incorporation bias is its overestimating diagnostic accuracy.

## FINAL THOUGHTS AND GUIDANCE

There are a number of considerations one must make that go beyond diagnostic metrics and clinical tests and measures. First, as David Matcher implies, few tests markedly change clinical practice for the good of society.<sup>17</sup> One can argue that a minority of our clinical tests and measures are superfluous and do little in assisting in decision making for the long-term good of our athlete. This is likely why we have a proliferation of newly created clinical tests for diagnosis of the shoulder, the sacroiliac joint and other problematic regions.

It is imperative that differential diagnosis include a careful discussion with the athlete and the implications of the finding. Shared decision making is necessary for both parties to consider which treatment is appropriate for the condition. By being aware of the limitations highlighted in this chapter, clinical assessment and judicious use of imaging provides a great foundation for the treatment plan. In Chapter 15, we share some practical clinical approaches you can use to maximise your chances of arriving at the most likely diagnosis! The great clinician combines science and art.

# How to make the diagnosis

with ALI GUERMAZI, JON PATRICIOS and BRUCE FORSTER

*Wherever the art of medicine is loved, there is also a love of humanity.*

Hippocrates (c.460–370 BCE)

This chapter should be read in conjunction with Chapter 14. These chapters are very different from their fourth edition predecessors. In earlier editions of *Clinical Sports Medicine*, we argued for the importance of accurate pathological diagnosis. At times, this is realistic. A player falls on his or her wrist and sustains an acute scaphoid fracture. You can make a clinical diagnosis and confirm it with imaging. So far, so good. Accurate tissue diagnosis remains a foundation *where appropriate*.

In this fifth edition, we recognise that we previously overestimated the proportion of settings where *accurate, very specific* tissue diagnosis is possible. Consider patients who present with low back pain. Is the tissue diagnosis the facet joint, vertebra, fascia, muscle or disc? In these cases, can investigation, such as magnetic resonance imaging (MRI) provide the holy grail of tissue diagnosis? No, MRI cannot.

This chapter reinforces Chapter 14's key message—the art of diagnosis takes place against a backdrop of patient-based probabilities. Honest teachers will explain that the clinician is narrowing the odds from the 'pre-test probability' to a new 'post-test probability'. (See Likelihood ratios and Fagan's Nomogram, Chapter 14.)

## DOES 'DIAGNOSIS' MEAN 'TISSUE DIAGNOSIS'?

Is there a difference between a diagnosis of: 1. 'swimmer's shoulder'; 2. 'rotator cuff tendinopathy'; and 3. 'shoulder pain related to training load errors and suboptimal biomechanics'? The first of these ('swimmer's shoulder') represents a 1970s advance in sports medicine. Alongside labels such as tennis elbow, goalie's elbow, hockey player's groin and footballer's ankle, 'diagnosis' consisted

of the name of a sport paired with a commonly injured body part. This was an advance at the time, as many doctors were not aware of sports medicine conditions and sports physiotherapy had not yet emerged in many countries.

The major limitation of this type of label is lack of precision. Each of those labels (e.g. hockey groin) could apply to a number of pathological entities which may benefit from distinct treatment. Such labels have no place in 21st-century sports medicine.

What about 'rotator cuff tendinopathy'? Is that a valid diagnosis? The fourth edition of *Clinical Sports Medicine* asserted that accurate pathological diagnosis was essential for the following reasons.

- *It enabled the clinician to explain the problem and the natural history of the condition to the athlete, who will want to know precisely for how long he or she will be affected. A patient may present with an acute knee injury but the diagnosis of anterior cruciate ligament (ACL) tear has markedly different implications to the diagnosis of minor meniscal injury.*
- *It enabled optimum treatment. Numerous conditions have similar presentations but markedly different treatments. For example, consider the differences in treatment between: lateral ligament sprain of the ankle and osteochondral fracture of the talus; patellofemoral joint syndrome and meniscal tear; and hamstring tear and hamstring pain referred from the lumbar spine.*
- *It enabled optimum rehabilitation prescription. For example, rehabilitation after shin pain due to stress fracture will be more gradual than that after identical shin pain due to chronic compartment syndrome.*

In that edition, we acknowledged that 'occasionally' it can be impossible to make a precise pathological diagnosis as in the case of back pain mentioned above. In such cases, it is still possible to exclude certain causes of low back pain (e.g. spondylolysis) and identify abnormalities such as areas of focal tenderness, altered soft tissue consistency or abnormalities of range of motion. Treatment then aims to resolve the condition. How treatment affects symptoms and signs can help determine how each particular abnormality contributes to the overall picture. An important final step in management is to address the cause/s: intrinsic and extrinsic.

#### PRACTICE PEARL

Our current perspective is that we overestimated the number of cases where a 'tissue diagnosis' is accurate and we certainly underestimated the role of the psychosocial factors in the patient's perception of the injury.

The biopsychosocial model featured in the fourth edition of *Clinical Sports Medicine* but only in the chapter on neck pain, rather than in Part A: Fundamental Principles. We failed to feature the biopsychosocial model in the diagnosis or treatment chapters but amend that in this edition (Fig. 15.1).

It is widely appreciated that in many clinical settings 'accurate tissue diagnosis' is impossible. Despite that, the clinician can guide the patient by assessing impairments, documenting the patient's level of function, providing reassurance based on epidemiological evidence of clinical outcomes and natural history. In sum, the clinician contributes his/her knowledge of best evidence rehabilitation to the shared decision.<sup>1,2</sup>

#### KEYS TO ACCURATE DIAGNOSIS

Diagnosis relies on taking a careful history, performing a thorough physical examination and using appropriate investigations. Today, patient-reported outcome measures (PROMs) may also be essential as part of the initial assessment and this is introduced in the next chapter (Chapter 16). Useful PROMs are also included in the regional injury chapters in Part B of this book. 'Over-reliance on sophisticated investigations and neglected clinical skills' has been a mantra of senior medical educators for decades and the problem may be worsening.

Keys to accurate diagnosis in patients presenting with apparent musculoskeletal pain include:

- the age of the patient
- the mechanism of injury

**Figure 15.1** The biopsychosocial (BPS) model of disease provides an important context for the patient's experience (a) In a purely biomedical model, pathology explains the patient's pain experience and this is considered virtually equivalent to the patient's experience (b) The biopsychosocial model provides a holistic approach to diagnosis. Many factors, not only the tissue pathology, should be taken into account. Psychological and social/sport factors, depicted here, contribute to a more complete diagnosis. See also Chapters 5 and 6 that explain pain in sports injuries

- whether the symptoms are of musculoskeletal origin (Chapter 7)
- possible local causes of the patient's symptoms
- sites that could be referring pain to the site of the symptoms (Chapters 5, 6)
- the relevant kinetic chain (e.g. the back and lower limb in a shoulder injury of a tennis player)
- biomechanics (Chapters 8 and 9)
- other possible causative factors (e.g. metabolic)
- patient expectations and understanding.

## HISTORY

History remains the keystone of accurate diagnosis; it will provide the diagnosis in the majority of cases. Please consider the following principles when taking a history.

### Allow enough time

The patient must feel that the clinician has time available to allow the story to unfold, otherwise important symptoms will not surface. In addition to the details of the injury, there must be time to take the history of the training program including details of training workload where this is available. Look into possible causes of injury. Diet history may be appropriate (i.e. contributing to stress fracture likelihood). As a minimum, 30 minutes is required to assess a patient with a new injury but in complex chronic cases up to one hour may be necessary.

### Be a good listener

The clinician must let the story unravel. Appropriate body language and focus on the patient, and not the medical record or computer screen, will aid this. The sports clinician is in the fortunate position that many patients have good body awareness and are generally able to describe symptoms very well.

### Know the sport

It is helpful to understand the technical demands of a sport when seeing an athlete as this engenders patient confidence. More importantly, knowledge of the biomechanics and techniques of a particular sport (see Chapter 9) can assist greatly in both making the primary diagnosis and uncovering the predisposing factors.

### Discover the exact circumstances of the injury

The first task in history taking is to determine the exact context of the injury. The patient's age is the first clue: knee pain in an adolescent is more likely to be an apophysitis such as Osgood-Schlatter disease while in an elderly person degenerative causes are more likely; 'tennis elbow' in a child would be unusual but not in

middle age. Next, the mechanism of injury warrants careful consideration. Most patients will be able to describe in considerable detail the mechanism of injury. In acute injuries, this is the single most important clue to diagnosis. For example, an inversion injury to the ankle strongly suggests a lateral ligament injury, a valgus strain to the knee may cause a medial collateral ligament injury, and a pivoting injury accompanied by a 'pop' in the knee and followed by rapid swelling suggests an ACL injury.

### Obtain an accurate description of symptoms, both at the time of injury and at the initial consultation

Common musculoskeletal symptoms include pain, swelling, instability and loss of function.

### Pain

Consider the characteristics of the patient's pain.

1. Location. Note the exact location of pain. Detailed knowledge of surface anatomy can be invaluable. If the pain is poorly localised or varies from site to site, consider the possibility of referred pain.
2. Onset. Speed of onset helps determine whether the pain is due to an acute or overuse injury. Was the onset of pain associated with a snap, crack, tear or other sensation?
3. Severity. Severity may be classified as mild, moderate or severe. Using a pain score (e.g. numerical rating scale [NRS]) or a specific outcome measure may be useful to gauge severity and monitor improvement. Another very helpful method is to have the patient detail the most important activity for them, and rate that with a score. Assess the severity of the pain immediately after the injury and subsequently. Was the patient able to continue the activity?
4. Irritability. This refers to the level of activity required to provoke pain and how long it subsequently takes to settle. The degree of irritability is especially important because it affects how vigorously the examination should be performed and how aggressive the treatment should be.
5. Nature. This refers to the quality of the pain. It is important to allow patients to describe pain in their own words. For example, 'burning pain' can suggest neural involvement.
6. Behaviour. Is the pain constant or intermittent? What is the time course of the pain? Is it worse on waking up or does it worsen during the day? Does it wake the patient at night?
7. Pain site and distribution. Does the pain radiate at all? If so, where?

8. Aggravating factors. Which activity or posture aggravates the pain?
9. Relieving factors. Is the pain relieved by rest or the adoption of certain postures? Do certain activities relieve the pain? Is the pain affected by climatic changes (e.g. cold weather)?
10. Associated features. These include swelling, instability, sensory symptoms (such as pins and needles, tingling or numbness) and motor symptoms (such as muscle weakness).
11. Previous treatment. What was the initial treatment of the injury? Was ice applied? Was firm compression applied? Was the injured part immobilised? If so, for how long? What treatment and rehabilitation has been performed and what effect did that treatment have on the pain? The latter is particularly important when you are providing a second or subsequent opinion in cases of long-standing problems.

### Swelling

Immediate swelling following an injury may indicate a severe injury such as a fracture or major ligament tear accompanied by haemarthrosis. Record the degree of swelling (mild, moderate or severe) and subsequent changes in the amount of swelling.

### Instability

Any history of giving way or feeling of instability is significant. Try to elicit the exact activity that causes this feeling. For example, in throwing, does the feeling of instability occur in the cocking phase or the follow-through?

### Function

It is important to know whether the athlete was: 1. able to continue activity without any problems immediately after the injury happened; 2. able to continue with some restriction; or 3. unable to continue. Note subsequent changes in function with time. When patients present with chronic conditions, or have been receiving treatment already, see what level of function they have reached. Have they just failed to rehabilitate to the necessary level of function?<sup>3</sup> (See Chapter 18.)

### History of a previous similar injury

If the athlete has had a previous similar injury, record full details of all treatment given, response to each type of treatment and whether any maintenance treatment or exercises have been performed following initial rehabilitation. Previous injury is the most important risk factor for recurrence.

### Other injuries

Past injuries may have contributed to the current injury; for example, an inadequately rehabilitated muscle tear that has led to muscle imbalance and a subsequent overuse injury. Because of the importance of spinal abnormalities as a potential component of the athlete's pain (Chapter 5), the patient should always be questioned about spinal symptoms, especially pain and stiffness in the lower back or neck. Past or present injuries in body parts that may at first seem unrelated to the present injury may also be important. For example, a hamstring injury in a throwing athlete can impair the kinetic chain leading to the shoulder, alter throwing biomechanics and thus contribute to a rotator cuff injury.

### General health

Is the patient otherwise healthy? Musculoskeletal symptoms are not always activity related (Chapter 7). Red flags for serious medical conditions masquerading as sports injuries include:

- no specific mechanism of injury
- pain unrelated to activity
- night pain
- associated symptoms and signs such as weight loss, fever, malaise, lymphadenopathy
- poor response to treatment.

Consider asking specifically about diabetes, possible undiagnosed inflammatory conditions (e.g. skin problems of psoriasis, bowel complaints associated with spondyloarthropathies) and familial conditions.

### Work and leisure activities

Work and leisure activities can play a role in both the aetiology and subsequent management of an injury. For example, a patient whose job involves continual bending or who enjoys gardening may aggravate his or her low back pain. It is important to know about these activities and to ascertain whether they can be curtailed.

### Consider why the problem has occurred

Predisposing factors should be considered not only in overuse injuries, but also in medical conditions and in acute injuries. In an athlete struggling to return to play after an ACL injury for example, there may be an underlying psychological component.

An athlete with an acute hamstring tear may have a history of low back problems or, alternatively, a history of a previous inadequately rehabilitated tear. Recurrence can only be prevented by eliminating the underlying cause.

### Training/activity history

In any overuse injury, a comprehensive training history is required. This is best done as a weekly diary as most athletes train on a weekly cycle (Chapter 12). It should contain both the quantity and quality of training and describe any recent changes. Note the total amount of training (distance or hours depending on the sport) and training surfaces. Ideally, the patient will have a detailed training history that includes perception of how hard training was. Training can be measured as (i) 'internal load', such as measured by rating of perceived exertion (RPE), or (ii) 'external load', such as training volume in distance covered or balls pitched or bowled. Continual activity on hard surfaces or a recent change in surface may predispose to injury. In running sports, pay particular attention to footwear (Chapter 8). For both training and competition shoes, note the shoe type, age and wear pattern. Record recovery activities such as soft tissue therapy, spa/sauna and hours of sleep. Asking patients to bring a training diary or history to the consultation is a useful pre-emptive tactic.

### Equipment

Inappropriate equipment may predispose to injury (Chapter 12). For example, a bicycle seat that is set too low may contribute to patellofemoral pain.

### Technique

Patients should discuss technique problems that either they, or their coach, have noted. Faulty technique may contribute to injury. For example, a 'wristy' backhand drive may contribute to extensor tendinopathy at the elbow (Chapter 9).

### Overtraining

Symptoms such as excessive fatigue, recurrent illness, reduced motivation, persistent soreness and stiffness may point to overtraining as an aetiological factor.

### Psychological factors

Injury can be caused or exacerbated by a number of psychological factors that may relate to sport (i.e. pressure of impending competition), or may concern personal or business life. The clinician needs to consider this possibility and approach it sensitively.

### Nutritional factors

Inadequate nutrition can predispose to the overtraining syndrome and may play a role in the development of musculoskeletal injuries. Eating disorders may also inhibit

healing. In an athlete presenting with excessive tiredness, a full dietary history is essential.

### Drugs: prescription and others

As with all complete medical histories, a history of medication use may be appropriate. Fluoroquinolone antibiotics may be the cause of a patient's tendinopathy, while cold and influenza medications have been associated with arrhythmias. Athletes may take social drugs such as cocaine, and performance-enhancing anabolic steroids have a range of systemic side effects. Athletes are unlikely to volunteer this information, and direct questioning is not only appropriate but reveals a good clinical understanding of the context of injury in sport.

### History of exercise-induced anaphylaxis

Exercise-induced anaphylaxis (EIA) and food-dependent, exercise-induced anaphylaxis (FDEIA) are rare, but potentially life-threatening clinical syndromes in which association with exercise is crucial. It is a clinical syndrome in which anaphylaxis occurs in conjunction with exercise. Given the rarity of the condition, our current understanding relies on case studies alone and is acknowledged as being very limited.<sup>4</sup>

### Determine the importance of the sport to the athlete

The level of commitment to the sport, which will not necessarily correlate with the athlete's expertise, has a bearing on management decisions. Be aware of the athlete's short- and long-term future sporting commitments to schedule appropriate treatment and rehabilitation programs.

### Differential diagnosis

At the conclusion of taking the history, it is important to consider the differential diagnosis and the possible aetiological factors. Then proceed to a thorough focused examination.

## PHYSICAL EXAMINATION

In this practical chapter, we share a number of general principles that might speed the novice clinician towards better physical examination. We acknowledge the limitations of physical examination (Chapter 14)<sup>5</sup> and of imaging (below), but they still provide valuable information that increases the likelihood of making the correct diagnosis and thus of choosing evidence-based treatment for a patient's complaints.

## Develop a routine

Use a specific routine for examining each joint, region or system as this forms a habit and allows you to concentrate on the findings and their significance rather than thinking of what to do next. In Part B we outline a routine for examining each body part.

Remember that in most sports the athlete functions in the upright position. Avoid the temptation to only examine the patient in a supine or prone position. Moreover, running sports involve supporting the body on one leg or the other most of the time. Simulate this in your examination. Consider starting the examination assessing posture and having the patient perform various stress tests on one leg (e.g. hopping, one-legged squat).

## Where relevant, examine the other side

With some aspects of the examination (e.g. ligamentous laxity or muscle tightness), it is important to compare sides using the uninjured side as a control.

## Consider possible causes of the injury

Try to ascertain the cause of the injury. It is not sufficient to examine the painful area only (e.g. the Achilles tendon). Acknowledge the importance of the kinetic chain. Examine joints, muscles and neural structures proximal and distal to the injured area, seeking predisposing factors (e.g. limited dorsiflexion of the ankle, tight gastrocnemius-soleus complex, lumbar facet joint dysfunction). A useful tip is to examine all the areas that may possibly contribute to the injury before honing in on the site of pain.

## Attempt to reproduce the patient's symptoms

It is helpful to reproduce the patient's symptoms if possible. This can be achieved both by active and/or passive movements and by palpation either locally or, in the case of referred pain, at the site of referral. It may require you to send the patient for a run or some other test of function prior to examination (see below).

## Assess local tissues

Assess the joints, muscles and neural structures at the site of pain for tenderness, tissue feel and range of motion.

## Assess for referred pain

Assess the joints, muscles and neural structures that may refer to the site of pain (Chapter 4).

## Assess neural mechanosensitivity

Neural mechanosensitivity (Chapters 5 and 6) should be assessed using one or more of the neurodynamic tests (see below).

## Examine the spine

Many injuries have a spinal component to the pain or dysfunction. Abnormal neural mechanosensitivity suggests a possible spinal component. In lower limb injuries, examine the lumbar spine and the thoracolumbar junction. In upper limb injuries, examine the cervical and upper thoracic spines. Examine for hypomobility of isolated spinal segments as this may contribute to distant symptoms. See the routine for spinal examination later in this chapter.

## Biomechanical examination

As biomechanical abnormalities are one of the major causes of overuse injuries, it is essential to include this examination in the assessment of overuse injuries (Chapters 8 and 9). The biomechanical examination of the lower limb is illustrated in Chapter 8. The mechanics of the lower limb may be relevant to an upper limb injury (e.g. weak hip stabilisers resulting in overload of the elbow in sports involving repetitive throwing).

## Functional testing

If a particular manoeuvre reproduces the patient's pain, then have the patient perform that manoeuvre in an attempt to understand why the pain has occurred. This can sometimes be done in the office (e.g. a deep squat) or it may be necessary to watch the athlete perform the activity at a training venue (e.g. a long jumper taking off or a gymnast performing a backward walkover). Video analysis may be helpful.

## The examination routine

### Inspection

It is important to observe the individual walking into the office or walking off the field of play as well as inspecting the injured area. Note any evidence of deformity, asymmetry, bruising, swelling, skin changes and muscle wasting. There may, however, be a degree of asymmetry due to one side being dominant, such as the racquet arm in a tennis player.

### Range of motion testing (active)

Ask the athlete to perform active range of motion exercises without assistance. Look carefully for restriction of range of motion, the onset of pain at a particular point in the range, and the presence of abnormal patterns of movement. In many conditions, such as shoulder impingement or patellofemoral pain, the pattern of movement is critical to making a correct diagnosis.

If a patient's pain is not elicited on normal plane movement testing, examine 'combined movements' (i.e. movements in two or more planes). By combining movements and evaluating symptom response, additional information is gained to help predict the site of the lesion. Other movements, such as repeated, quick or sustained movements, may be required to elicit the patient's pain.

### Range of motion testing (passive)

Passive range of motion testing is used to elicit joint and muscle stiffness. Injury may be the cause of joint stiffness. Alternatively, stiffness may already have been present and predispose to injury by placing excessive stress on other structures (e.g. a stiff ankle joint can predispose to Achilles tendinopathy). Range of motion testing should include all directions of movement appropriate to a particular joint, and should be compared both with normal range and the unaffected side. Overpressure may be used at the end of range to elicit the patient's symptoms.

### Palpation

Palpation is a vital component of examination and precise knowledge of anatomy, especially surface anatomy, optimises its value. At times it is essential to determine the exact site of maximal tenderness (e.g. in differentiating between bony tenderness and ligament attachment tenderness after a sprained ankle). When palpating soft tissues, properties of the soft tissue that need to be assessed include:

- resistance
- muscle spasm
- tenderness.

Palpate carefully and try to visualise the structures being palpated. Commence with the skin, feeling for any changes in temperature or amount of sweating, infection or increased sympathetic activity. When palpating muscle, assess tone, focal areas of thickening or trigger points, muscle length and imbalance.

It is important not only to palpate the precise area of pain (e.g. the supraspinatus tendon attachment), but also the regions proximal and distal to the painful area, such as the muscle belly of the trapezius muscle. Determine whether tenderness is focal or diffuse. This may help differentiate between, for example, a stress fracture (focal tenderness) and periostitis (diffuse tenderness).

To palpate joints correctly, it is important to understand the two different types of movement present at a joint. Physiological movements are movements that patients can perform themselves. However, in order to achieve a full range of physiological movement, accessory movements are required. Accessory movements are the involuntary, interarticular movements, including glides, rotations and tilts that occur in both spinal and peripheral joints during normal physiological movements. Loss of these normal accessory movements may cause pain, altered range or abnormal quality of physiological joint movement. Palpation of the spinal and peripheral joints is based on these principles. An example of palpation of accessory movements involves posteroanterior pressure over the spinous process of the vertebra, producing a glide between that vertebra and the ones above and below.

### Ligament testing

Ligaments are examined for laxity and pain. Specific tests have been devised for all the major ligaments of the body. These involve moving the joint to stress a particular ligament. This may cause pain or reveal laxity in the joint. Laxity is graded into +1 (mild), +2 (moderate) and +3 (severe). Pain on stressing the ligament is also significant and may indicate, in the absence of laxity, a mild injury or grade I ligament sprain. A number of different tests may assess a single ligament; for example, the anterior drawer, Lachman's and pivot shift tests all test ACL laxity.

### Strength testing

Muscles or groups of muscles should be tested for strength and compared with the unaffected side. Muscle weakness may occur as a result of an injury (e.g. secondary to a chronic joint effusion) or may be a predisposing factor towards injury. Muscle strength can be assessed manually or with the use of a hand-held dynamometer.

### Testing neural mechanosensitivity

Advances in the understanding of neural mechanosensitivity have improved our awareness of why pain occurs in chronic overuse injuries and pain syndromes. Changes in neural mechanosensitivity are an important component of these disorders; see Chapter 4 (overuse) and Chapters 5 and 6 (pain).

Just as restrictions of the normal mechanics of joints and muscles may contribute to symptoms, restriction of the normal mechanics of the nervous system may also produce pain. Certain movements require considerable variations in nerve length. Neurodynamic testing (formerly known as 'neural tension tests') examines restriction of these normal mechanics and their effect on the patient's symptoms. Treatment aims to restore normal nerve mechanics.

Neurodynamic tests use movement to systematically increase neural mechanosensitivity. The tests may provoke the presenting symptoms or, alternatively, other symptoms such as pins and needles or numbness. The amount of resistance encountered during the test is also significant, especially when compared with the uninjured side. The assessment of symptom production and resistance may be affected by each step in the neurodynamic test (see Figs 15.2 to 15.5). This may give an indication of the location of the abnormality.

The main neurodynamic tests are:

- straight-leg raise (SLR) (Fig. 15.2a and b)
- slump test (Fig. 15.3a–e)
- neural Thomas test (Fig. 15.4a and b)
- upper limb neurodynamic test (Fig. 15.5a–e).

(a)

(b)

**Figure 15.2** Straight leg raise (a) Patient lies supine. The examiner places one hand under the Achilles tendon and the other above the knee. The leg is lifted perpendicular to the bed with the hand above the knee, preventing any knee flexion (b) Dorsiflexion of the ankle is added. Eversion and toe extension may sensitise this test further. Other variations can be added (Table 15.1)

(a)

(b)

**Figure 15.3** Slump test (a) Patient slumps forward and overpressure is applied. The sacrum should remain vertical (b) Patient is asked to put chin on chest and overpressure is applied

(c)

(e)

**Figure 15.3 (cont.)** (c) Patient actively extends one knee (d) Patient actively dorsiflexes the ankle and overpressure may be applied (e) Neck flexion is slowly released. Steps (d), (e) and (f) are repeated with the other knee. Other variations can be added (Table 15.1)

(d)

(a)

**Figure 15.4** Neural Thomas test (a) Patient lies supine over the end of the couch in the Thomas position

(b)

**Figure 15.4 (cont.)** (b) Patient's neck is passively flexed by the examiner, then the examiner passively flexes the patient's (right) knee with his leg

(b)

(a)

(c)

**Figure 15.5** Upper limb neurodynamic test (a) Patient lies supine close to the edge of the couch. Neck is laterally flexed away from the side to be tested (b) The shoulder is depressed by the examiner's hand (left) and the arm abducted to approximately  $110^\circ$  and externally rotated (c) The forearm is supinated and the wrist and fingers extended

(d)

(e)

**Figure 15.5 (cont.)** (d) The elbow is extended to the point of onset of symptoms (e) The neck position returns to neutral and is then laterally flexed towards the side of the test. Any change in symptoms is noted. Other variations can be added (Table 15.1)

A summary of the tests, the methods, user guidance, normal responses and variations of each test is shown in Table 15.1.

A neurodynamic test can be considered positive if:

- it reproduces the patient's symptoms
- the test response can be altered by movements of different body parts that alter the neural mechanosensitivity
- differences in the test occur from side to side and from what is considered normal.

Neurodynamic tests are non-specific but form an extremely useful part of the examination. Abnormalities of neural mechanosensitivity should lead the clinician to examine possible sites of abnormality, especially the spine. The techniques used in neurodynamic tests can also be used as a treatment procedure. This is discussed in Chapter 17.

### Spinal examination

Clinical experience suggests that spinal abnormality (e.g. hypomobility) can present in various ways. The

presentation may be as pain or injury, and this may occur either locally (at the spine) or distantly. Examples for both upper limb and lower limb spinal abnormalities are given in Table 15.2. The pathophysiology underlying these concepts has been discussed in Chapters 5 and 6.

In patients presenting with upper limb pain, examine the cervical and upper thoracic spines. Examine the lumbar spine (including the thoracolumbar junction) in any patient presenting with lower limb pain. An abnormal neurodynamic test strongly indicates a spinal component to the pain. However, a negative neurodynamic test does not rule out the possibility of a spinal component.

Begin examining the relevant area of the spine by assessing range of movement with the patient standing. The patient should then lie prone on a firm examination table so the examiner can palpate the vertebrae centrally over the spinous processes and laterally over the apophyseal joints to detect any hypomobility and/or tenderness. Hypomobility or tenderness at a level appropriate to that of the patient's symptoms indicate the site is a possible source of referred pain (Chapters 5 and 6).

**Table 15.1 Neurodynamic tests**

Test	Method	Indications	Normal response	Variations
Straight leg raise (Fig. 15.2)	Patient lies supine Leg extended Clinician lifts leg	Leg pain Back pain Headache	Tightness and/or pain in posterior knee, thigh and calf	Ankle dorsiflexion Ankle plantarflexion/ inversion Hip adduction Hip medial rotation Passive neck flexion
Slump test (Fig. 15.3)	Patient sitting Slumps Neck flexion Knee extension Ankle dorsiflexion Release neck flexion	Back pain Buttock pain Leg pain	Upper thoracic pain Posterior knee pain Hamstring pain	Leg abduction (obturator nerve) Hip adduction Hip medial rotation Ankle and foot alterations
Neural Thomas test (Fig. 15.4)	Patient lies supine Hip extension Neck flexion Knee flexion	Groin pain Anterior thigh pain	Quadriceps pain and/or tightness	Hip abduction/adduction Hip medial/lateral rotation
Upper limb neurodynamics test (Fig. 15.5)	Patient supine towards side of couch Cervical contralateral flexion Shoulder girdle depression Shoulder abducted to 110° and externally rotated Forearm supination Wrist/fingers extended Elbow extended	Arm pain Neck/upper thoracic pain Headache	Ache in cubital fossa Tingling in thumb and fingers	Forearm pronation Wrist deviation Shoulder flexion/extension Add straight leg raise

**Table 15.2 Examples of how spinal abnormality can manifest locally or distantly, with either pain or injury in the upper limb and lower limb**

Presentation	Local manifestation	Distant manifestation
Upper limb		
Pain	Hypomobility of C5–C6 joint presenting as neck pain	Hypomobility of C5–C6 joint presents as elbow pain
Injury		Hypomobility of C5–C6 joint predisposing to lateral elbow tendinopathy in a tennis player
Lower limb		
Pain	Hypomobility of L5–S1 joint presenting as lumbosacral pain	Hypomobility of L5–S1 joint presents as buttock and hamstring pain
Injury		Hypomobility of L5–S1 joint predisposing to a hamstring tear in a sprinter

After detecting spinal abnormality on examination, perform a trial treatment (Chapter 17) and then reassess the patient's symptoms and signs. If there is a change in the pain and/or range of movement, then this strongly suggests that the spine is contributing to the symptoms.

Occasionally, palpation of a particular site in the spine will actually reproduce the patient's symptoms distant from the spine. It is important to understand, however, that even if the symptoms are not produced by palpation of the spine, this does not rule out the possibility of a spinal component.

### Biomechanical examination

The role of abnormal biomechanics in the production of injuries, especially overuse injuries, is discussed in Chapters 8 and 9. Because abnormal biomechanics can contribute to any overuse injury, all clinicians need to perform a biomechanical examination. As with other components of the examination, it is important to develop a routine for the assessment of biomechanical abnormalities. A routine for the assessment of lower limb biomechanics is illustrated in Chapter 8.

### Technique

Faulty technique is another common cause of injury. Technique faults associated with particular injuries are discussed in Chapter 9. While the clinician cannot be aware of all techniques in various sports, he or she should be able to identify the common technique faults in popular activities (e.g. pelvic instability while running or faulty backhand drive in tennis). Clinicians should seek biomechanical advice and assistance with assessment from the athlete's coach or a colleague with expertise in the particular area. Video analysis with slow motion or freeze frame may be helpful.

### Equipment

Inappropriate equipment predisposes to injury (Chapter 12). Inspect the athlete's equipment, such as running shoes, football boots, tennis racquet, bicycle or helmet.

### Differential diagnosis

At the conclusion of the examination, consider the differential diagnosis and possible predisposing factors. If the clinician is certain of the diagnosis and of the predisposing factors, then counselling and treatment can begin. However, in many cases, further information may be required and the clinician must decide what, if any, investigations may be needed.

## DIAGNOSTIC IMAGING

This section introduces imaging—which has provided dramatic advances for sports medicine, and is widely used

in clinical medicine. As well as providing remarkable insight to sports medicine pathologies, superior imaging capability has brought with it new challenges for clinicians: 'Yes, that bright signal is abnormal most of the time but what does that mean in this patient?'. But before we tackle that difficult question, we begin with what we know to be true—the five habits of highly effective clinicians, with respect to imaging. Every top sports clinician is highly skilled at interpreting sports imaging and he or she works closely with top musculoskeletal radiologists to perform at the level that champions expect, and every patient who sees a specialist deserves.<sup>6</sup>

### The five imaging-related habits of highly effective sports medicine clinicians

In certain clinical settings, appropriate investigations can confirm or exclude a diagnosis suggested by the history and physical examination. A conventional radiograph can confirm that a cyclist has fractured her clavicle. Computed tomography (CT) with multiplanar reformat and three-dimensional volumetric rendering can provide the precise configuration of that fracture. MRI can rule out a stress fracture in a dancer's foot if there is no sign of any abnormal signal.

#### PRACTICE PEARL

*In many clinical contexts imaging does not identify a single structure that is the source of pain. Imaging the patient with back pain is the historical example used to illustrate that point but there are many more examples.*

As an example, MRI of a professional baseball player's painful shoulder or elbow illustrates the point clearly.<sup>7-9</sup> Most baseball players have structural changes visible on MRI of their shoulder and elbow (e.g. thickening of their ulnar collateral ligament); one needs to consider if this appearance is 'normal' for that player or not. Other very prominent regions where structural changes are often evident on MRI but which may or may not be symptomatic include the tennis player's elbow, the football player's ankle, the fast bowler's back in cricket. The take-home message is that imaging alone cannot substitute for careful history taking and a comprehensive examination (Chapter 14). Because diagnosis is complex, the leading clinicians in our field have embraced the following behaviours.

## 1. Understand imaging results

The sport and exercise medicine physician must be able to interpret investigation results him or herself. Learn imaging anatomy of the musculoskeletal system—it is only a fraction of what radiologists have to know.<sup>10</sup> It is unwise to rely blindly on imaging reports. A competent sports clinician knows that about 25% of asymptomatic elite jumping athletes have ultrasound appearances of structural change in their patellar tendons (hypoechoic regions, Fig. 15.6a and b).<sup>11, 12</sup> This is critical knowledge as the patient may have no pain there; in fact, the extremity may have been scanned as the asymptomatic contralateral knee for comparison with the symptomatic side. Without requisite clinical awareness, the clinician could let the test guide him or her to a potentially 'false positive' result (depending on the criteria for 'positive', see below). Management must be guided by clinical assessment, not by imaging appearance.

- *Timing of imaging tests.* Imaging may be performed too early to detect a pathology. That radiography can

(a)

(b)

**Figure 15.6** Variations from 'normal' imaging are common among athletes who place great loads on tissue. (a) Grey-scale and (b) Doppler ultrasound appearances of the patellar tendon in a volleyball player, demonstrating hypoechoic regions (arrows in a) and hyperaemia (arrows in b). Clinical reasoning needs to consider the high prevalence of these findings in asymptomatic players<sup>12</sup>

be performed too early to detect a stress fracture is widely known and therefore a 'negative' result does not exclude this diagnosis (high or moderate negative likelihood ratio, so not good for ruling out that pathology).

- *A 'true' finding may be age-related.* For example, triangular fibrocartilage tears of the wrist seen on MRI can be a normal finding, even in a non-athlete, for patients over 50 years of age. Clinical correlation with the patient's symptoms and the physical examination is crucial.
- *The wrong test can give false positive or false negative information.* For example, a routine MRI of the shoulder in a 26-year-old baseball pitcher will miss most labral tears; an MR arthrogram is needed to make the diagnosis. Radiologists are not only 'image interpreters', they are also consultants who can advise on the choice of imaging tests to best demonstrate pathology. Indeed, the most accurate imaging test for a given musculoskeletal pathology may not necessarily be the most sophisticated or complicated test.
- *Be able to judge the adequacy of the quality of obtained images for diagnostic purposes.* Be alert so as not to draw conclusions from imaging tests that may be incomplete or are limited by image degradations. Also, one needs to understand that each imaging test may be specifically obtained to evaluate for one type of pathology but not others. For example, two-view radiographs of the shoulder in internal and external rotation to evaluate for calcific tendinopathy should not be used to exclude glenohumeral dislocation.
- *Intravenous contrast is usually reserved for CT or MRI cases in which the diagnosis of neoplasm or tumour is being considered.* It is very important to indicate as such on the requisition if these need to be ruled out.
- *It is important to minimise ionising radiation, especially in children and adults aged under 30 years.* The dose is especially significant in nuclear medicine bone scans, positron emission tomography (PET) scans and CT scans. If any of these tests are truly indicated, the principle of ALARA (as low as reasonably achievable) with respect to dose should be respected by the imaging department. Note that there is no ionising radiation in MRI, and the dose is negligible in routine conventional radiographs.

Why do we share these detailed examples about clinicians needing to understand tests? Because the days of thinking that 'imaging reveals X, therefore treatment is Y' are essentially over. Imaging fits into the treatment algorithm and helps update the clinician's thinking of the likelihood of a diagnosis (See Likelihood ratios, Chapter 14). The clinician must understand imaging because it is a tool, not a solution, and far from a panacea.

## 2. Only order imaging that will influence management

It is inappropriate to perform imaging to confirm an already obvious diagnosis, or a diagnosis for which the investigation result will not influence management. Most concussions are diagnosed clinically and do not need brain CT or MRI. Most cases of back pain in sport are not helped by adding low back imaging (radiography, CT or MRI). If an ankle sprain does not appear to have caused a fracture (and there are clinical guidelines to help with the assessment), initial management does not include any imaging. Players/athletes can put clinicians under pressure to order tests; in theory this should always be resisted. In real life, it can be difficult to resist such pressure in the professional sport setting so we will not pretend that ideal management is always followed. But understanding the usefulness of tests and test metrics (Chapter 14) as well as normal patterns of imaging in sport (principle 1, above), allows the clinician to have a valuable conversation with the patient/athlete, and the patient to make an informed decision (see also Figure 2.1 in Chapter 2).

## 3. Explain the imaging to the patient

Give the patient an understanding of the rationale behind each imaging test. An athlete who complains of persistent ankle pain and swelling several months after an ankle sprain may need a radiograph and MRI. If the patient is merely told that radiography is necessary to exclude bony damage, he or she might become confused when told that the radiograph is normal, but that further investigations are required to exclude bony or osteochondral damage. Also, be sure to alert patients undergoing a procedure that involves contrast (e.g. MR arthrogram) that there will be an injection. It is helpful to provide the patient with resources (either as printed material or as weblinks to videos) explaining the investigation. Follow-up plans should be made explicit in the clinical consultation.

## 4. Provide relevant clinical findings on the requisition

Accurate and complete clinical information on requisition forms helps to avoid imaging and reporting errors. When particular radiographic views are required, they should be specified. If you cannot remember the names of certain views, write that down on the request forms—the radiographer will generally know them and, if not, the radiologist will. If there is uncertainty, it is always helpful to call the radiologist in advance to discuss the best way to image a patient. Do not assume that radiographers are familiar with the specific views required for sports-related musculoskeletal conditions (e.g. correct anteroposterior [AP], 'frog' and Dunn views for hip femoroacetabular impingement [FAI], skyline views for patellofemoral joint evaluation, the Bernageau view

for shoulder instability). Remember that weight-bearing views are important to assess suspected osteoarthritis at the hip, knee and ankle. 'Functional' views (with the patient placing the joint in the position of pain) are useful for anterior and posterior impingement of the ankle (Chapter 42).

## 5. Develop a close working relationship with investigators

Optimising communication between colleagues improves the quality of the service.<sup>6</sup> Discuss optimal imaging sequences with radiographers, and view the images together with radiologists providing clinical input. Regular clinical-radiological rounds or case presentations should be encouraged. Digital imaging and telemedicine has made this much easier.

## SPECIFIC IMAGING MODALITIES

In this overview of imaging modalities commonly used in sports medicine, our goal is to highlight some key principles that junior clinicians have told us they would have liked to have known earlier in their careers. Read this together with other resources such as the comprehensive, authoritative and beautifully illustrated text in this field: *Imaging in Sports-Specific Musculoskeletal Injuries* (Fig. 15.7).<sup>10</sup>

**Figure 15.7** A great resource for specialists who work in sports medicine.

### Conventional radiography

Even as we approach 2020, radiography still provides diagnostic information about bony abnormalities, such as fractures, dislocations, dysplasia and calcification (Fig. 15.8), and is highly cost-effective. Correctly positioning the patient is vital for obtaining radiographic images that are meaningfully interpretable. A minimum of two orthogonal views is required to evaluate any bone adequately. Complex joints such as the ankle, wrist or elbow may require additional or specialised views. Weight-bearing or 'stress' views may give further information for weight-bearing structures and joints.

### MRI: massive blessing for active patients

The 2003 Nobel Prize was awarded to the inventors of MRI. This imaging method has revolutionised sports medicine by providing clinicians with remarkably detailed information about structure, especially soft tissues, and helpful information about dynamic pathophysiology. Because of MRI's unparalleled contrast resolution, commonly injured musculoskeletal tissues such as the menisci in the knee, the labrum in the shoulder and hip, spinal discs and joint surfaces can be visualised non-invasively and without ionising radiation.

MRI allows clinicians to appreciate fairly dynamic processes such as bone and cartilage turnover, changes in tendon structure even in the absence of rupture, and recovery of ligament after acute sprain.

The physics that underpins MRI is well beyond the scope of this book. At a most superficial level, MRI can be understood to rely on the biology that free water protons exist within a tissue sample. Those protons align with the external magnetic field of the magnet. When a series of radiofrequency (RF) pulses are applied to the tissue sample in the magnet, protons change their alignment relative to the external magnetic field and release energy which creates the MR image.

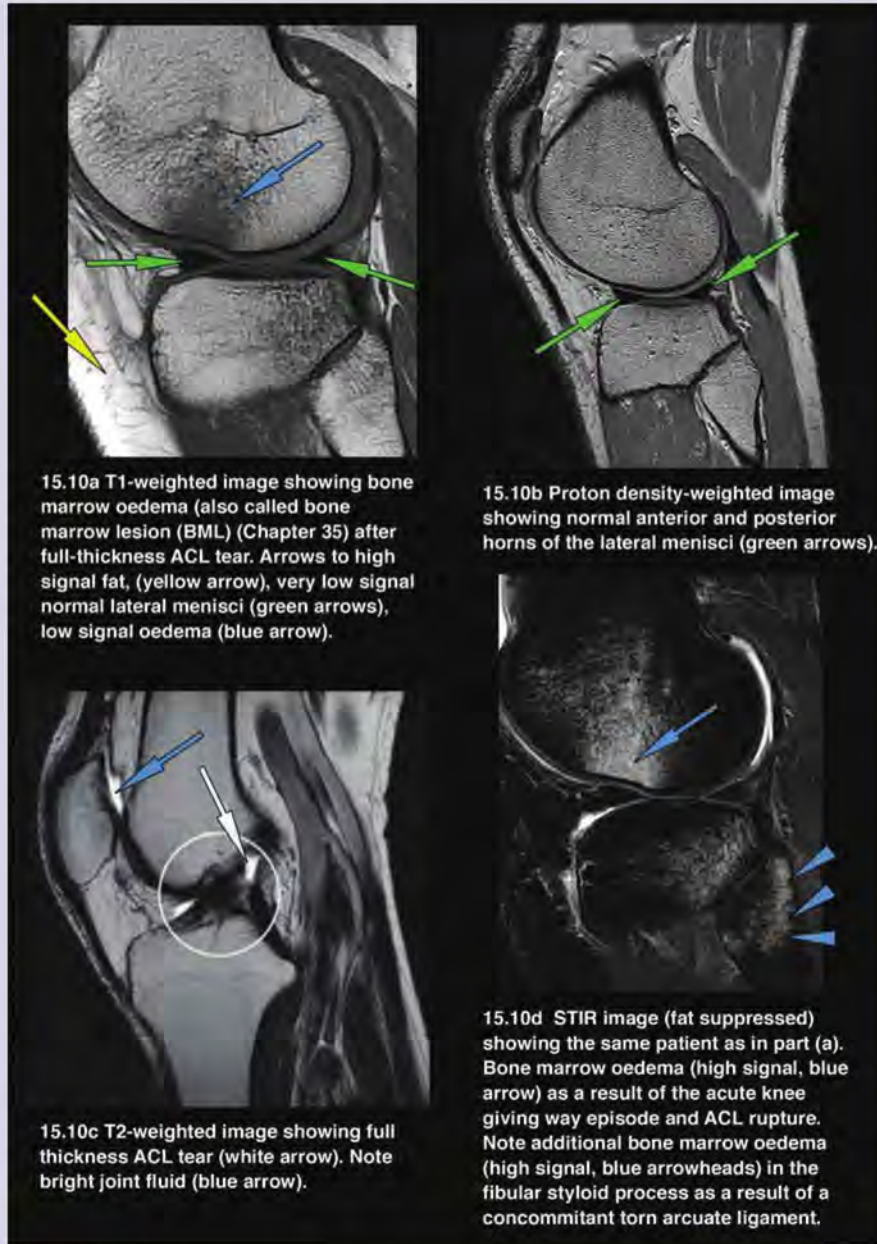

Unparalleled sensitivity to detect deviation in structure from anatomical norms does not, however, equal unparalleled accuracy in diagnosis for the patient (Chapter 14). Erroneous interpretation of an MRI can have serious clinical consequences. For example, if a 50-year-old person's knee MRI is misinterpreted, a patient who in reality has patellofemoral pain may be inappropriately slated for arthroscopic meniscal surgery (Fig. 15.9).

**Figure 15.9** Incidental MRI-detected meniscal pathology occur in 19% of women aged 50–59 years<sup>13</sup>. The figure shows a horizontal cleavage tear of the posterior horn of the medial meniscus (arrow). Whether or not this MRI-detected lesion is clinically relevant in a patient presenting with knee pain depends on the entire clinical picture, including detailed history and physical examination findings. The take-home message is that a clinician cannot, and should not, make a diagnosis and decide how to treat the patient solely based on MRI findings

## What does this MRI tell me? Tips for clinicians

The four most common sequences a clinician will see are outlined below and shown in Figure 15.10.

**Figure 15.10** The legend for the arrows/arrowheads to structures in the four MRI sequences is as follows: fat = yellow; tendon and ligament = off-white; water = blue; menisci = green

- 1. T1-weighted** provides sharp anatomical detail, shows bone marrow and is good for meniscal pathology. It lacks the sensitivity to detect soft tissue injury (Fig. 15.10a). MRI signal key: fat = bright; muscle = intermediate; water, tendons and fibrocartilage all dark.
- 2. Proton density-weighted** is good for imaging menisci and ligaments (Fig. 15.10b). MRI signal key: fat = bright or intermediate signal, calcium, tendons and fibrocartilage, all dark; water = intermediate.
- 3. T2-weighted** is highly sensitive for most soft tissue injury, especially tendons. Abnormal tendons have high signal intensity (bright) which contrasts with normal tendons black (arrowhead) (Fig. 15.10c). MRI signal key: water = bright; fat = intermediate muscle, hyaline and fibrocartilage all dark.
- 4. STIR** highlights excess water (blue arrow and blue arrowheads) which can occur due to bone stress and bone marrow oedema (shown), joint fluid and soft tissue pathology. This is the sequence of choice for bone stress injuries or subtle, radiographically occult fractures (Fig. 15.10d). MRI signal key: water = very bright; fat, muscle, menisci all dark.

The price of additional medical data is that the clinician who cares for the patient needs to determine how heavily to weigh the imaging information. Specifically, the clinician must arrive at a post-test probability of a diagnosis based on how much the MRI result (positive or negative) changes the pre-test probability of the diagnosis. (See Fagan's nomogram, Chapter 14.)

### Specific features and patient benefits of MRI

MRI is now a routine part of the medical landscape the world over, although access to MRI for sports medicine imaging is limited in some regions. The tide is heading powerfully in one direction towards greater and greater utilisation of MRI in sports medicine. Paradoxically, in developed countries that have private medicine (radiology), too much imaging and overdiagnosis, associated with overtreatment (particularly arthroscopic surgery) has a deleterious effect on health. So the challenge for both policy makers and skilled clinicians is to choose imaging wisely. Towards that aim, we first review the features of MRI as a tool for clinicians working in sport and promoting physical activity.

MRI has the following features which translate into patient and clinician benefits.

- MRI is non-invasive, so it has dramatically reduced the need for diagnostic arthroscopy.
- It can provide images in multiple planes. Need a sagittal view of the knee to image the patellar tendon? Sure! How about a coronal to assess joint surfaces and menisci? No problem!
- MRI does not involve ionising radiation. This is particularly important in the age group often treated by clinicians in sports medicine: adolescents, as well as for professional athletes who may have many clinical encounters and thus need many scans.
- MRI has superb contrast resolution for soft tissues, allowing accurate assessment of most ligaments, tendons and hyaline and fibrocartilage. Note that although bones are also well-assessed, if the clinical concern is one of primarily bony pathology (e.g. lumbar spondylolysis), CT may be more appropriate, bearing in mind radiation dose.
- It is ideal to assess patients who have had soft tissue trauma (e.g. contact injuries) and it complements the use of CT in high-velocity injuries.
- MRI has an emerging role in helping clinicians evaluate overuse injuries. Anatomy in patients in the sports medicine setting is markedly affected by microtrauma/adaptation to load and this is increasingly being well characterised. In the late 1980s, journals commonly carried treatment recommendations from 'experts' based on false premises of what was 'normal' in athletes.<sup>14</sup> The problem was that 'normal' for an elite athlete had

not been well documented. The subspecialty of sports radiology and greater experience of musculoskeletal radiologists with sport is addressing that challenge.<sup>6</sup> As with all research, knowledge translation remains a challenge; getting the key messages to the community of clinicians who will apply it.

### Difference added by MRI sequences

Spin echo (SE), gradient echo (GRE) and inversion recovery (IR) sequences are the basic categories of sequences used in musculoskeletal imaging.<sup>3</sup> T1-weighted, T2-weighted, proton density-weighted and short tau inversion recovery (STIR) sequences are often utilised (Figure 15.10). Fat-suppressed fast spin echo sequences are used in almost every musculoskeletal protocol to demonstrate bone marrow oedema, focal cartilage defects and tendon/ligament pathology with the highest conspicuity.

### Other clinical points about MRI

The clinical workhorse for sports MRI is the 1.5 T (Tesla) MRI platform. For almost all clinical indications, MRI at this field strength is generally sufficient. The 3 T magnets, which are more expensive to purchase, offer higher spatial resolution, and therefore may offer advantages in evaluating small structures, such as tendon pulley injuries in rock climbers (although there are currently no trials to support this). Advanced applications in 3 T may prove useful in the future in dedicated cartilage imaging.

The contrast agent for MRI is gadolinium, which has an excellent safety profile, even more so than the safe iodinated contrast agents used in CT. It is used intravenously for musculoskeletal imaging in cases in which tumour or neoplasm are being considered, and in an intra-articular fashion to optimally evaluate hyaline cartilage, such as shoulder and hip labra.

A less common architecture for MRI is so-called 'open' units, which do offer advantages in allowing patients with claustrophobia to be scanned; this occurs at the expense of image quality. The weight-bearing and kinematic options that these units provide are still investigational in nature (Fig. 15.11).

Physiologic (also called compositional) imaging of cartilage can be performed at 1.5 T and 3 T, but not accurately at lower field strengths. Special sequences can assess for loss of cartilage proteoglycan content (T1-rho mapping and dGEMRIC) and for collagen degradation (T2 mapping). These techniques hold great promise in biochemical, pre-morphologic chondral assessment in early osteoarthritis, and for follow-up of interventions (e.g. chondral surgery and, one day, biologics that can block the progression of osteoarthritis). However, currently their clinical role is undefined.

**Figure 15.11** The 'open' MRI instrument allows the patient to be weight-bearing. In this figure the model is wearing a knee coil

IMAGE COURTESY OF CENTRE FOR HIP HEALTH AND MOBILITY, UNIVERSITY OF BRITISH COLUMBIA [HTTP://WWW.HIPHEALTH.CA/](http://www.hiphealth.ca/)

There are a few strict contraindications to MRI (e.g. certain brain aneurysm clips, neurostimulators and cardiac pacemakers) but, contrary to popular medical opinion, patients with metallic orthopaedic hardware and metallic surgical clips outside the brain, in place for more than 6 weeks, can be safely scanned.

MRI can be overly sensitive to abnormal tissue signals and, thus, provide false positive results. In asymptomatic athletes in numerous studies, MRI revealed structural appearances consistent with significant injury but the athletes were asymptomatic and high functioning.<sup>12, 13</sup> This emphasises the need for the appropriate selection of patients for investigation and careful clinical-imaging correlation.<sup>1</sup> As with any medical investigation, diagnostic errors can occur; ideally, images should be read by an experienced musculoskeletal MRI radiologist.

### Ultrasound scan (for diagnosis)

High-resolution ultrasound scanning (Fig. 15.12) with 10–12 MHz probes is a painless method of imaging tendons, muscles and other soft tissues without exposing the patient to any radiation.<sup>15</sup> It allows clinical correlation—imaging with the patient reproducing his or her pain and providing feedback to the radiologist. Adding to its diagnostic utility, both sides can be readily imaged for comparison. Other advantages include its dynamic nature (the patient can move the part and/or reproduce pain during the examination), short examination time and ability to guide therapeutic aspiration or injection under real time.

Ultrasound is the imaging instrument of choice 'in clinic'.<sup>16, 17</sup> As it is an excellent way to visualise tendon and muscle, it can be the workhorse in a sports clinician's office where patients present with injuries of these tissues.

**Figure 15.12** High-resolution ultrasound scanning with 10–12 megahertz (MHz) probes is a painless method of imaging tendons, muscles and other soft tissues without exposing the patient to any radiation

Units are priced to be affordable in the clinic because the unit cost, installation and service are of the order of 100 times cheaper than MRI.

### PRACTICE PEARL

Ultrasound has been referred to as the sports physician's stethoscope and the analogy applies to the portability of ultrasound—small units can be used on the sideline.<sup>18</sup> Laptop-sized portable units have a different level of image quality to the larger units that are designed to stay in the clinic.

Clinicians in sport might consider ultrasound equipment as having three different levels.

1. The most expensive, best quality equipment would be located at a specialist radiology clinic. The radiologist and his/her team with the full battery of complementary imaging modalities provides the tertiary resource as well as continuing professional education (formal and informal) and research partnerships as appropriate.
2. Leading specialised clinical practices often choose to have quality ultrasound imaging capacity at the clinic to assist with speed of diagnosis, for injections with ultrasound imaging and because having ultrasound skills advances those clinicians understanding of anatomy.
3. Portable sideline equipment (laptop scanner shown in Fig. 15.13) still provides quality images but the users appreciate the limitation compared with that outlined in point 1.

Disadvantages of ultrasound include the less graphic images, the fact that it is more operator-dependent with

**Figure 15.13** Portable sideline ultrasound unit  
REPRODUCED WITH PERMISSION OF GE HEALTHCARE

respect to image quality than any other modality, and the fact that it cannot penetrate tissues to show deeper structures, such as shoulder/hip labra or anterior cruciate ligaments/menisci. The most commonly examined areas are large tendons, (e.g. the Achilles, patellar and rotator cuff tendons) and the muscles of the thigh and calf. Ultrasound can also demonstrate muscle tear, haematoma formation or early calcification, and may be useful in localising foreign bodies.

Ultrasound scanning is able to distinguish complete tendon rupture from other tendon abnormalities (e.g. tendinopathy). As with MRI, ultrasound imaging of elite athletes reveals morphological 'abnormalities' that are not symptomatic and do not appear to predict imminent tendon pain.

Real-time ultrasound examination during active movement (dynamic ultrasound) is particularly helpful in the evaluation of shoulder impingement. The use of ultrasound to help guide injection is discussed in Chapter 17.

### The role of colour Doppler

Colour Doppler ultrasound gained popularity in sports medicine for the assessment of tendons in the early 2000s, as it was hoped that abnormal tendon flow detected using

**Figure 15.14** Sagittal colour Doppler ultrasound scan showing abnormal blood flow (arrow) at the mid- and deep surface of the patellar tendon near the patellar attachment

the colour Doppler feature would provide a better guide as to whether or not tendons were painful (Fig. 15.14). Longitudinal studies failed to show that colour Doppler ultrasound findings of vascularity predicted changes in symptoms.<sup>19</sup> Also, exercise affects the level of vascularity, which adds a challenge to the clinical utility of this method. This modality is proving useful in certain areas of medicine but has dropped off the 'hot topics' list in sports medicine. To return to a theme from early in this chapter, there appears to be no substitute for careful clinical examination and patient monitoring to track patients' current progress and to predict outcomes.

### The role of ultrasound tissue characterisation

In the 2010s, a novel ultrasound modality, called ultrasound tissue characterisation (UTC), was introduced to evaluate human tendons (Fig. 15.15).<sup>20</sup> The innovation aims to provide a three-dimensional image of the tendon where structure is quantified (in contrast to conventional greyscale ultrasound which provides no numerical data). Data are obtained from the stability of pixel attributes (brightness) over a set scan length to a maximum of 25 scan slices at present. UTC has high reproducibility with excellent intra-observer and interobserver reliability.<sup>20</sup> Detailed descriptions of the use of this emerging technology are reported in various clinical research reports.<sup>20, 21</sup>

Is this method ready for general use in 2017? No. Ultrasound tissue characterisation is currently a research instrument with potential that marketers would say is at the early stage of the 'product life cycle'.<sup>22</sup> As with any new technology, there will be extreme claims as to its potential capacity; over time a body of evidence will emerge as to the best ways for clinicians and patients to benefit from the technological advance.<sup>21</sup> At the time of writing, there is only one manufacturer of this patented technology (UTC imaging, Stein, The Netherlands) and the cost of an instrument is in the range of US\$40 000 to US\$60 000, depending on service costs and the options that the user chooses for elements such as probes.

(a)

(b)

**Figure 15.15** Ultrasound tissue characterisation (UTC) of the Achilles tendon. Standard image (axial plane) in (a), and put in context in (b) with yellow being subcutaneous tissue. The tendon tissue would all be green in a normal tendon. This tendon has collagen pathology which is seen as blue, red and black signal. Green = echo-type I (normal tendon); blue = echo-type II; red = echo-type III; black = echo-type IV. Echo-types II–IV are abnormal

### CT scanning

CT scanning (Fig. 15.16) allows cross-sectional imaging of soft tissue, calcific deposits and bone. CT scanning is particularly useful in evaluation of the spine, fractures in small bones and fractures in anatomically complex regions, such as the ankle, foot or pelvis. CT scanners provide high-resolution reconstructions of the imaging

**Figure 15.16** Axial CT scan showing cross-section of osteochondral lesion of the posteromedial talar dome (arrow)

data in any plane. Remember that CT defines bone details and can detect small areas of calcification better than MRI can, even though the latter will reveal occult bony abnormalities. Advances in multidetector CT technology allow rapid image acquisition and superb multiplanar reconstruction. The disadvantage of CT scanning is the significant radiation dose, especially in children.

### Radioisotopic bone scan

Radioisotopic bone scan (scintigraphy) has fallen out of favour in sports medicine practice because of the availability of MRI with appropriate pulse sequences (e.g. STIR) which can often provide similar information about bone while adding anatomical localisation that was limited with bone scan. The high sensitivity and low negative likelihood if negative for stress fracture meant that the test was useful for ruling out stress fractures. Does radioisotopic bone scanning still have a role? Very rarely. Expert and experienced radiologists may use it at times to seek a tibial or a metatarsal stress fracture but it has essentially been superseded by MRI and CT.

Single photon emission computed tomography (SPECT) techniques are also used in sports medicine, particularly in the detection of stress fractures of the pars interarticularis of the lumbar spine, although the correct MRI sequence should be able to detect these changes.

# Patient-reported outcome measures in sports medicine

with NATALIE COLLINS, KAY CROSSLEY and EWA M ROOS

*The operation was entirely successful, but the patient succumbed.*

*Manual of Operative Surgery, published 1887*

Sports medicine clinicians likely had their first encounter with patient-reported outcome measures (PROMs) in the research setting, as PROMs are commonly used to capture treatment response. However, PROMs can also be useful in clinical practice. This chapter outlines what PROMs are, why they are important to use in clinical practice and what constitutes a 'good' PROM. It also provides examples of generic PROMs to use in sports medicine patients, which can be used to complement more specific measures outlined in the regional chapters. We emphasise that the key letters in the term 'PROMs' are the first two—P and R—for 'patient-reported.' That is what differentiates PROMs from 'objective' clinical measures such as range of motion or strength.

## WHAT ARE PROMS?

PROMs are measures in which the patient provides his or her own perspective of a health condition or treatment. This is particularly useful when the aspect of interest is either impossible or impractical to observe directly, such as pain or high-level sporting function.<sup>1</sup> PROMs can be specific for the region (e.g. knee), condition (e.g. tendinopathy) or intervention (e.g. anterior cruciate ligament reconstruction or exercise). The clinician may be familiar with measures such as the IKDC (International Knee Documentation Committee) for knee function, the Western Ontario and McMaster Universities Arthritis Index (WOMAC) score for osteoarthritis, and the Victorian Institute of Sport Assessment (VISA) score which rates patients who have tendinopathy. All of these are examples of various types of PROMs.

A type of PROM can also provide a generic measure of overall health status (i.e. not 'disease-specific').<sup>2</sup> PROMs can

measure a variety of constructs, such as pain, symptoms, physical function and quality of life. An example of a very simple, commonly used PROM in clinical practice is asking the patient to rate their pain severity on a scale from zero to ten—a visual analogue scale (VAS). Contemporary PROMs provide more comprehensive insight into a number of aspects that are important to consider in the patient's condition.

## WHY IS IT IMPORTANT TO USE APPROPRIATE PROMS IN SPORTS MEDICINE?

Clinicians who work in sports and exercise often use standard clinical tests to evaluate physical aspects, such as joint range of motion, ligament integrity and functional performance. While these provide important information about particular aspects of the patient's condition, they are unable to measure how the patient feels and performs. PROMs complement clinical tests to evaluate the patient's overall health and performance status more comprehensively.

In sports medicine, PROMs are mostly used to evaluate the effectiveness of treatment. However, they may also:

- focus the clinical appointment toward aspects that most concern the patient (i.e. by asking the patient to complete the PROM prior to the appointment)
- build a profile of the patient's health condition over time and quickly identify those who have experienced improvement or deterioration and may require refinements to their training or management<sup>3</sup>
- identify dimensions that the patient deems to be important in their treatment planning and goal setting

- predict which patients are likely to have a good prognosis or respond to a particular treatment
- decide a patient's readiness for return to activity<sup>3</sup>
- empower the patient to monitor his or her own health profile over time, by providing benchmarks for the ideal health state (vs peers, normative cohorts)
- screen patients for injury risk
- provide a method of standardising health status reporting, to allow pooling of data from international cohorts (e.g. ACL registries) and detect clinical patterns that may influence prognosis and response to treatment.

### CONSIDERATIONS FOR WHAT CONSTITUTES A 'GOOD' PROM FOR USE IN SPORTS MEDICINE

Several factors should be considered before integrating PROMs into clinical practice. This will ensure that implementing the PROM is feasible and it will help to ensure that the PROMs provide relevant, reliable and valid information about the patient and can measure change in the patient's condition over time. Clinicians can obtain this information from a variety of sources, including the PROM's original publication (e.g. journal article, book), online resources (e.g. specific PROM websites such as [www.koos.nu](http://www.koos.nu)) and systematic reviews of PROMs. It is also important to recognise that measurement properties are often population-specific. This means that clinicians should confirm that the PROM has been evaluated in the specific patient cohort relevant to their patient (e.g. ACL-reconstruction versus knee osteoarthritis).

#### Is the PROM easy to use in a sports medicine setting?

One of the perceived barriers to integrating PROMs into clinical practice is the burden on patients and clinicians, and how this will affect sports medicine services in the clinic, clubrooms, or during competition and travel. At the elite level, patients are accustomed to completing regular log-books to track factors such as their training load, dietary intake and sleep patterns. As such, the inclusion of appropriate PROMs is unlikely to be too burdensome, especially if it provides information that they see to be relevant to their injury or health condition and goals, and is delivered in the same format as their regular log-books (i.e. mobile device or paper diary).

By definition, PROMs should be patient-administered, without input from the clinician or others, as this captures the patient's impression of their health condition and minimises the potential for bias introduced with clinician-completed measures. This is also likely

to minimise the burden on clinicians, as patients can complete the PROMs prior to their appointment or in the waiting room.

Another consideration regarding patient burden is the format and layout of the PROM. Are the items logical and easy to interpret, or does the patient need to read each item carefully to ensure that they provide the correct response? For example, some PROMs reverse the wording or responses to some items and then invert the scoring (e.g. items 4, 8, 12 and 16 of the Tampa Scale for Kinesiophobia).

Although it may be preferable in clinical practice to use PROMs with the shortest completion time, this needs to be considered along with the information that the PROM provides. Some PROMs that take longer to complete may provide substantially more information about different aspects of the patient's condition (e.g. PROMs such as the Knee Injury and Osteoarthritis Outcome Score (KOOS) and Copenhagen Hip And Groin Outcome Score (HAGOS) that provide separate subscales for pain, function and quality of life take 5–10 minutes to complete) than shorter PROMs that only measure one construct (e.g. numerical rating scale for pain taking seconds to complete). The completion time is also important to consider in the context of how frequently the PROM will be administered. If the frequency is at least 3 months apart, longer PROMs are feasible, while shorter PROMs are more feasible if daily, weekly or monthly administration is desired.

The clinician should also consider how burdensome the PROM is to score and interpret in the sports medicine setting. To minimise clinician burden, we recommend that electronic or online data collection platforms be used where possible. This allows clinicians to receive scores in real time using computer algorithms, which enhances their clinical utility.<sup>3</sup> Electronic questionnaires have high agreement with their paper-based predecessors.<sup>4</sup> Furthermore, information needs to be made available to clinicians regarding how to interpret PROM scores, relate them to the patient's condition and use them to make decisions about treatment.<sup>3</sup> The availability of a user guide for the PROM will facilitate ease of administration and scoring.

Finally, the accessibility of the PROM should be considered. Many PROMs are open access and freely available for clinical use (e.g. KOOS). However, some PROMs have licensing requirements and fees associated with their use, even in clinical practice (e.g. WOMAC). Given that sports medicine clinicians can manage patients of various cultural and language backgrounds, they should also consider whether a particular PROM is available in languages other than English and whether non-English versions have undergone cross-cultural validation. This ensures that the same meaning of the items and stability

of measurement properties (e.g. reliability, validity, responsiveness) is retained when the PROM is translated into another language.

### **Does the PROM evaluate dimensions that are relevant for the patient?**

In selecting a PROM for use in sports medicine, it is vital that it evaluates specific dimensions, subscales, items or questions that are relevant for the particular patient. The first step in determining relevance of dimensions is to obtain information regarding the patient group that the PROM was intended for. This is generally available in the PROM's original publication. For example, the iHOT-33 was intended for young active patients with hip disorders,<sup>5</sup> which would be suitable for use in athletic populations. In comparison, the KOOS was intended for use in young, middle-aged and elderly patients with knee injuries and/or osteoarthritis.<sup>6</sup> Thus, items in the subscale pertaining to function during sport and recreational activities (e.g. running, jumping, twisting/pivoting) may be more relevant to younger active patients than function in activities of daily living (e.g. putting on socks/stockings).

Validity refers to the degree to which a PROM measures the constructs that it intends to measure.<sup>7</sup> This is an important consideration when making inferences based on PROM scores.<sup>1</sup>

Content validity is the degree to which the content of the PROM adequately reflects the constructs to be measured, with respect to their relevance and comprehensiveness.<sup>1, 7</sup> A PROM has adequate content validity if the developers provide a clear description of the measurement aim, the target population, concepts to be measured and item selection.<sup>8</sup> Importantly, patients from the target population should have been involved in the development or selection of included items.<sup>8</sup> Face validity is a component of content validity that is useful for clinicians. This refers to the degree to which, on face value, the items of a PROM look as though they adequately reflect the construct to be measured.<sup>7</sup> Clinicians should ensure that PROMs demonstrate content validity and that they do not overrule dimensions that patients deem to be important—it is the patient who is the expert in this scenario.

Construct validity refers to how well the PROM measures its intended constructs.<sup>2</sup> This is typically evaluated by testing hypotheses regarding the expected relationship between the PROM and other instruments. Evidence for convergent construct validity is provided when higher correlations are found between the PROM and existing measures that evaluate similar constructs.<sup>8</sup> Evidence for divergent construct validity is provided when lower correlations are observed between the

PROM and existing measures that evaluate dissimilar constructs.<sup>8</sup> For example, in patients who had undergone hip arthroscopy, the pain subscale of the Copenhagen Hip And Groyn Outcome Score (HAGOS) demonstrated larger correlations with the SF-36 bodily pain subscale and smaller correlations with the mental health subscale.<sup>9</sup>

Clinicians may also see reference to another form of validity in the literature, termed criterion validity. This refers to how well the scores of an instrument reflect a 'gold standard'.<sup>7</sup> Because there is no gold standard measure of patient-reported outcome,<sup>10</sup> criterion validity is not applicable to PROMs.

### **Do all items within a PROM measure the same construct?**

For scoring and interpretation purposes, it is important that all items within a PROM or individual subscales reflect the same dimension.<sup>11</sup> The internal consistency measures how well all items within a PROM are correlated and thus measure the same construct.<sup>8</sup> This is an important consideration for PROMs that use multiple items to measure a single construct (e.g. Tampa Scale for Kinesiophobia), to ensure that all items are likely to respond in a similar way to a change in the patient's condition.

The first step in determining the internal consistency of a PROM is to examine the structural validity. During the development phase of the PROM, specific analyses (principal component analysis or exploratory factor analysis) are used to determine whether the items form one overall dimension (unidimensionality) or more than one dimension (multidimensionality).<sup>8</sup> For PROMs that consist of a single overall score (e.g. VISA Score), all items should reflect a single construct.<sup>1</sup> For PROMs that consist of several subscales that are scored individually (e.g. HAGOS), several dimensions should be demonstrated.<sup>1</sup> Clinicians should confirm that all items within an overall score or subscale score, as appropriate, reflect only one dimension.

Once the unidimensionality of the PROM or its subscales has been established, Cronbach's alpha can be used to measure the interrelatedness of all items within a (sub)scale.<sup>7, 8</sup> Cronbach's alpha is considered adequate if it falls between 0.7 and 0.95. A low Cronbach's alpha (<0.7) indicates that the items are not well correlated and that a single summary score is not appropriate.<sup>8</sup> A very high Cronbach's alpha (>0.95) is also not ideal and suggests that one or more items within the (sub)scale are redundant.<sup>8</sup>

### **Can the PROM be trusted to detect true change in the patient and be free from error?**

To be able to trust and interpret PROM scores, it is important to establish the error associated with the PROM.

This gives clinicians an idea as to whether any change observed in the PROM between repeated administrations reflects a true change in the patient's condition or is due to error inherent in the measure.

The test-retest reliability of a PROM indicates how stable the results are when you measure a patient's unchanged condition on two separate occasions.<sup>2</sup> For PROMs that are patient-completed, reliability is considered to be intra-rater, as the same person (the patient) completes the PROM on different occasions.<sup>7</sup> Typically, test-retest reliability is reported using intraclass correlation coefficients (ICC). This indicates the strength of the relationship between the two administrations, from 0 (no relationship) to 1 (the relationship between the repeated administrations can be predicted without error).<sup>1</sup> Interpretation of ICCs differs depending on whether clinicians intend to use the PROM in individual patients or in groups of patients (e.g. sporting teams).

#### PRACTICE PEARL

Test-retest reliability is considered adequate for use in individual patients if the ICC is greater than 0.9,<sup>12</sup> and for use in groups if the ICC is greater than 0.7.<sup>9</sup>

The absolute measurement error or agreement can also be determined. This provides clinicians with a value, expressed in the measurement unit of the specific PROM, which can be used to determine whether a PROM change score is greater than the error of the measure. The standard error of measurement (SEM) estimates one standard deviation of the error associated with one measurement.<sup>1</sup> This is then used to calculate the minimal detectable change (MDC), also known as the smallest detectable change (SDC). The MDC can be determined for individuals ( $MDC_{ind} = 1.96 \times \sqrt{2} \times SEM$ ), reflecting the smallest change occurring within a patient that can be interpreted as 'real' change (at the 0.05 significance level).<sup>8</sup> It can also be determined for groups ( $MDC_{group}$ ), by dividing the  $MDC_{ind}$  by  $\sqrt{n}$  (where  $n$  is the number of participants).<sup>8</sup> In clinical practice, if a patient's change score on a PROM is greater than the  $MDC_{ind}$ , clinicians can interpret this as a true change in the patient's condition.

#### Is the PROM sensitive enough to detect real change in the patient's condition?

Because PROMs are frequently used to evaluate a patient's response to treatment or monitor their condition over time, they must be sufficiently sensitive to be able to detect real changes in a patient's condition. Responsiveness refers to the ability of a PROM to detect change over time in the

measured construct.<sup>7</sup> This is arguably the most important measurement property, as it gives an indication of how robust the PROM is on all other measurement properties (e.g. validity, reliability). Responsiveness is specific to the population and treatment of interest, so clinicians should seek evidence from studies that test responsiveness in cohorts that have similar characteristics to the specific patient (e.g. age, injury/condition/treatment).

The difficulty for clinicians is the lack of consensus regarding the optimal method of evaluating responsiveness for PROMs. Earlier studies frequently present effect sizes as a measure of responsiveness. However, this is more a reflection of treatment effects (i.e. the magnitude of the change score), rather than whether the PROM can detect change over time (i.e. validity of the change score).<sup>11</sup> More recently, the COSMIN group recommended that responsiveness should be evaluated in a similar way to construct validity, by testing predefined hypotheses regarding the expected correlation between change scores of two PROMs that are administered simultaneously or expected differences in changes between 'known' groups.<sup>13</sup> PROMs may be compared to a 'global rating of change' (GROC) scale, which is an adequate estimate of the magnitude and direction of health status change,<sup>14</sup> or to other measures of the same construct.<sup>15</sup> Thus, responsiveness can be viewed as longitudinal validity.<sup>8</sup> Clinicians can gain evidence of PROM responsiveness from studies where predefined hypotheses regarding change scores (e.g. effect sizes) are supported. Effect sizes are also useful when comparing PROMs head to head, or when comparing groups that are better, unchanged or worse.

The other component of responsiveness relates to whether the PROM can distinguish clinically important change from measurement error.<sup>13</sup> This is particularly important for clinical practice, as clinicians need to be confident that changes they are observing in their patient, measured using PROMs, represent meaningful change in the patient's condition. The minimal clinically important difference (MCID), also known as the minimal important change (MIC), is the smallest change in a PROM score that patients consider to be important.<sup>11</sup> The MCID provides clinicians with an estimate of the average amount of change in PROM score that patients would typically consider to represent a meaningful improvement.<sup>1</sup>

#### PRACTICE PEARL

When interpreting MCIDs, clinicians should ensure that the MCID is larger than the MDC, indicating that the magnitude of important change is greater than the error associated with the PROM.<sup>8</sup>

One consideration with the ability of a PROM to detect change is whether it demonstrates any floor or ceiling effects when used in particular patient groups. Floor effects occur when patients score the lowest possible value on the (sub)scale at baseline measurement, meaning that there is no room for the PROM to detect further deterioration. Ceiling effects occur when patients score the highest possible value, meaning that the PROM is unable to detect improvements in the condition.

Athletic patients may demonstrate ceiling effects on PROMs that were originally designed for use in older, more inactive cohorts. For example, the KOOS subscale for activities of daily living often demonstrates ceiling effects when used in young ACL-injured<sup>16</sup> and reconstructed patients,<sup>17</sup> as the items in this subscale relate to low-level daily activities such as putting on socks. Also, older patients with osteoarthritis may demonstrate floor effects on PROMs designed for younger, more active cohorts. For example, the KOOS subscale for sport and recreation may demonstrate floor effects when used in older patients who have moderate to severe knee osteoarthritis after ACL reconstruction, because they have extreme difficulty participating in running, jumping and twisting activities.

For PROMs that have multiple subscales, it is up to the clinician to decide whether all subscales are relevant to the patient of interest. Since scores are calculated and presented per subscale, individual subscales can be omitted in the population of interest or at specific time points. For example, it may not be relevant to evaluate the KOOS sport/rec subscale 2 weeks after ACL reconstruction. Floor and ceiling effects are considered acceptable if less than 15% of patients score the lowest or highest score, respectively.<sup>8</sup>

## SUMMARY

PROMs measure items that matter to patients. They can add valuable information to the assessment and management of patients. Selected PROMs are easy to integrate into the sports medicine setting, evaluate patient-relevant constructs, represent single dimensions and can detect real changes in the patient's condition (beyond a defined measurement error). The reader is directed to Part B chapters for recommendations regarding PROMs for specific body regions, conditions and interventions.

Table 16.1 gives some examples of commonly used generic PROMs, while an example of the clinical use of a PROM is shown in the box below.

### Examples of generic PROMs appropriate for use in clinical sports medicine

A number of generic PROMs can be applied across a variety of patient groups (i.e. different conditions or injuries) and interventions. Table 16.1 lists some commonly used generic

PROMs that measure constructs that are applicable for sports medicine patients.

**Table 16.1** Commonly used generic PROMs

#### Pain

##### Pain Numerical Rating Scale (NRS)<sup>18</sup>

- Single item
- Most commonly 11-point scale, anchored with 'no pain' (0) and 'worst imaginable pain' (10)
- Patient selects the number that represents their pain severity over the nominated time period (e.g. last 24 hours, past week)
- Manual scoring, score range 0–10
- Freely available

#### Function

##### Patient-specific Functional Scale<sup>19</sup>

- 3–5 items, single aggregate score
- Patient nominates up to 5 activities that are difficult because of their injury/condition, then rates the difficulty for each activity on an 11-point NRS (0 = 'unable to perform activity'; 10 = 'able to perform activity at same level as before injury or problem')
- Manual scoring (average of all scores), score range 0–10
- Freely available

*continued*

**Health-related quality of life****SF-36<sup>20</sup>**

- 36 items across domains of physical functioning, physical role, bodily pain, general health, vitality, social functioning, emotional role and mental health; can also derive two aggregate summary measures: physical component summary and mental component summary
- Scored by recording some items, summing responses and transforming scores to a 0–100 scale (higher score = better health state). Computer scoring algorithms are necessary and freely available
- Normative data available in multiple populations<sup>21</sup>
- Original version available in English and Arabic, free of charge ([www.rand.org](http://www.rand.org)). Most recent version (developed in 1998) requires licence and is available in more than 170 languages ([www.optum.com/optum-outcomes/what-we-do/health-surveys/sf-36v2-health-survey.html](http://www.optum.com/optum-outcomes/what-we-do/health-surveys/sf-36v2-health-survey.html))

**AQoL-6D<sup>22</sup>**

- 20 items across 6 domains (independent living, mental health, relationships, senses, coping, pain)
- Scoring algorithms and an online scoring service are available ([www.aqol.com.au](http://www.aqol.com.au)). Score range –0.04 (health state worse than death) to 0.0 (death) and 1.00 (full health)
- Available in 6 languages
- Normative data available
- Freely available; requires registration for use in studies, but not clinical practice

**Health-related quality of life****Pain Catastrophising Scale<sup>23</sup>**

- 13 items across 3 subscales (rumination, magnification, helplessness)
- Manual scoring by summing items. Single aggregate score can be calculated (0–52), as well as individual subscale scores. Higher scores represent higher degree of catastrophising
- Freely available in 21 languages (<http://sullivan-painresearch.mcgill.ca/pcs.php>)

**Tampa Scale for Kinesiophobia<sup>24</sup>**

- 17 items evaluating kinesiophobia
- Manual scoring by summing all items (after converting individual scores of 4 items). Total score ranges from 17 to 68, where a high score indicates a high degree of kinesiophobia
- Freely available<sup>25</sup>

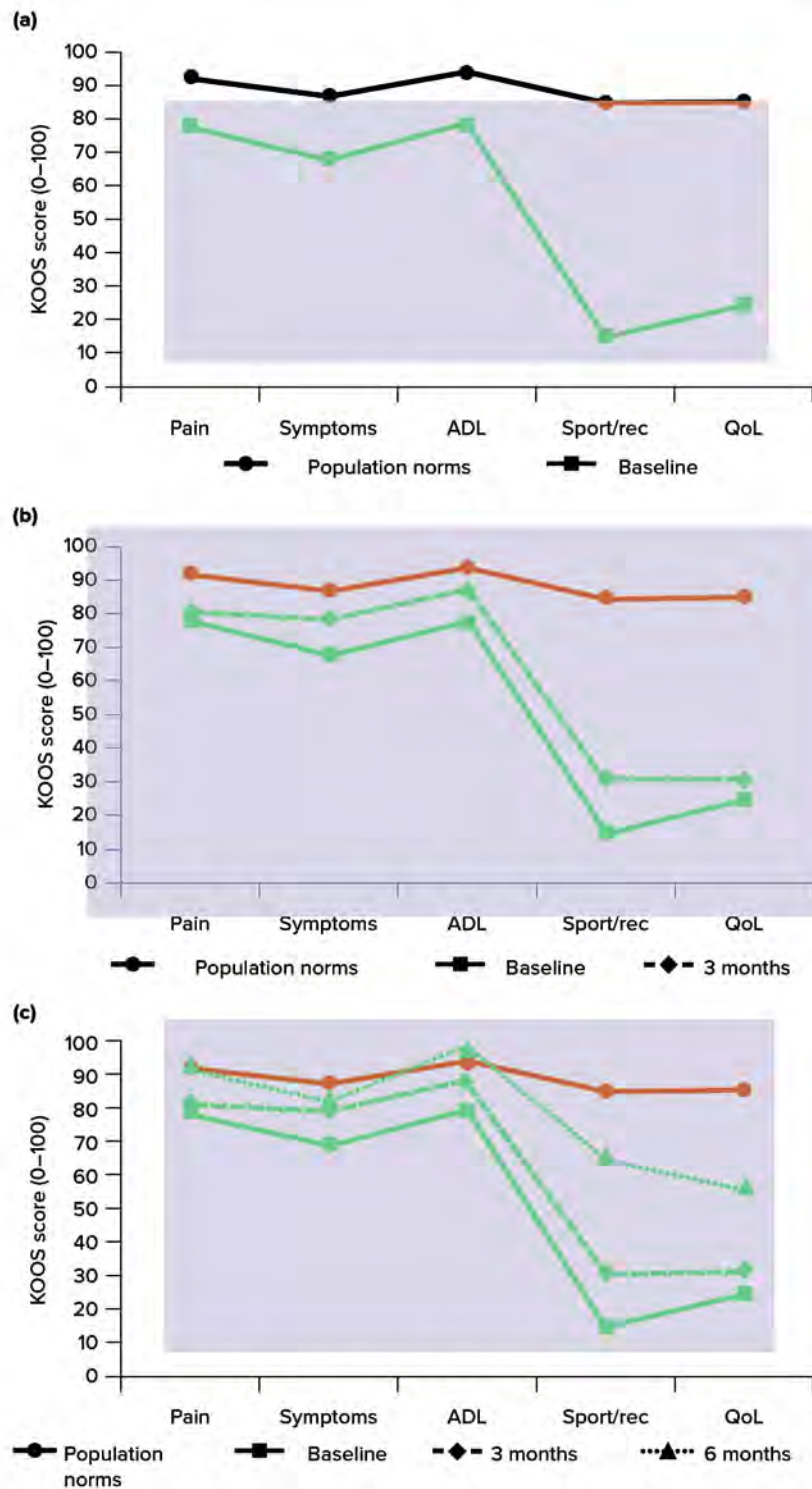

**Case study: Measuring knee symptoms, function and quality of life after ACL reconstruction**

David is a 34-year-old man who underwent an ACL reconstruction (ACL) (hamstring tendon autograft) of his right knee 7 years ago. He returned to social soccer 18 months after surgery. He has recently been experiencing pain and stiffness in his right knee, and has stopped playing soccer and running as he fears that this may increase his pain and any damage in his knee. His family physician ordered X-rays, which revealed mild to moderate osteoarthritis in his right patellofemoral and tibiofemoral joint compartments. David was then referred for physiotherapy management.

In addition to performing his usual clinical assessment, David's physiotherapist administered the KOOS to better

understand David's knee condition. The KOOS was developed for patients with knee injuries and/or osteoarthritis. It consists of five individually scored subscales: pain, symptoms, function in activities of daily living (ADL), function in sport and recreation activities and knee-related quality of life (QoL). The KOOS is reliable and valid in patients with ACL injury and/or knee osteoarthritis.<sup>26</sup> The minimal detectable change (MDC), for individuals in adults with mild OA after ACL reconstruction is: pain 20; symptoms 24.9; ADL 14.4; sport/rec 24.9; QoL 20.5 (calculated from SEM data<sup>27</sup>.)

Figure 16.1a shows David's KOOS scores at baseline (at his first physiotherapy session) compared to population normative data.<sup>28</sup> There are marked differences in scores

**Figure 16.1** David's KOOS profiles of the five subscale scores at (a) baseline, (b) 3 months and (c) 6 months, compared to population normative data

*continued*

for the sport/rec and QoL subscales. In comparison, the differences in scores for the pain, symptoms and ADL subscales are smaller. This may be because younger patients who undergo ACL reconstruction are more concerned with sport/rec function and QoL and it may reflect ceiling effects observed in this population. However, the difference between David's scores and population norms for the ADL, sport/rec and QoL subscales are greater than the  $MDC_{ind}$ , indicating that real differences are present.

The physiotherapist implements a rehabilitation program of lower limb strengthening and neuromuscular control exercises, combined with manual therapy and patella taping to address pain and symptoms.

David's KOOS scores after 3 months are presented in Figure 16.1b. Although his scores are better on the symptoms, ADL and sport/rec subscales, the change scores from baseline are within the error of the measure and therefore may not represent real change. Furthermore, while his scores on the pain, symptoms and ADL subscales are

approaching population norms, the sport/rec and QoL scores remain substantially lower.

Based on these outcomes, the physiotherapist decides to integrate some interventions to address QoL into David's rehabilitation program. Specifically, she uses some graded exercises, combined with education, to improve David's confidence in his knee (assessed by KOOS QoL item 3) and reduce any fear-avoidance of potentially damaging activities (KOOS QoL item 2). She continues to progress his strength and neuromuscular exercises, in preparation for return to sport.

From Figure 16.1c you can see that David's pain, symptoms and ADL scores are almost identical to population norms. His sport/rec and QoL scores have also increased by an amount that exceeds the  $MDC_{ind}$ . The physiotherapist interprets these findings as representing a true change in David's knee condition. At the last appointment, the physiotherapist hands over the KOOS profiles to David and asks him to score himself from time to time to keep track of his status.

# Treatment of sports injuries

with BEN CLARSEN

*Healing is a matter of time, but is sometimes also a matter of opportunity.*

Hippocrates (c.460–370 BCE)

This chapter is integrally linked to the following chapter on the principles of injury rehabilitation. While the terms *treatment* and *rehabilitation* are often used synonymously, we define *treatment* as specific interventions aimed at tissue pathology, impairments or symptoms. Examples of treatments include targeted tendon loading (therapeutic exercise), mobilisation of a cervical spine facet joint (manual therapy), extra-corporal shockwave therapy (electrotherapy) and non-steroidal anti-inflammatory drugs (therapeutic medications). In contrast, we define *rehabilitation* as a holistic process aimed at restoring the athlete to his or her pre-injury function—a part of which involves the application of the right treatments at the right time.

This chapter provides essential background for the treatments detailed in Part B: Regional Problems. Evidence for treatment effectiveness is continually changing. However, remember that our craft remains as much art as science. Level 1 evidence is not always available (see box) and the decision to use (or not to use) certain treatments is also influenced by our experience, professional training and patient's expectations (see 'A cautionary tale' below and Chapters 1 and 2). Nevertheless, clinicians should have a solid understanding of the theoretic rationale for the treatments they provide, as well as up-to-date knowledge of the evidence of their effectiveness.

The effect of each treatment should be evaluated by objectively comparing symptoms and signs before and after the treatment, and at the next visit. Functional testing and patient-reported outcome measures (PROMs—Chapter 16) should also be used regularly throughout the course of treatment. This enables the clinician to choose

the most appropriate mode of treatment for the specific injury and individual. In presentations that fail to improve, this also allows the clinician to change modalities or pursue further investigations.

### High-level evidence is not always available

There are no randomised controlled studies to demonstrate that jumping out of a plane with a parachute leads to superior outcomes than jumping without one.<sup>1</sup> The best evidence for the effectiveness of parachutes comes from retrospective case series (level 4 evidence; Fig. 17.1). Would this stop you from recommending their use?

**Figure 17.1** The level of research evidence supporting the use of parachutes is low. CORBIS

## A cautionary tale

with KIERAN O'SULLIVAN

Before we launch into specific treatments and the evidence that underpins them, we need to share a cautionary tale. Just as Chad Cook (Chapter 14) alerted us that clinical assessment is not as accurate as the 1990s textbooks made out, treatment is not what a glitzy pharmaceutical video might suggest it is.

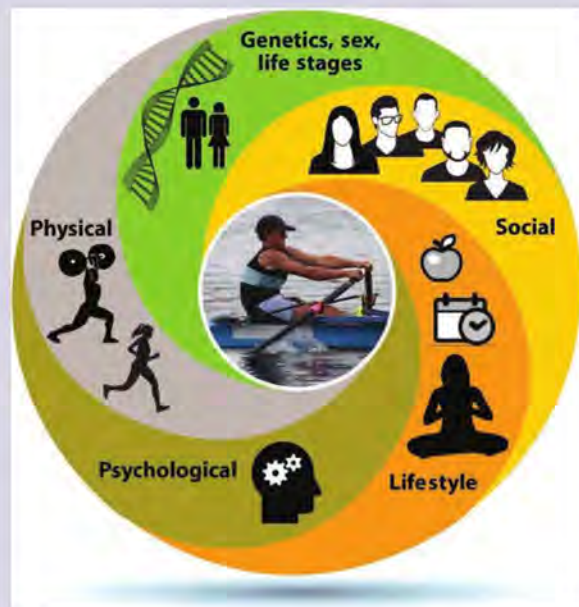

Unfortunately, several very important factors—that are unrelated to the pathology of a condition itself—can influence treatment outcomes. You have seen patients who are positive in their outlook and others who seem to live in a world of gloom and doom. You probably suspect that this might affect the outcome of treatment, and evidence indicates it most certainly does.

Patients' response to treatment is greatly influenced by *cognitive* (e.g. thoughts, self-efficacy, hypervigilance), *psychological* (e.g. depression, stress, anxiety, perceived injustice), *social* (e.g. work, family, financial, cultural, social support, life events) and *lifestyle* (e.g. poor sleep, sedentary behaviours, physical activity levels, diet, smoking) factors (Fig. 17.2). These systemic factors are widely acknowledged as being key in the onset and maintenance of pain<sup>2–4</sup> among non-sporting populations reporting pain or injury (e.g. chronic low back pain, hip and knee osteoarthritis). Sports medicine is just beginning to embrace this undeniably important concept.

### PRACTICE PEARL

Psychosocial, cognitive and lifestyle factors are related to (i) the onset of symptoms,<sup>5,6</sup> (ii) treatment response<sup>7,8</sup> and (iii) return to sport.<sup>9,10</sup>

While these systemic factors are often perceived as difficult to modify, they are likely to be at least as modifiable as many physical factors (e.g. posture, muscle thickness), which are often the main targets for treatment, but which often do not objectively change as the athlete recovers.<sup>11,12</sup> Successful clinical outcomes after treatments typically considered to be 'physical', such as exercise, are often mediated by changes in cognitive and psychological factors.<sup>13</sup> Critically, there is evidence that these systemic factors are related to more traditional physical factors (e.g. fear affects movement patterns and, thus, can slow the athlete's return to sport).<sup>14,15</sup>

**Figure 17.2** A wide range of factors influence patients' response to treatment

### PRACTICE PEARL

Rather than considering rehabilitation from injury as physical or psychological, rehabilitation might often need to combine these aspects in a manner that best matches the individual needs of each athlete.

For example, as discussed below, exercise is a core component of injury rehabilitation. Since exercise can enhance a range of systemic factors (e.g. sleep, mood, catastrophising, fear, self-efficacy), there may be occasions when athletes benefit more from the health-enhancing systemic effects of exercise (e.g. it aids relaxation and sleep) than from local loading tissue effects (e.g. an athlete whose pain or injury is not explained by the typical tissue injury model). In situations such as this, clear communication with athletes regarding the mechanism of effect of exercise, and the context in which that exercise is completed, is critical. Furthermore, traditional rehabilitation can then evolve to incorporate additional treatment components (e.g. relaxation, cognitive behavioural therapy, sleep hygiene, dietary advice) to influence several of these wellness factors as required with each athlete.

## THERAPEUTIC EXERCISE

The health benefits of regular physical activity have been recognised since before the time of Hippocrates and proven more and more convincingly since Jeremy Morris' London bus study in the 1950s. The slogan 'exercise is medicine' has been adopted by many public health groups aiming to prevent non-communicable diseases such as cardiac disease, type 2 diabetes and cancer.

'Exercise is medicine' also applies to the treatment of musculoskeletal injury. There is abundant evidence for exercised-based therapy as treatment of a wide range of conditions including tendinopathy,<sup>16</sup> osteoarthritis<sup>17, 18</sup> and lower back pain.<sup>19</sup>

The following section will review a number of mechanisms that may explain the benefits of therapeutic exercise, such as stimulation of tissue repair and remodelling, altering biomechanics and exercise-induced hypoalgesia.

### PRACTICE PEARL

Abundant high-level evidence supports therapeutic exercise as a first-line treatment across a wide range of conditions. It should be considered as a first-line treatment for almost any musculoskeletal condition.

## Stimulation of repair and remodelling: mechanotherapy

The prescription of therapeutic exercise to promote beneficial tissue adaptations has been called 'mechanotherapy'.<sup>20</sup> This refers to the employment of mechanotransduction—the process by which cells convert physiological mechanical stimuli into biochemical responses—to promote repair and remodelling of injured tissue (see boxed text).

### Mechanotransduction: how loading tissue can stimulate repair and remodelling

The process of mechanotransduction is integral to the homeostatic maintenance of the musculoskeletal system in the absence of injury. It also explains how therapeutic exercise can strongly influence injured tissue.

Mechanotransduction consists of three steps:

(i) mechanocoupling, (ii) cell–cell communication and (iii) the effector response. Here we use tendon tissue to illustrate this process, but the fundamental principles also apply to other musculoskeletal tissues such as bone, muscle, ligament and articular cartilage.

#### Mechanocoupling—the loading trigger

Mechanocoupling refers to physical load (often shear or compression) causing a physical perturbation to cells that make up a tissue. For example, with every step, the Achilles tendon receives tensile loads generated by the three elements of the gastrocnemius–soleus complex and, thus, the cells that make up the tendon (Fig 17.3a) experience tensile and shearing forces (Fig. 17.3b). Tendon cells can also experience compression forces (Fig. 17.3c). These forces elicit a deformation of the cell that can trigger a wide array of responses depending on the type, magnitude and duration of loading.<sup>21</sup> The key to mechanocoupling, as the name suggests, is the direct or indirect physical perturbation of the cell, which is transformed into a variety of chemical signals both within and among cells.

#### Cell–cell communication—distributing the loading message

The previous paragraph illustrated mechanocoupling by focusing on a single cell, but let us draw back to examine a larger tissue area that contains thousands of cells embedded

(a)

**Figure 17.3** The various elements of the tendon cell (a)

*continued*

(b)

(c)

**Figure 17.3 (cont.)** The various elements of the tendon cell undergo shear (b) and compression (c) during a loading cycle

within an extracellular matrix (Fig. 17.4). The signalling proteins for this step include calcium and inositol triphosphate ( $IP_3$ ). The process of cell–cell communication is best understood by illustration (Fig. 17.4). The critical point is that stimulus in one location (location 1 in Fig. 17.4c) leads to a distant cell registering a new signal (location 2 in Fig. 17.4e) even though the distant cell does not receive a mechanical stimulus.<sup>21</sup>

#### Effector cell response

To illustrate the third part of mechanotransduction (effector cell response), we focus on a single cell at the boundary of the extracellular matrix (Fig. 17.5). With movement, integrin proteins located in the cell membrane activate at least two distinct pathways that influence the cell nucleus to initiate the production of new proteins. These pathways include physical and biochemical signals (Fig. 17.5d).

**Figure 17.4** Tendon tissue provides an example of cell–cell communication (a) The intact tendon consists of extracellular matrix (including collagen) and specialised tendon cells (arrowheads)

**Figure 17.4 (cont.)** (b) Tendon with collagen removed to reveal the interconnecting cell network. Cells are physically in contact throughout the tendon, facilitating cell–cell communication. Gap junctions are the specialised regions where cells connect and communicate small charged particles. They can be identified by their specific protein, connexin 43. Time course of cell–cell communication from (c) the beginning, through (d) the midpoint to (e) the end. The signalling proteins for this step include calcium (red spheres) and inositol triphosphate (IP<sub>3</sub>)

*continued*

**Figure 17.5** Mechanical loading stimulates cells to synthesise protein (a) A larger-scale image of the tendon cell network for orientation. We focus on one very small region (b) Zooming in on this region reveals the cell membrane, the integrin proteins that bridge the intracellular and extracellular regions, and the cytoskeleton, which functions to maintain cell integrity and distribute mechanical load. The cell nucleus and the DNA are also illustrated (c) With movement (shearing is illustrated), the integrin proteins activate at least two distinct pathways (d) One pathway involves the cytoskeleton that is in direct physical communication with the nucleus (yellow arrow) (i.e. tugging the cytoskeleton sends a physical signal to the cell nucleus). Another pathway is triggered by integrins activating a series of biochemical signalling agents, which are illustrated schematically (green lever). After a series of intermediate steps, those biochemical signals also influence gene expression in the nucleus (e) Once the cell nucleus receives the appropriate signals, normal cellular processes are engaged. mRNA is transcribed and shuttled to the endoplasmic reticulum in the cell cytoplasm, where it is translated into protein. The protein is secreted and incorporated into the extracellular matrix (f) In sum, the mechanical stimulus on the outside of the cell promotes intracellular processes leading to matrix remodelling

A range of studies have shown or implied a potential for mechanotherapy to promote healing of muscle, tendon, ligament, cartilage and bone. The key to successful clinical application of mechanotherapy is most often finding the correct dosage (and thus progression of exercises).

In some cases, such as patellar and Achilles tendinopathy, literature exists to guide the clinician's exercise prescription. 'Research-proven' treatment regimens, such as tendon training protocols (Chapter 40) or 'heavy slow resistance training'<sup>22</sup> have considerable clinical popularity and are

often applied to a variety of other injury types. However, we warn against taking a 'one size fits all' approach. General training principles of progressive overload, periodisation and specificity should be followed (Chapter 10), and exercise prescription should be individualised according to each patient's functional capacity, sport-specific demands and treatment response.

The following section reviews the specific mechanisms and clinical application of mechanotherapy for muscle, tendon, cartilage and bone.

## Muscle

Muscle offers one of the best opportunities to exploit and study the effects of mechanotherapy as muscle is highly responsive to changes in loading. Increasing load on muscle leads to the immediate, local upregulation of mechanogrowth factor (MGF), which in turn stimulates muscle hypertrophy via activation of satellite cells.<sup>23</sup> The opposite mechanism is at play in cases where athletes are forced to rest a body part (immobilise or greatly reduce muscle load), such as after a fracture or surgery. In such cases, mechanotransduction causes catabolism of tissue—the tissue adapts to the load it senses.

The benefits of loading include improved alignment of regenerating myotubes, faster and more complete regeneration, and minimisation of atrophy of surrounding myotubes.<sup>24</sup> We revisit this topic later in the section on acute injury management.

## Tendon

Tendon is a dynamic, mechanoresponsive tissue. One of the major load-induced responses in tendon, which has been shown both *in vitro*<sup>25</sup> and *in vivo*,<sup>26–28</sup> is an upregulation of insulin-like growth factor (IGF-I). This upregulation of IGF-I is associated with cellular proliferation and matrix remodelling within the tendon. However, other growth factors and cytokines in addition to IGF-I are also likely to play a role.<sup>29</sup>

Recent studies show a significant increase in stiffness, Young's modulus and cross-sectional area in human tendons subjected to mechanical loading programmes.<sup>30</sup> However, the extent of tissue adaptation appears to be highly dependent on the applied loading parameters. In particular, several studies indicate that high-intensity muscle contractions (70–90% of maximum) are necessary to increase tendon stiffness,<sup>31–34</sup> and that interventions longer than 12 weeks are necessary to achieve optimal adaptations.<sup>35, 36</sup> The mechanical, material and morphological properties of tendons respond similarly to high-intensity loading programmes involving eccentric, concentric-eccentric and isometric muscle contractions.<sup>16, 30, 37</sup> However, plyometric training may not lead to optimal adaptations.<sup>30</sup>

## Articular cartilage

Like other musculoskeletal tissues, articular cartilage is populated by mechanosensitive cells (chondrocytes), which signal via pathways highly comparable to those described for tendon. Animal studies have shown that immobilisation leads to cartilage atrophy and loss of stiffness, whereas cartilage subjected to high loads has a higher proteoglycan content and higher cell volume, and is stiffer.<sup>38</sup>

Recent advances in magnetic resonance imaging (MRI) technology, in particular the ability to estimate cartilage glycosaminoglycan (GAG) content,<sup>39</sup> have improved our understanding of loading on human articular cartilage. A 16-week moderate loading program increased the GAG content of articular cartilage among patients at high risk of developing tibiofemoral osteoarthritis.<sup>40</sup> Vigorous loading programs have provided mixed results. Some led to improved cartilage quality among people with<sup>41</sup> and without<sup>42</sup> osteoarthritic changes, whereas others were detrimental in people with pre-existing bone marrow lesions.<sup>43</sup>

There is little high-level evidence to guide loading dosage for articular cartilage injuries—the dose-response curves are still being determined. However, there was clinical improvement among 48 patients with full-thickness femoral condyle lesions who utilised a 3-month progressive exercise program consisting of moderate resistance training (3–4 sets of 8–10 repetitions at 40–60% of maximum), as well as neuromuscular and cardiovascular training.<sup>44</sup> A key clinical principle of loading articular cartilage lesions is to avoid pain and swelling during or after training.<sup>44, 45</sup>

## Bone

The process of mechanotransduction has been well described in human bone.<sup>46</sup> Appropriate loading of osteocytes, which are believed to be the primary mechanosensors, activates a number of extracellular and intracellular signalling pathways which stimulate osteoblast proliferation and new bone formation. However, both insufficient and excessive loading of bone stimulates osteoclast activity, which leads to a loss of bone tissue.<sup>46</sup>

There is growing evidence that mechanotransduction can be exploited to improve fracture healing, through either active load bearing (e.g. partial weight-bearing mobilisation), pneumatic compression or electrophysical agents.<sup>47</sup> There are no definitive guidelines on the amount of loading required to optimise bone formation, particularly as many factors influence each case, such as the loading type, the site and size of the fracture, and the patient's age and hormonal status. However, studies agree that dynamically applied loads are more effective than static loads in stimulating bone remodelling.<sup>47</sup>

## Altering biomechanics: motor-control training

In addition to stimulating repair and remodelling of injured tissues, clinicians also prescribe therapeutic exercise to influence the way a patient moves his or her body. We often refer to this as 'neuromuscular' or 'motor-control' training.

Clinicians usually prescribe motor-control training in an attempt to:

1. Directly or indirectly unload injured or sensitised tissue. For example, overhead athletes with rotator cuff tendinopathy are often prescribed scapular retraction and upward rotation exercises to reduce posterior impingement of their cuff tendons during throwing (Chapter 24).
2. Reduce the risk of injury or re-injury by improving strength, balance, coordination and/or sensorimotor control. For example, patients recovering from anterior cruciate ligament injury are prescribed a wide range of neuromuscular exercises throughout the entire rehabilitation process to optimise their functional outcome and reduce the risk of re-injury (Chapter 35).

There are no definitive guidelines for the dosage of motor control training. However, neuromuscular 'perturbation' programs performed three times per week over a period of 3–4 weeks have been shown to alter motor control patterns in uninjured<sup>48</sup> and ACL-injured athletes,<sup>49</sup> and to improve ACL rehabilitation outcomes.<sup>50</sup> Similarly, training programmes aiming to improve neuromuscular control during standing, cutting, jumping and landing have been shown to prevent injuries in female handball and football players when performed for 15 minutes, three times per week (Chapter 12).<sup>51, 52</sup> As for all types of skill acquisition, regular high-quality practice is necessary to learn and engrain new motor patterns.

#### PRACTICE PEARL

Effective motor control training programmes focus on movement quality and are sport-specific. Athletes need to concentrate hard throughout the training session and should understand what they are trying to achieve and why it is important. When introducing a new exercise, the clinician should provide a lot of feedback; however, athletes should always be encouraged to assess their own performance.

Motor control training programmes should target specific deficits identified during the clinical assessment. Complex movements should first be broken down into separate components, before the whole task is trained. As pain (or the distraction caused by pain) may interfere with the normal neuroplastic changes that occur with skill training,<sup>53</sup> motor-control training should be pain-free.

## Exercise-induced hypoalgesia

In addition to stimulating local repair and remodelling and altering biomechanics, clinicians may prescribe therapeutic exercise due to its hypoalgesic effects. There is a large body of evidence demonstrating that in healthy adults and a range of patient populations, exercise attenuates experimentally-induced pain.<sup>54</sup> This is achieved by elevating pain thresholds and pain tolerance, as well as by reducing pain intensities during and after exercise.<sup>55, 56</sup>

Exercise-induced hypoalgesia is likely to be caused by a combination of factors, including the release of endogenous opioids and other non-opioid substances affecting pain perception such as endocannabinoids, serotonin and norepinephrine (noradrenaline),<sup>56, 57</sup> as well as activation of spinal or supraspinal mechanisms of pain inhibition.<sup>58, 59</sup> Different exercise parameters may alter the predominant mechanism.<sup>56, 60</sup>

## Exercise type and dose to maximise hypoalgesia

Aerobic exercise, isometric muscle contractions and traditional resistance training have all been shown to reduce pain, with isometric exercise having the largest effect.<sup>54</sup> Although a recent meta-analysis was unable to calculate the exact dosage required to maximise exercise-induced analgesia, the dose-response relationship favours moderate to high intensities for both aerobic and isometric exercise.<sup>54</sup> Current recommendations, therefore, are that aerobic exercise be performed at intensities above 75% of maximal aerobic capacity ( $\text{VO}_{2\text{max}}$ ) for at least 10 minutes,<sup>54</sup> and isometric contractions should be above 50% of maximum voluntary contraction (MVC) held for long durations or until task failure.<sup>61, 62</sup> Recent studies of athletes with patellar tendinopathy have found that five 45-second isometric contractions at 70% of MVC with two minutes' rest between contractions significantly reduced pain for at least 45 minutes after training.<sup>63</sup> Based on these findings, isometric training is currently recommended in the early management of tendinopathy (Chapter 4).

In certain groups of patients with generalised chronic pain such as fibromyalgia syndrome, vigorous-intensity exercise has been shown to increase pain. However, low- to moderate-intensity aerobic and isometric exercise has an effective hypoalgesic effect in this group.<sup>54</sup>

#### PRACTICE PEARL

As the hypoalgesic effects of exercise are transient, regular exercise is necessary to reduce pain effectively. For example, isometric contractions for the treatment of painful tendinopathy should be performed several times every day.

## ACUTE INJURY MANAGEMENT

Acute soft tissue injury causes an immediate inflammatory response that manifests clinically as pain, redness, swelling and loss of function. Inflammation is an essential process that initiates tissue regeneration and repair. However, excessive bleeding and oedema can delay recovery and may cause secondary ischaemic damage to nearby tissues.<sup>64</sup> The goal of acute injury management, therefore, is to prevent excessive bleeding and oedema, reduce pain and promote faster return to function.

The principles of acute injury management are based largely on expert opinion and laboratory studies (level 4-5 evidence), and there are few randomised controlled trials upon which to base recommendations.<sup>65, 66</sup> Traditionally, treatment is guided by one of the most commonly known acronyms in sports medicine: PRICE (**P**rotection, **R**est, **I**ce, **C**ompression and **E**levation). Recently, however, a call has been made to change the acronym to POLICE:<sup>67</sup>

- P** Protection
- OL** Optimal loading
- I** Ice
- C** Compression
- E** Elevation

### Protection

A brief period of complete immobilisation is necessary to prevent excessive distention at the injury site, reduce the size of the haematoma and thus minimise the size of the connective tissue scar.<sup>68</sup> During this period, the clinician may consider the use of casts, splints or rigid braces to protect the injured body part, as well as crutches for severe lower-limb injuries.

Although protection is important in the period immediately following trauma, prolonged immobilisation has a detrimental effect on healing in a range of soft tissues, including ligament, tendon and muscle.<sup>68-71</sup> Immobilisation also affects surrounding structures, leading to joint stiffness, degenerative changes in articular cartilage, osteopenia, muscle atrophy and loss of strength. It is therefore important that tissues remain completely unloaded for as short a period as possible. This will vary depending on the extent and nature of the injury and the tissue involved. For most muscle injuries, two days is sufficient before the forming scar has adequate tensile strength to withstand gentle stress.<sup>24</sup> Severe ligament sprains (grades II and III) may require up to ten days of immobilisation before the patient can begin controlled loading.<sup>72, 73</sup>

### Optimal loading

*Optimal loading* replaces *rest* in the acute management acronym due to concerns that the word *rest* may encourage an overly conservative approach that fails

to harness the benefits of early tissue loading through exercise.<sup>67, 74</sup>

In comparison to immobilisation, early loading has been shown to have a range of beneficial strength, morphological and functional effects on regenerating tissue, and on the wider neuromusculoskeletal system.<sup>67, 75</sup> For example, early mobilisation of lateral ankle sprains has been shown to improve subjective function, patient satisfaction, swelling, and return to activity, work and sports participation (level 1 evidence).<sup>76, 77</sup> Basic science studies also support early loading compared to immobilisation for a range of soft tissue injuries.<sup>68-71</sup> For example, early mobilisation of muscle injuries improves capillarisation and muscle fibre regeneration, and leads to a more parallel orientation of the regenerating myofibres compared to immobilisation (Fig. 17.6).<sup>68</sup> Muscle injuries demonstrate persisting weakness when treated with prolonged immobilisation (Fig. 17.7).<sup>68</sup>

A major challenge facing the clinician is to determine the 'optimal' loading for each individual at each phase of healing. This should be driven by the tissue type and pathological presentation, as well as the tissue adaptation required; for example, increased tensile strength, collagen reorganisation, increased muscle-tendon unit stiffness or neural reorganisation.<sup>74</sup>

The clinician needs to consider a range of variables when attempting to achieve optimal loading, such as the magnitude, duration, frequency, direction, intensity and direction of load. Manipulation of these variables will not only affect local tissue healing processes, but also stimulate central nervous system adaptations leading to improved motor learning and movement efficiency.

Variable loading offers a range of potential benefits. First, small variations in the magnitude, direction and rate of loading may provide injured tissues with a degree of stress shielding from overload. Second, load variability

**Figure 17.6** Muscle injury treated with (a) immobilisation and (b) early mobilisation. ADAPTED FROM JÄRVINEN ET AL.<sup>68</sup>

**Figure 17.7** Strength improvements in rat skeletal muscle injuries treated with a progressive exercise protocol after two days of immobilisation (shown in green) and in injuries treated with the same protocol after 21 days of immobilisation (shown in red). Note that strength did not naturally return during the immobilisation period. ADAPTED FROM JÄRVINEN ET AL.<sup>68</sup>

may provide a better mechanotransductive effect through broader stimulation of mechanoreceptors and prevention of accommodation. Finally, variable tensile, compressive and torsional forces may promote the creation of a stronger biological scaffold that is better able to withstand a range of loading types.<sup>74</sup>

The characteristics of optimal and suboptimal loading are outlined in Table 17.1.

## Ice

Ice (or other forms of cryotherapy) is one of the most common treatment modalities used in the initial management of acute musculoskeletal injuries.<sup>65</sup> Cryotherapy aims to decrease oedema through vasoconstriction and reduce secondary hypoxic injury by lowering the metabolic demand of injured tissues.<sup>65, 68</sup> Local analgesia is thought to occur when the skin temperature drops below 15°C because of decreasing nerve conduction velocity.<sup>78, 79</sup>

Laboratory studies show that cooling injured tissue to between 5°C and 15°C reduces cellular metabolism, white blood cell activity, necrosis and apoptosis.<sup>64, 80</sup> However, this amount of cooling is difficult to achieve in practice, with human studies showing that intensive cooling leads to tissue temperatures of between 21°C and 25°C. The actual metabolic effects of cryotherapy may therefore be questionable, particularly for deep injuries or in patients with higher levels of adipose tissue.<sup>80</sup>

Nevertheless, the analgesic effects of cryotherapy are well established and icing remains a part of current acute injury management guidelines.<sup>81</sup> Ice is typically applied for 20 minutes every two hours for the first 48–72 hours following injury. Intermittent application—for example, 10 minutes on, 10 minutes off—may enhance analgesia and reduce the risk of adverse reactions such as skin burns and nerve damage.<sup>78, 81</sup> Ice should not be applied where local tissue circulation is impaired (e.g. in Raynaud's phenomenon or peripheral vascular disease), or to patients who suffer from a cold allergy.

Although there are many commercial cryotherapy products available, in most situations a plastic bag containing crushed ice and water remains the modality of choice.<sup>82</sup> A wet towel should be placed between the ice pack and the skin. Cryotherapy modalities are summarised in Table 17.2.

## Compression

Compression is often used following acute soft tissue injury in order to increase pressure gradients in the venous and lymphatic systems, thereby counteracting oedema. Combining compression with ice may also help reduce tissue temperatures.<sup>83</sup> Although there are a number of specific products commercially available, such as cold compression wraps and devices, a standard elastic bandage is a cheap, versatile and effective solution. Compression can be focussed on certain tissues by applying ice packs underneath the elastic bandage. Similarly, pressure peaks

**Table 17.1** Characteristics of optimal and suboptimal loading<sup>74</sup>

Optimal loading	Suboptimal loading
Directed to appropriate tissues	Non-specific generalised loading
Loading through functional ranges	Loading through limited ranges of movement
Appropriate blend of compressive, tensile and shear loading	Loading exclusively in a single manner
Variability in magnitude, direction, duration and intensity	Constant, unidirectional load
Include neural overload	Minimal neural stimulus
Tailored to individual characteristics	Generic, non-individualised
Functional	Non-functional, isolated segmental loading

Table 17.2 Cryotherapy modalities used to treat sports injuries

Modality	Description	Special concerns	Surface temperature	Duration	Exercise during application	Expense
Reusable cold packs	Durable plastic packs containing silica gel that are available in many sizes and shapes	Apply a towel between the bag and skin to avoid nerve damage or frostbite	$\leq 15^{\circ}\text{C}$ ( $59^{\circ}\text{F}$ )	20–30 min	No	Inexpensive
Endothermal cold packs	Packets are squeezed or crushed to activate: convenient for emergency use	Single use only	$20^{\circ}\text{C}$ ( $68^{\circ}\text{F}$ )	15–20 min	No	Expensive
Crushed ice bags	Crushed ice moulds easily to body parts	Apply a towel between the bag and skin to avoid nerve damage or frostbite	$0^{\circ}\text{C}$ ( $32^{\circ}\text{F}$ )	5–15 min	No	Inexpensive
Vapocoolant sprays	Easily portable therapy for regional myofascial pain syndrome, acute injuries, pain relief, and in rehabilitation with spray and stretch techniques	Intermittently spray the area for $<6$ sec to avoid frostbite	Varies depending on duration of treatment	Multiple brief sprays	Spray $<6$ sec and stretch to increase range of motion	Expensive
Ice water immersion	An athlete's body part is submerged in cold water	Carries the most risk of hypersensitivity reactions; restrict amount of extremity immersion	$0^{\circ}\text{C}$ ( $32^{\circ}\text{F}$ )	5–10 min	Allows motion of the extremity during treatment	Inexpensive
Ice massage	Used to produce analgesia: freeze water in a foam cup, then peel back cup to expose the ice; massage area as often as needed	Apply for short intervals to avoid frostbite; avoid excess pressure	$0^{\circ}\text{C}$ ( $32^{\circ}\text{F}$ )	5–10 min	Can allow supervised, gentle, stretching during analgesia	Inexpensive
Refrigerant inflatable bladders	When cold and compression are needed	Avoid excess compression	$10\text{--}25^{\circ}\text{C}$ ( $50\text{--}77^{\circ}\text{F}$ )	Depends on temperature	No	Expensive
Thermal cooling blankets	To provide constant temperature, such as after surgery	Scrutinise temperature settings	$10\text{--}25^{\circ}\text{C}$ ( $50\text{--}77^{\circ}\text{F}$ )	Depends on temperature	No	Expensive
Contrast baths	Transition treatment between cold and heat for a subacute injury, sympathetic mediated pain, stiff joints	Do not use in acute setting due to potential to increase blood flow	Hot bath $40.5^{\circ}\text{C}$ ( $105^{\circ}\text{F}$ ) Cold bath $15.5^{\circ}\text{C}$ ( $60^{\circ}\text{F}$ )	4 min hot, 1 min cold	Allows motion of the extremity during treatment	Inexpensive

**Figure 17.8** Applying compression to a lateral ankle sprain: horseshoe-shaped felt around the ankle malleolus may help distribute compression pressures more evenly

around bony prominences can be avoided by applying felt or other material to fill gaps (Fig. 17.8).

Despite a lack of consensus on the optimal compression pressures, there is some evidence that high pressures (80 mmHg) are ineffective.<sup>81</sup> Standard protocols often recommend light to moderate pressures of 15–35 mmHg. Bandaging should start just distal to the injury site, with each layer of bandage overlapping the underlying layer by one-half. It should extend to at least a hand's breadth proximal to the injury margin.

### Elevation

The rationale for elevation stems from the fundamental principles of physiology and traumatology. Elevation of an injured extremity above the level of the heart results in a decrease in hydrostatic pressure and, subsequently, reduces the accumulation of interstitial fluid.<sup>24</sup> Elevation can be achieved by using a sling for upper limb injuries and by resting lower limbs on a chair, pillows or bucket. It is important to ensure that the lower limb is above the level of the pelvis. A graduated return to standing after elevation is likely to minimise rebound swelling and discomfort.<sup>81</sup>

### Do no HARM!

In the 72 hours following injury, **HARM**-ful factors should be avoided:

#### **H** Heat and heat rubs

Heat may increase the bleeding at the injured site. Avoid hot baths, showers, saunas, heat packs and heat rubs.

#### **A** Alcohol

A moderate consumption of alcohol after eccentric-based leg exercises has shown to significantly increase

the loss of dynamic and static quadriceps strength.<sup>84</sup> Alcohol may mask pain and severity of injury and therefore increase the risk of re-injury.<sup>85</sup> To minimise exercise-related losses in muscle function and to accelerate recovery, avoidance of alcohol post injury is paramount.

#### **R** Running/moderate activity

Running or any form of moderate activity can cause further damage at the injury site.

#### **M** Massage/vigorous soft tissue therapy

Vigorous massage should be avoided in the first 24–48 hours. It could cause further bleeding and swelling to the injury site.

## MANUAL TREATMENTS

In this section, we refer to 'hands-on' treatments, including techniques targeting joints (mobilisation and manipulation), soft tissues (massage/myofascial release techniques) and nerves (neurodynamic techniques). There is a substantial body of evidence demonstrating immediate effects of manual treatments, such as altered pain sensation, muscle activation and joint range of motion.<sup>86–91</sup> However, these effects are unlikely to be maintained over time, or to change the natural history of a disorder. Therefore, clinicians should regard manual treatments as an adjunct to addressing the underlying causes of injury.

Manual treatments are typically directed at specific tissues or structures identified as being abnormal on physical examination, such as stiff joints, tight muscles or restricted nerves (Chapter 15). Traditionally, the rationale for using manual treatments is their proposed local biomechanical and physiological effects; for example, to reduce joint stiffness, increase intramuscular temperature and circulation, or break up adhesions in connective tissue. However, the following factors suggest that local tissue changes are unlikely to explain the clinical benefits of manual treatments:

- Spinal manipulations are only associated with transient increase in joint mobility; there is no evidence of lasting changes in mobility<sup>92</sup> or joint position.<sup>93</sup>
- There is no evidence that massage affects passive or active muscle stiffness, and the effect on global range of motion and muscle blood flow is marginal.<sup>94</sup>
- Clinical methods for assessing joint position, joint motion and soft tissue qualities have poor reliability.<sup>95–98</sup> Different clinicians are therefore unlikely to agree upon which structures require treatment.
- The effect of manual treatments may be distant from the area treated. For example, treatment of the thoracic and cervical spine may affect lateral elbow pain (Chapter 25).<sup>99, 100</sup>

The actual mechanism of manual treatment is thought to be a complex neurophysiological response from the peripheral and central nervous system, initiated by a local biomechanical stimulus.<sup>95</sup> Mechanical stimulation of afferent neurones located in skin, joints and muscle can activate a number of responses such as pain inhibition<sup>86, 101-103</sup> and neuromuscular inhibition or facilitation.<sup>100, 104-106</sup> Manual treatments also have been shown to have autonomic,<sup>107-109</sup> endocrine,<sup>110, 111</sup> immunologic<sup>112</sup> and psychological effects,<sup>113</sup> which may further explain their potential clinical efficacy.

### Joint techniques: mobilisation and manipulation

There are a number of different philosophical approaches towards manual treatment of joints, such as those of Cyriax, Kaltenborn, Maitland, McKenzie and Mulligan.<sup>114-117</sup> Each philosophy differs in its approach to patient assessment and in their justification for treatment selection. The Cyriax and Kaltenborn approaches, for example, base their examination and treatment selection on arthrokinematic and biomechanical theories such as capsular patterns, coupled motions and concave-convex rules. In contrast, the Maitland, McKenzie and Mulligan approaches place more emphasis on patient response during assessment and treatment (symptom provocation and resolution) rather than rigid biomechanical theories.<sup>118</sup>

Irrespective of the clinical reasoning paradigm, the most common manual techniques applied to joints include mobilisations and manipulations. Mobilisations are rhythmic, low-velocity, oscillatory movement techniques applied to spinal or peripheral joints. They are usually passive techniques performed within the patient's tolerance (Fig. 17.9) and may involve physiological joint motion (movements that patients could perform themselves) and/or accessory motions (movements that patients cannot actively control, such as distraction, compression, sliding, spinning and rolling).

The aim of mobilisation is often to restore full, pain-free range of motion to a joint found to be stiff or painful on clinical examination. Treatment parameters such as the location, direction and magnitude of applied force, and the duration of loading, will vary based on patient

**Figure 17.9** Grades of mobilisation: (a) beginning of range of movement; (b) end of range of movement

presentation, clinical examination findings and response to treatment. In general, however, highly irritable joints should initially be treated with low-grade mobilisations (grades I-II, see Table 17.3), whereas higher grades (III-IV) can be used for stiff, non-irritable joints.

Mobilisations may also be combined with active movements (mobilisation with movement, see Fig. 17.10), and in some cases patients may be able to perform mobilisations themselves (self-mobilisation, see Fig. 17.11).

Joint manipulations are high-velocity thrust techniques exerted at the end of joint range, using either a long or a short lever arm. Long-lever techniques move many joints simultaneously, such as rotatory manipulations of the cervical spine. Short-lever techniques involve a low-amplitude thrust aimed at a specific joint or spinal segment. This is achieved through careful positioning of the patient, using arthrokinematic principles to isolate movement in the target joint and 'lock' surrounding joints. Manipulation differs from mobilisation due to the velocity of the technique; patients can theoretically prevent the movement during mobilisation but with manipulation they cannot.

Manipulations are usually associated with an audible 'pop' sound, which is thought to be caused by an event called cavitation (Fig 17.12). This refers to the formation of bubbles (or cavities) within synovial fluid due to reductions in hydrostatic joint pressure. Cavitation is traditionally viewed as the sign of a successful manipulation.<sup>119</sup> However, a number of studies have shown that there is little association between an audible pop and the clinical outcomes of spinal manipulation techniques.<sup>120-123</sup>

### Safety of manipulation techniques

Manipulation has been associated with a variety of adverse effects, ranging from minor short-term reactions

**Table 17.3** Maitland's grades of mobilisation<sup>117</sup>

Grade	Degree of mobilisation
I	Small amplitude movement performed at the beginning of range
II	Large amplitude movement performed within the free range but not moving into any resistance or stiffness
III	Large amplitude movement performed up to the limit of range
IV	Small amplitude movement performed at the limit of range

**Figure 17.10** Mobilisation with movement technique for ankle dorsiflexion

**Figure 17.11** Self-mobilisation of cervical rotation

such as headache, stiffness and local discomfort, to severe catastrophic events including stroke and death. Minor reactions can be surprisingly common, with one study finding that more than 60% of patients experienced a mild adverse reaction in the 24 hours after receiving a spinal manipulation.<sup>124</sup> While a vast majority of side effects are benign, self-limiting problems, clinicians should inform patients of their likelihood prior to treatment.

Fortunately, severe injuries caused by spinal manipulations are extremely rare. While the actual risk is unknown, estimates range from one case in fifty thousand manipulations to one in five million.<sup>124</sup> A majority of catastrophic injuries caused by cervical spine manipulation are due to the proximity of the vertebral artery to the lateral vertebral joints. However, thoracic and lumbar spine manipulations may also cause serious injury, such as rib fractures and cauda-equina syndrome.<sup>125-128</sup>

**Figure 17.12** The principle of cavitation explains the audible popping sound made during joint manipulation (a) During separation of the joint surfaces, the outer regions of the circular contact zone become pointed. This deformation occurs because at high speeds, the central region of the contact zone separates before the outer region moves, creating a circular rim (b) Joint surfaces snap back at the circular rim where the cavity initially forms, forming small bubbles (c) Small bubbles collect to form a single large bubble (d) The newly formed spherical bubble reaches its maximum size (e) Because of its instability, the single bubble collapses to form a 'cloud' of many smaller bubbles (demonstrable by radiography as a radiolucent region), which later shrink as the gas and vapour dissolve. IMAGE ADAPTED, FROM EVANS.<sup>119</sup>

Manipulations should only be performed by practitioners with formal training in manipulative skills. Cervical artery function should be tested prior to manipulation of the cervical spine (see Chapter 23), and short-lever techniques should be used in preference to long-lever techniques.

Clinicians also need to be aware of the contraindications to the use of mobilisation and manipulation techniques (Table 17.4).<sup>118</sup>

## Soft tissue therapy

with ROBERT GRANTER

Direct treatment of soft tissues, using hands or treatment tools, to treat specific pain or injury is commonly referred to as soft tissue (or massage) therapy (see Chapter 13 for the use of soft tissue massage techniques in post-exercise recovery). As with other manual treatments, soft tissue therapy is traditionally directed at subjective clinical examination findings such as reduced quantity and quality of joint movement, muscles with increased tone, soft tissue thickening, or muscles containing taut, sensitive bands that may refer pain in distinct patterns, often referred to as myofascial trigger points (Chapter 4).

This section provides an overview of several key techniques that clinicians can use to treat muscular pain, and alert the reader to some self-treatment options.

### Treatment position

For successful soft tissue therapy, the clinician should place the target tissue in a position of either tension or laxity.

**Table 17.4 Absolute and relative contraindications for mobilisation and manipulation techniques**

Absolute contraindications—high risk of a deleterious consequence		
	Mobilisation	Manipulation
Malignancy or tumour in the targeted region	×	×
Cauda equina lesion producing bladder or bowel disturbance	×	×
Fractures	×	×
Local bony infection (e.g. osteomyelitis, tuberculosis)	×	×
Systemic disturbance	×	×
Rheumatoid collagen necrosis	×	×
Unstable upper cervical spine	×	×
Signs of coronary or vertebral artery dysfunction	×	×
Practitioner lack of ability		×
Spondylolisthesis (symptomatic)		×
Gross foraminal encroachment		×
Children/adolescents with open epiphyseal plates		×
Pregnancy (last trimester)		×
Joint fusions		×
Psychogenic disorders		×
Immediately postpartum		×
Relative contraindications—possibility of deleterious consequences		
	Mobilisation	Manipulation
Active inflammatory conditions	×	×

Treating soft tissue in an elongated position can make focal sites of abnormality more easily palpable, and may enhance referral patterns from myofascial trigger points. Treating in a position of laxity enhances the ability to access and assess deeper layers of soft tissue.

### Digital ischaemic pressure

Digital ischaemic pressure describes the application of direct pressure perpendicular to the skin towards the centre of a muscle with sufficient pressure to evoke a temporary ischaemic reaction (Fig. 17.13).

(a)

**Figure 17.13** (a) Digital ischaemic pressure to the infraspinatus trigger point using the clinician's thumb  
(b) Digital ischaemic pressure to the gluteus medius trigger point using the clinician's elbow

(b)

The aims of this technique are to stimulate the mechanoreceptors within muscle and fascia to reduce resting muscle tone, to provide an analgesic response in soft tissue by eliciting a release of pain-mediating substances, and to deactivate symptomatic trigger points which may optimise muscle activation patterns.<sup>129</sup>

The clinician can apply digital ischaemic pressure using the thumb (Fig. 17.13a), elbow (Fig. 17.13b) or a hand-held device such as a T-shaped bar.

### Sustained myofascial tension

Sustained myofascial tension is performed by applying a tensile force with the thumb, braced digits, or forearm (Fig. 17.14) to an assessed site of fascial thickening or reduced fascial glide in the direction of greatest restriction, or in the direction of elongation necessary for normal function. Tension is developed in the tissue by application of compression to the appropriate fascial layer, then moving the thumb, braced digit or forearm through the target tissue to impart a shear force. Greater shear force can be imparted using passive through-range movement or active movement in the direction

of assessed restriction in conjunction with the local tissue contact.

### Friction

Friction massage is applied selectively to a localised area palpated as an abnormal tissue thickening; for example, due to excessive intramuscular scar formation following acute muscle injury. It is essential to assess pain and restrictions in muscle length and/or neural mobility before, during and at the end of each treatment session to monitor its effectiveness.

Sufficient pressure must be applied so that the clinician's finger/thumb and the patient's skin move as one, and the friction must work deeply enough and be of sufficient sweep to impart a friction movement to the target tissue. The friction is normally applied at 90° (perpendicular) or at 45° to the target structure, and must be applied at a level that maintains contact with the target tissue and is within the patient's pain tolerance.

It is vital to ensure that the region being treated is totally relaxed. Pressure should be increased gradually to reach the required treatment level within the

**Figure 17.14** Sustained myofascial tension

patient's pain tolerance. Ice can be applied to the region post-treatment in a position of pain-free stretch for 5–10 minutes, particularly for the initial application, to minimise post-treatment tenderness.

### Depth of treatment

Granter and King developed a grading system for depth of soft tissue therapy as a guide for clinicians and researchers to adopt consistency in describing treatment dosage (Table 17.5).

The scale of treatment depth is based on two factors: first, the patient's perceived level of pain during the treatment (grade I–IV); and second, the clinician's sense of soft tissue resistance to palpation (A–C).

### Combination treatment

If soft tissue techniques are aimed at restoring joint range of motion, they can be followed by static, contract/relax or dynamic stretching to maximise the effect.

**Table 17.5** Granter–King scale for grading the depth of soft tissue therapy

Pain grade (P)	Patient's perception of pain
I	No pain perceived
II	Commencement of pain
III	Moderate level of pain
IV	Severe level of pain (seldom used)
Resistance grade (R)	Clinician's perception of tissue resistance
A	No sense of base tissue resistance
B	Onset of base tissue resistance
C	Moderate level of base tissue resistance

### Lubricants

Many soft tissue techniques require a lubricant applied to the skin to aid both patient comfort and the clinician's ability to palpate the tissue for abnormalities. There should be sufficient lubricant particularly when palpating areas with large amounts of hair, as irritation of hair follicles may result in contact dermatitis.

With techniques such as sustained myofascial tension, skin contact should be maximal. Therefore, no lubricant is required. As there are fewer repetitive movements used in this technique, there is less risk of irritation to hair follicles.

### Vacuum cupping

The aim of vacuum cupping is to restore optimal length and mobility of soft tissues, with changes most likely achieved through neurophysiological responses. Oil is applied to the skin to contain the negative pressure created in the cup by a vacuum pump. Within the vacuum cup, the soft tissue is 'drawn' upwards in a unique perpendicular direction, thereby stretching the soft tissue in a regulated, sustained stretch. The cup contains a one-way valve that allows the pump to be removed.

Cupping can cause significant capillary rupture and damage to the periosteum if used with excessive vacuum pressure or with incorrect placement. The skin colour should be monitored closely and the cup removed if the skin becomes more deeply rose-coloured than normal reactive hyperaemia. Generally, the longer a cup is left *in situ* or the more vacuum force is applied, the more bruising can develop. This is unnecessary and can be avoided by diligent observation during application. The cup should not be applied to vulnerable regions of the body, such as cubital and popliteal fossae and soft tissue attachment sites to bone.

## Self-treatment

In recent years, there has been an increase in the popularity of using devices such as spiky balls, tennis balls and foam rollers for self-treatment of soft tissues (Fig. 17.15). A number of studies have found that this approach leads to a short-term increase in range of motion, without any detriment in sports performance.<sup>130-133</sup> Self-treatment may also be aimed at treating myofascial trigger points.

Self-treatment can be undertaken daily and should not cause excessive or lasting pain that adversely affects training or increases symptoms. Typically, self-treatment involves the application of a sustained force to the identified sites, with a sustained pressure until tone/tension reduces and pain or referred symptoms resolve. Functional re-assessment should be carried out after an initial trial period, for example 1-2 minutes, to ensure that positive changes are occurring. As initial presenting symptoms, soft tissue characteristics and patient responses vary, clinicians and patients need to individualise dosage in relation to time and repetitions to achieve optimal results.

## Dry needling

The terms 'acupuncture' and 'dry needling' are often used interchangeably in sports medicine to describe treatments using thin monofilament needles without injectate.<sup>134</sup> However, *acupuncture* denotes the use of the modality

within a traditional Chinese medical paradigm, in which needles are used to unblock the flow of vital energy, 'qi', along meridians or channels,<sup>135</sup> whereas *dry needling* implies the use of a modern biomedical paradigm.

Dry needling is thought to have a range of neural and biochemical effects that can contribute to pain relief.<sup>135</sup> Insertion of needles stimulates free nerve endings, sensory receptors and autonomic fibres in skin, muscle and connective tissue. It also causes the release of a range of neuroactive mediators, including endogenous opioids, which can inhibit transmission of nociceptive signals in the peripheral and central nervous system and alter pain perception.<sup>135, 136</sup> Local tissue injury caused by needle insertion is also thought to cause 'positive' inflammatory and immune responses, which can contribute to analgesia.<sup>134, 135</sup>

Dry needling is most commonly used to treat intramuscular trigger points, but techniques targeting joints, tendons, ligaments, bone and scar tissue are also described.<sup>134</sup> Trigger point techniques often aim to produce a local muscular twitch response, thought to be caused by stimulation of a spinal reflex loop.<sup>137</sup> This has been linked to an immediate reduction in extracellular neurotransmitter concentration in muscle tissue surrounding a trigger point,<sup>138</sup> and a twitch response is anecdotally associated with an improved treatment effect.<sup>139</sup>

There is a vast amount of research on the effects of dry needling and acupuncture. However, interpretation of the literature is complicated by the wide variety of conditions treated, differing underlying treatment paradigms (traditional Chinese medicine versus a modern biomedical model), as well as a large variation in treatment protocols and methodological quality. It is particularly difficult to blind patients and clinicians in RCTs which is problematic as needling is associated with a potent placebo effect.

Nevertheless, a substantial body of level 1 evidence suggests needling is more effective than placebo or sham treatments for a range of musculoskeletal conditions such as chronic lower back, neck and shoulder pain, chronic muscular pain, headache, and knee osteoarthritis.<sup>140-144</sup>

Clinicians should consider the following points when using dry-needling techniques.

- The patient is comfortably positioned with the target region well-supported.
- The target tissue is clearly identified, a taut band is palpated within the muscle and symptoms are reproduced by palpation. This site is 'marked' by compressing a used guide-tube onto the skin above the identified site (Fig. 17.16a).
- The correct equipment is prepared. Sterile, single-use needles must be used. Tubed needles are recommended

**Figure 17.15** Self-treatment: treating the gluteus medius with a tennis ball

to expedite placement and reduce the risk of touching the needle shaft. Cotton swabs and a sharps container should be within easy reach.

- A hygiene protocol is followed. The patient's skin is cleaned and disinfected with an alcohol swab. The clinician should wash his or her hands and wear latex gloves (at least on the palpating hand most likely to be exposed to blood).

(a)

(b)

**Figure 17.16** Dry needling (a) A needle tube can be pressed into the skin to temporarily mark the injection site (b) The target muscle should be supported by one hand while the other hand focuses on accurate insertion of the needle

- The target muscle is supported to maximise accurate needle penetration. For example, when treating the upper trapezius, the muscle should be held anteriorly and posteriorly between the fingers and thumbs of one hand while the other hand focuses on accurate insertion of the needle (Fig. 17.16b).
- The needle and guide tube are placed perpendicular to the skin on the marked site and the needle is inserted with a short, sharp tap to the top of its handle.
- The guide tube is removed and the needle is fully inserted to the appropriate depth by only touching the needle handle, never the shaft.
- Various dry needling techniques can be utilised (see below).
- The needle is removed and local compression is applied over the site via a cotton swab for approximately 30 seconds.
- The joints associated with the muscle treated should be moved passively through their full comfortable range of motion after treatment.
- Needles and equipment are disposed of by correct medical waste disposal protocols.

The most commonly used dry needling technique involves inserting the needle into focal trigger points within a palpable taut band and leaving it in place for a few minutes. There is no clear consensus on the time left in situ—some authors have suggested time ranges from 10–30 minutes.<sup>134</sup> This will vary according to patients' experience with dry needling, as well as their emotional and physiological responses and the degree of presenting symptoms.

Some clinicians also apply electrical stimulation to the inserted needles. However, there are no clear guidelines for treatment parameters and no evidence that electrostimulation improves the treatment effect.

Alternatively, the clinician can insert the needle into the muscle and then repeatedly move the needle in and out (such that it still remains in the sub-dermal region), constantly trying to find specific points that reproduce the patient's local or referred pain, or produce a 'twitch' response. Initially, the needle may be 'grasped' by the muscle, followed by a gradual relaxation.

Clinicians can apply needles to a number of trigger points during each treatment session. Usually, pain relief lasts 3–4 days after the first treatment session. The duration of the pain relief may be longer following subsequent sessions. Up to three or four treatments may be required initially to eliminate a trigger point, and no single trigger point should be needled more than twice in a week.

Various research studies have compared dry needling to injection of local anaesthetic and various other substances. There is some evidence that dry needling can be just as effective.<sup>145, 146</sup>

### Risks of adverse events during dry needling

The most common adverse effect associated with dry needling is soreness in the first 24 hours post treatment.<sup>147</sup> Application of heat and stretching exercises may minimise this,<sup>147</sup> and aggressive treatment should be avoided until the patient's reaction to dry needling is known. High quality needles, which are sharper and thinner, may also reduce pain during and after treatment. If there is excessive resistance to needle removal, the needle should be removed more slowly.

In patients unfamiliar with or apprehensive about dry needling, it is possible to induce an episode of vasovagal syncope. The risk of this occurring can be minimised by careful patient selection—it is especially important to identify those with needle phobias. Clinicians should avoid excessive stimulation of specific sites until the patient learns to tolerate this new treatment. The patient's response should be closely monitored during treatment, with constant communication to ensure patient comfort. If at any stage the patient becomes distressed with the treatment, needles should be removed. Contraindications to dry needling include bleeding disorders, active infection, blood-borne diseases, allergies to metal, unstable epilepsy and the third trimester of pregnancy. Additionally, extreme care should be taken when dry needling near the lungs as there is a risk of causing a pneumothorax.

### Neurodynamic techniques

The nervous system needs to adapt to mechanical loads. It can do this through elongation, sliding, cross-section change, angulation and compression.<sup>148</sup> However, when the nervous system cannot cope under loads, it can lead to neural oedema, ischaemia, fibrosis and hypoxia—all of which can alter neurodynamics.<sup>148</sup> This change in neurodynamics may make a significant contribution to the patient's symptoms and signs in certain injuries. Unless these abnormalities are addressed in addition to other soft tissue abnormalities associated with the injury, full recovery as indicated by full pain-free range of motion may not occur.

Neural tension was a term used in the past to describe peripheral nervous system dysfunction, but was thought to only address the mechanical aspects of the dysfunction.<sup>148</sup> Nowadays the term *neurodynamics* is employed to describe the biomechanical, physiological and structural dysfunction of the nervous system.<sup>148</sup>

Neural stretching (mobilisation) is a treatment modality that addresses neurodynamics. Neural stretches aim to restore dynamic balance of the nervous system.<sup>148</sup> Proposed benefits include facilitation of nerve gliding, decrease in nerve adherence, dispersion of noxious fluids, increased neural vascularity and improved axoplasmic flow.<sup>148</sup>

These stretches are adaptations of the neural tension tests (Chapter 15). The two most commonly used neural stretches are adaptations of the upper limb tension test (Fig. 17.17a) and the slump test (Fig. 17.17b).

A systematic review<sup>148</sup> evaluated the effectiveness of neural mobilisations and found that even though the identified studies did report positive effects, low methodological quality and limited number of studies suggest that currently there is limited evidence for their use. However, these stretches can often be helpful in the treatment of conditions in which neurodynamics are

(a)

(b)

**Figure 17.17** Common neurodynamic techniques (a) Upper limb neurodynamics stretch test (b) Slump stretch

abnormal, and variations of these tests may be used for both diagnosis and treatment.

Clinicians should take particular care when considering neural mobilisation exercises for acute or irritable conditions, as they may aggravate the patient's symptoms. Stretches should always begin gently, and gradually increase under the close supervision of an experienced clinician. As with other methods of treatment, neural stretches alone are rarely sufficient to correct all abnormalities present. They can be particularly effective in long-standing, chronic conditions where neural hypersensitivity is common.

## TAPING

with SAM BLANCHARD

Taping was the third-most utilised intervention at the London 2012 Olympic Games polyclinic,<sup>149</sup> reflecting its current popularity as a treatment modality and injury prevention intervention. However, research into both the mechanisms and effects of taping is limited and marked by heterogeneous results,<sup>150, 151</sup> making it difficult for clinicians to draw firm evidence-based conclusions on its benefits and application.

### Proposed mechanisms of taping

Taping is proposed to have a range of effects depending on the application method and the type of tape used. Traditionally, clinicians have applied rigid strapping tape in an attempt to restrict patients' range of motion or to alter their anatomical alignment; for example, to realign the patella within the femoral trochlea (Fig. 17.18).<sup>152</sup> More recently, the use of flexible cloth tape, often referred to as kinesiology tape, has also gained popularity.

**Figure 17.18** Taping is often used to relieve patellofemoral pain

Taping also appears to have a range of neurophysiological effects.

- Cutaneous stimulation by tape may inhibit afferent nociceptive signals at the spinal level (pain-gate theory).<sup>153</sup>
- Tape application has been shown to alter brain activity in a variety of areas, including the motor cortex, sensory cortex, thalamus, basal ganglia and cerebellum.<sup>154</sup> This may have a wide range of effects, including improved proprioception<sup>155</sup> and motor coordination, and explain how taping influences factors such as muscle activation timing<sup>156</sup> and concentric/eccentric control.<sup>157</sup>
- Restriction of the range and amplitude of joint motion may enable increased reaction time of surrounding musculature during high-velocity injury situations.<sup>150, 157-159</sup>
- Patients' conscious and subconscious expectations of the effects of taping may relieve pain (i.e. placebo effect).<sup>153</sup> Once thought to be a 'purely psychological' phenomenon, it is now considered to be at least partly caused by the secretion of endogenous opioids in response to treatment.<sup>58</sup>

However, the proposed mechanisms of taping remain largely speculative or controversial. For example, tape intended to limit range of motion has been shown to loosen after 10-30 minutes,<sup>160, 161</sup> and recent systematic reviews disagree on whether patellofemoral joint taping influences VMO onset timing and knee extensor moments.<sup>156, 162</sup> Research in this area is ongoing.

### Evidence of efficacy

Although taping is used for a wide range of conditions across the body, high-level evidence of its efficacy is scant. The available evidence is of varying quality—one of the main challenges when studying taping is the inability to blind patients or practitioners.<sup>156, 166</sup>

#### Patellofemoral pain

A number of systematic reviews have investigated the use of patellar realignment taping (often referred to as McConnell taping—see Chapter 36) in patients with patellofemoral pain syndrome.<sup>156, 166, 167</sup> Although their results are somewhat conflicting, there is moderate evidence that taping provides an immediate reduction in pain,<sup>156, 167</sup> particularly when an individualised taping technique is used.<sup>156</sup> However, its benefit seems to be limited to the short term, and prolonged use is not supported. The effect of kinesiology tape on patellofemoral pain remains unclear; one randomised crossover trial found that McConnell and kinesiology taping were equally effective in immediately reducing pain,<sup>168</sup> whereas two

## Kinesiology tape: valuable tool for athletes or fashion statement?

Kinesiology tape has gained considerable popularity in recent years, as demonstrated by the large number of athletes using it at the Olympic Games and other major sporting events (Fig. 17.19). The approach was developed in Japan in the 1970s and is claimed to permit unrestricted range of movement while supporting the fascia, muscles and joints.<sup>163</sup> Kinesiology tape has been proposed to improve pain and blood flow via dermal lifting, which decreases the pressure on cutaneous nerve receptors and capillaries, decreasing nociceptive input and increasing afferent feedback.<sup>163</sup> However, these effects last less than 24 hours and may be trivial, and the actual benefits for injured athletes are yet to be established in high-quality studies.<sup>164</sup> The use of kinesiology tape remains controversial among clinicians, with some even claiming it may provide a psychological crutch for athletes.<sup>165</sup>

**Figure 17.19** Kinesiology tape has gained popularity among athletes in recent years (note player on left, tape on knee and thigh) IMAGE COURTESY OF ROCKTAPE UK

randomised controlled trials found kinesiology tape was ineffective in reducing pain.<sup>169, 170</sup>

### Ankle sprains

Three studies have suggested that taping is effective in prevention of ankle sprains.<sup>171-173</sup> However, the highest-quality prevention research has focussed on the effects of rigid or semi-rigid prefabricated braces, and it is unclear whether taping is equally effective.<sup>174</sup> Irrespective of the form of support used, any preventive effect of taping and bracing seems to be limited to athletes with a history of ankle sprain. As the risk of re-injury is increased sevenfold in the year following an initial sprain,<sup>174</sup> taping or bracing could be used in that time (Chapter 12).

### Other conditions

There is some evidence that taping may be effective in treating pain and strength with lateral epicondylalgia,<sup>175</sup> de Quervain's tenosynovitis,<sup>176</sup> plantar fasciopathy pain<sup>153, 177, 178</sup> and shoulder pain.<sup>153, 163, 179</sup> However, many of these studies are of low quality with a moderate to high risk of publication bias. These conditions are covered in Part B.

### Practical considerations

In practice, taping is applied across a far wider range of conditions than there exists evidence for, and should be considered just as much an art as a science.<sup>174</sup> Clinicians should consider not only the available literature, but also the diagnosis, the scenario (e.g. competition, acute management, rehabilitation), and the patient's preference and expectations.

We recommend the use of a trial-and-error approach. A 'treatment direction test', first proposed by Professor Bill Vicenzino for the prescription of orthotic insoles,<sup>180</sup> can be applied whenever tape is used to relieve pain. In order for the intervention to be judged worthwhile, it should lead to a substantial reduction in symptoms (at least 50% on a visual analogue scale) during a relevant functional task.

Much like any exercise program should be progressive, the use of taping should be gradually reduced over time.<sup>72</sup> When taping is successful in alleviating a chronic condition such as patellofemoral pain, clinicians should make a plan to wean the patient off the use of tape to avoid creating a dependence on a passive treatment. Following an acute injury, taping may provide immediate pain relief and restrict excessive movement.<sup>181</sup> Controlled stress (optimal loading) can then be facilitated by gradually reducing the amount of support taping provides over subsequent days and weeks.

### PRACTICE PEARL

For long-term application of tape, consider teaching the athlete to tape him- or herself. This will increase the sense of control over his or her own management, decrease dependency on the clinician and save valuable time in a busy treatment clinic.

In order to protect the patient's skin from irritation, hypoallergenic tape can be applied under rigid sports tape. This is particularly important when tape containing zinc

oxide is used for longer durations. In some situations, such as prophylactic ankle taping, pre-wrap may be applied under the tape. This does not alter the amount of motion restriction, the time to maximum range or the velocity of range;<sup>159</sup> however, it may reduce the cutaneous stimulus.

#### PRACTICE PEARL

Where possible, new taping techniques should be introduced to athletes in a controlled environment prior to competition.

Despite the limited and conflicting evidence base, taping continues to play an important role in clinical sports medicine practice. Clinicians should consider the available literature, retain a healthy scepticism towards commercial claims and trends, and take a trial-and-error approach. Clinical experience and athlete preference should not be discredited.

### ELECTROPHYSICAL AGENTS

with NICK GARDINER, ADAM GLEDHILL, LAWRENCE MAYHEW and VASILEIOS KORAKAKIS

Electrophysical agents (electrotherapy) have been used to treat musculoskeletal conditions for over 70 years.<sup>182</sup> Although their popularity appears to be waning in favour of active treatments, traditional modalities such as ultrasound and interferential stimulation, and newer ones such as extracorporeal shockwave therapy remain highly used in clinical practice. In this section, we review the proposed mechanisms and evidence of effect of the most common electrophysical agents currently used in sports medicine.

The decision of whether to use electrotherapy will be individual and influenced by factors such as time and resource availability, patient expectation and clinician preference. However, it should be stressed that electrophysical agents should never be used in isolation. If they are to be used at all, it should be as an adjunct to other forms of treatment, advice and education.

### Therapeutic ultrasound

Therapeutic ultrasound has traditionally played a large role in physiotherapy practice around the world,<sup>183-188</sup> and remains a popular treatment modality among physiotherapists and other health professionals such as osteopaths, chiropractors and sports therapists.<sup>183, 189</sup>

A range of proposed effects of ultrasound form the biological rationale for its therapeutic use. These include thermal effects such as increased local blood flow, metabolic activity and collagen extensibility,

as well as non-thermal effects such as stimulation of fibroblast activity, mast cell degranulation, growth factor production and angiogenesis.<sup>190</sup> Although these effects have largely only been demonstrated *in vitro*,<sup>183, 190</sup> they are commonly cited to justify the clinical use of ultrasound to treat a wide variety of musculoskeletal conditions, with the belief that it can reduce pain, inflammation and oedema, and enhance scar tissue remodelling, tissue extensibility and soft tissue healing.<sup>189</sup> Treatment is traditionally directed towards collagen-rich tissues such as ligament, tendon, fascia, joint capsule and scar tissue, as these are thought to absorb the greatest amount of energy.<sup>183</sup>

Despite the theoretical appeal of ultrasound, however, there is little high-quality evidence to support its clinical effectiveness.<sup>182, 191, 192</sup> For example, a recent systematic review of the effect of ultrasound on a range of lower-limb soft tissue conditions found that no placebo-controlled trials were able to demonstrate a significant difference between true and sham ultrasound therapy.<sup>191</sup>

Although some argue that this may be due to heterogeneous study populations, conditions treated and dosage parameters,<sup>183</sup> the current lack of research evidence supporting therapeutic ultrasound for soft tissue conditions should be taken into account by clinicians considering its use.

### Ultrasound as a stimulator of bone repair

In recent years, ultrasound has been increasingly used in the treatment of acute bone fractures. Although this was traditionally thought to be contraindicated, recent meta-analyses suggest that daily administration of low-intensity pulsed ultrasound (LIPUS) can accelerate the healing of fractures by approximately 35%.<sup>193-195</sup>

LIPUS appears to be most effective for conservatively managed diaphyseal fractures, reducing the time to clinical union by approximately 18 days.<sup>195</sup> The evidence is strongest for upper limb fractures, whereas it is conflicting for metaphyseal and operatively managed acute fractures.<sup>193, 195</sup>

LIPUS is typically applied for 20 minutes every day, which may be an excessive treatment regimen for many patients. However, in elite sports environments a faster return to training and competition might be very important. LIPUS may also be valuable in cases that fail conservative management (non-union) after bone-graft surgery is performed.<sup>193</sup>

Few studies have investigated LIPUS for the treatment of stress fractures; however, the available results are not encouraging.<sup>196, 197</sup> and its use cannot currently be recommended for this purpose. Similarly, there is currently no evidence that LIPUS is effective for soft tissue injuries.

## Transcutaneous electrical nerve stimulation

Transcutaneous electrical nerve stimulation (TENS) delivers biphasic electrical current with the use of electrodes applied to the skin.<sup>198</sup> There are several mechanisms by which TENS can provide short-term pain relief, including stimulation of opioid and noradrenergic receptors at the site of application, and opioid, serotonin and muscarinic receptors in the spinal cord and brainstem.<sup>199</sup>

Although there is no evidence that TENS improves long-term outcomes,<sup>200</sup> it may play an adjunct role in pain management in certain patient groups. It is reported to provide effective short-term pain relief in patients with spinal cord injuries,<sup>201, 202</sup> lumbar disc disease,<sup>203</sup> and chronic neck and lower back pain.<sup>204</sup> There is currently little evidence to support its use for knee osteoarthritis<sup>198, 205</sup> and it is not widely used in the athletic population.

TENS can be used in combination with exercise and medication.<sup>201, 206</sup> Potential adverse effects include mild erythema and itching underneath the electrodes.<sup>206</sup>

## Neuromuscular stimulators

Neuromuscular electrical stimulation (NMES) is purported to have a range of effects on healthy athletes, including enhanced recovery, improved sports performance and reduced muscle soreness. However, as discussed in Chapter 13, commercial claims regarding the benefits of NMES for athletes often go well beyond the existing evidence.<sup>207</sup> In a clinical setting, NMES may be valuable to enhance muscle strengthening after a major injury such as anterior cruciate ligament rupture.<sup>208</sup>

Traditionally, it has been thought that NMES improves muscle performance because it reverses the normal motor unit recruitment order, preferentially activating larger motor units composed primarily of fast-twitch fibres.<sup>209</sup> However, this theory has recently been challenged, with evidence suggesting that the normal clinical methods for applying NMES cause random, non-selective motor unit activation.<sup>210</sup> Nevertheless, there is high-level evidence

that combining NMES with traditional exercise training is more effective than training alone in improving quadriceps strength following anterior cruciate ligament reconstruction.<sup>208</sup>

The decision of whether or not to use NMES in rehabilitation is dependent on a number of factors. Effective therapeutic intensity may be uncomfortable, so a high degree of patient motivation is necessary. Clinicians should also remember that, for many patients, traditional strength training produces the desired results. However, a subset of patients experience persistent weakness following major joint injury due to arthrogenic muscle inhibition.<sup>211</sup> In this group, the use of NMES in combination with heavy strength training may be recommended.<sup>212</sup>

The recommended parameters to enhance muscle strengthening in rehabilitation are shown in Table 17.6.

## Interferential stimulation

Like therapeutic ultrasound, interferential stimulation has long played a role in traditional physiotherapy practice and remains widely used in some areas of the world.<sup>215, 216</sup> It is characterised by the interference of two medium-frequency currents passed through the tissues, causing analgesic effects. The analgesic effect may be due to stimulation of cutaneous receptors that inhibit c-fibre nociceptive transmission,<sup>217</sup> motor stimulation increasing the removal of pain-inducing substances<sup>218</sup> and the release of endogenous opioids.<sup>219</sup>

The pain-relieving effects of interferential stimulation are transient and there is little evidence to support its use in athletic populations. However, its efficacy in the management of knee osteoarthritis<sup>198, 217</sup> suggests potential benefits for athletes following major knee surgery such as ACL reconstruction.

## Laser

Low-level laser therapy (LLLT) is a non-invasive treatment in which non-thermal laser irradiation is applied to the site of pain using light generated by high-intensity electrical stimulation of a medium. It modulates cell and tissue

**Table 17.6 Recommended treatment parameters to maximise muscle strength gains using NMES<sup>210, 213, 214</sup>**

Stimulation intensity	The intensity should be as high as the patient can tolerate, and at least 50% of MVC
Pulse frequency	High-frequency stimulation (50–80 Hz) leads to higher force production, smoother contractions and greater muscle fatigue. Frequencies over 80 Hz may be more painful
Pulse duration (width)	A longer pulse duration (up to 600 µs) maximises force production for a given stimulation intensity. The currently recommended duration is 200–400 µs
Training regimen	3–10 s 'on-time' followed by 10–40 s recovery; 10–15 min per session
Program parameters	1–3 sessions per week for 4–6 weeks

physiology to obtain therapeutic effects,<sup>220</sup> including promotion of tissue repair,<sup>221, 222</sup> and inflammatory effects,<sup>223, 224</sup> thereby providing pain relief in common musculoskeletal disorders.<sup>220, 225, 226</sup>

LLLT may assist in pain relief following acute sports injury<sup>227</sup> and has been found to reduce pain and improve function in patients with rotator cuff tendinopathy, both as a stand-alone treatment and when used in combination with therapeutic exercise.<sup>228</sup> It may also improve outcomes for patients with chronic midportion Achilles tendinopathy when combined with an eccentric loading programme (Chapter 40).<sup>229</sup> Although there is some evidence that LLLT is an effective treatment in certain conditions, there is little knowledge of dose-response and no consensus on optimal treatment parameters for specific pathologies. Further research utilising large, homogenous samples of similar pathologies would clarify the efficacy of LLLT in sports injury management.<sup>227</sup>

### Electromagnetic therapy

Low-frequency pulsed electromagnetic field therapy (PEMF) is purported to have a wide range of local cellular and systemic effects affecting the healing process. Its use is recommended in wound care,<sup>230, 231</sup> and there is some evidence supporting the use of PEMF in the treatment of certain sports injuries.

Laboratory studies suggest that it may be valuable in the treatment of tendon, bone and cartilage pathology.<sup>232-235</sup> For example, when applied to human tendon cells, PEMF may cause cellular proliferation, tendon-specific gene expression, the release of growth factors, and the release of pro- and anti-inflammatory cytokines.<sup>234, 235</sup> Similarly, when applied to articular hyaline cartilage, PEMF can stimulate chondrocyte proliferation and the stimulation of proteoglycans and extra-cellular matrix.<sup>232</sup>

The results of clinical studies of PEMF in athletic populations are mixed.

- In athletes who underwent arthroscopic treatment of osteochondral defects of the talus, PEMF did not lead to earlier return to play than did a placebo treatment.<sup>236</sup>
- Compared to a placebo, patients who received PEMF after arthroscopic knee surgery had improved functional outcomes at 45 and 90 days and at a 3-year follow-up.<sup>237</sup>
- PEMF may have short-term functional, analgesic and anti-inflammatory benefits in shoulder and elbow tendon conditions.<sup>238, 239</sup> However, there is little evidence of any long-term benefits.<sup>239, 240</sup>
- A systematic review of the effects of PEMF and LIPUS on bone injuries found a reduction in healing time following acute diaphyseal fractures.<sup>195</sup> However, due to the small number of studies investigating PEMF, no conclusions on its specific effects could be made.

### Extracorporeal shockwave therapy

In 1980, extracorporeal shockwaves were first used in medicine to destroy kidney stones.<sup>241, 242</sup> Subsequent animal research on extracorporeal shockwave therapy (ECSWT) demonstrated dose-dependent destructive (high-energy) and regenerative (lower-energy) effects on a range of tissues, including bone and tendon.<sup>243, 244</sup> Since then, ECSWT has been used extensively in clinical practice to treat superficial musculoskeletal conditions (Fig. 17.20).<sup>245, 246</sup>

Several RCTs and case-control studies have shown ECSWT, either alone or in combination with exercises, to be beneficial for a number of musculoskeletal disorders including plantar fasciopathy,<sup>247, 248</sup> midportion and insertional Achilles tendinopathy,<sup>249-253</sup> medial tibial stress syndrome,<sup>254, 255</sup> patellar tendinopathy,<sup>256, 257</sup> proximal hamstring tendinopathy,<sup>258</sup> greater trochanteric pain syndrome,<sup>259</sup> medial and lateral epicondylitis,<sup>260, 261</sup> and calcific supraspinatus tendinopathy.<sup>262, 263</sup>

There is a growing body of evidence supporting the clinical use of shock wave therapy. However, even though level 1 and level 2 studies are available for data pooling and meta-analyses, clinicians should interpret the results of systematic reviews with caution. This is because the included studies are often marked by methodological flaws, biases and low reporting quality.<sup>264-266</sup> Furthermore, there is inconsistent reporting of the type of shock wave used (extracorporeal, radial, focused), the intensity (high, medium, low) and the method of application (focal, local, area of pain distribution).

Clinicians should consider the following when using ECSWT in clinical practice.

- ECSWT is not a panacea—its efficacy varies considerably for individual pathologies, and careful selection of patients is essential.<sup>267, 268</sup> For example, it is only effective in treating supraspinatus tendinopathy when

**Figure 17.20** Extracorporeal shock wave therapy

calcification is present. For normal (non-calcified) supraspinatus tendinopathy, it has no effect.<sup>245</sup>

- There is no universal agreement regarding the definition of low-, medium- and high-energy flux density.<sup>244, 263</sup> Resulting energy is dependent on the device and applicator and should be calculated.
- There is evidence of a dose-related ECSWT effect, with lower-energy flux densities requiring more sessions to obtain the same result.<sup>269</sup>
- Although there is no consensus on treatment parameters, successful RCTs have used 1–3 sessions of 1500–2000 impulses at weekly intervals,<sup>246</sup> regardless of the underlying pathology.<sup>241</sup>
- Treatment parameters should be individualised based on the patient's presentation. For example, the pre-treatment symptom duration was significantly correlated with the number of ECSWT sessions applied.<sup>270</sup>
- As for all electrophysical agents, ECSWT should not be used in isolation. Prescribing therapeutic exercise in addition to shock waves can lead to better results.<sup>250, 254</sup>

## THERAPEUTIC MEDICATION IN MUSCULOSKELETAL INJURY

with NOEL POLLOCK

Therapeutic drugs can be helpful in the management of musculoskeletal injury by treating pain, modulating inflammation and augmenting recovery. The use of therapeutic drugs should be aligned with the overall management plan and support the particular goals of that management phase. This section will discuss a range of oral and injectable therapeutic drugs used in the management of musculoskeletal injury.

Doctors prescribing medications to athletes should be fully aware of the current anti-doping regulations for the sport in which their patient is participating. This is updated annually by the World Anti-Doping Agency (WADA) and the current list can be found on the WADA website. There is also an online anti-doping resource for athletes and clinicians for products sold in Canada, USA, UK, Japan and Australia accessible at [www.globaldro.com](http://www.globaldro.com) where medication can be checked. The site also contains links for other nationalities.

### Analgesics

Analgesic medication is used to relieve and modulate pain, and is often prescribed in the acute phase after injury to reduce pain in conjunction with ice, compression or splinting. Analgesia may also facilitate early movement, although the medical team should decide the optimal initial load based on the diagnosis. Analgesic medication may also have a role in other management phases to treat central sensitisation or to facilitate desired movements in rehabilitation.

### Paracetamol

Paracetamol (acetaminophen) has an analgesic and antipyretic effect without affecting the inflammatory process. The mechanism of action is probably through the modulation of cannabinoid receptors. Adult oral doses are 1000 mg every 4–6 hours to a maximum daily dose of 4 g. At these doses, paracetamol is well tolerated and can be an excellent choice in acute sports injuries. Soluble paracetamol is more quickly absorbed and may be an effective choice in athletes who need a quicker onset of analgesia. At higher doses, paracetamol is hepatotoxic and it may be fatal in overdose.

### Codeine

Codeine is a more potent opiate analgesic and may be considered in the initial treatment of painful acute injury. However, codeine preparations are commonly associated with side effects such as nausea, dizziness and constipation, which limits prolonged use in the treatment of athletes.

### Emergency analgesia

In severe acute musculoskeletal injury, stronger and parenteral analgesia may be required. Clinicians that provide event cover should be familiar with the indications and risks of these medications and have access to appropriate emergency analgesia. This may include opiate-based medication, ketamine and Entonox<sup>®</sup>.

### Non-steroidal anti-inflammatory drugs (NSAIDs)

NSAIDs are drugs with analgesic and anti-inflammatory properties. The term non-steroidal is used to distinguish these drugs from corticosteroids that also produce anti-inflammatory effects. NSAIDs' mechanism of action is to inhibit the cyclo-oxygenase (COX) system. Cyclo-oxygenase has a key role in the inflammatory cascade that occurs at the site of acute injury. It converts arachidonic acid to prostaglandins and thromboxane which are key mediators of inflammation.<sup>271</sup> There are two cyclooxygenase iso-enzymes, COX-1 and COX-2, with different physiological roles (Fig. 17.21).

COX-1 is associated with the maintenance of the gastric mucosa and COX-1 inhibition with traditional NSAIDs can result in gastritis and ulceration. Selective COX-2 inhibitors have been available since 1999 with similar efficacy, but fewer gastro-intestinal side effects. The most commonly prescribed NSAIDs include aspirin, ibuprofen, diclofenac and naproxen, and the COX-2 selective NSAIDs, celecoxib and etoricoxib. The normally recommended dosage and frequency of administration varies between the different drugs (Table 17.7).

**Figure 17.21** Mechanism of action of NSAIDs

**Table 17.7** Commonly used NSAIDs

Drug	Some trade names	Usual dose (mg)	Half-life	Daily doses
Acetylsalicylic acid (ASA)	Aspirin®	650	30 mins	3–4
Celecoxib	Celebrex®	100–200	11–12 hours	1–2
Diclofenac	Voltaren®, Voltarol®	25–50	1–2 hours	2–3
Ibuprofen	Brufen®, Motrin®, Advil®	400	1–2.5 hours	3–4
Meloxicam	Mobic®	7.5–15	20–24 hours	1
Naproxen	Naprosyn, Anaprox®	250–1000	12–15 hours	1–2

Topical anti-inflammatory preparations are also available in creams and prolonged-release patches. These are effective delivery methods for superficial injuries, with less risk of side effects than orally administered NSAIDs.<sup>272</sup> Overnight patches or wraps may be particularly useful in limiting early morning stiffness that may be associated with excessive inflammation.

There is high-level evidence that topical NSAIDs are effective in relieving pain associated with acute musculoskeletal injuries such as sprain, strains and contusions,<sup>272, 273</sup> as well as with osteoarthritis.<sup>274</sup> Some of the pain relief they provide can be explained by a powerful placebo effect, which is greater with topical NSAID administration than with oral.

### NSAID use in sport

NSAIDs are widely used in competitive sport, with more than a third of all athletes at Olympic Games,<sup>275</sup> half of all players at recent soccer World Cups<sup>276</sup> and about a quarter of athletes in international track and field athletics<sup>277</sup> reporting in-competition NSAID use. They are commonly used in the treatment of injury, but also prior to competition in an attempt to reduce discomfort of potential future injury or post-exercise soreness in both elite and non-elite athletes.<sup>278–280</sup> This practice should be discouraged, as there is no evidence of a reduction in delayed onset muscle soreness (DOMS) or improved performance with prophylactic NSAIDs. However, player perception and the placebo effect can make behaviour

change challenging for team clinicians. Regular NSAID use causes significant health risks for the cardiovascular, renal and gastrointestinal systems. Clinicians should educate their athletes about these risks and seek safer alternatives, perhaps from nutraceutical products.

### NSAID use in the treatment of musculoskeletal injury

NSAIDs are usually an excellent choice in the short-term treatment of inflammatory conditions, such as bursitis or synovitis. However, the impact of NSAIDs on cellular metabolism and the tissues of the musculoskeletal system should be considered by athletes and clinicians using these medications in the treatment or prevention of injury. With this knowledge, NSAIDs may be prescribed for particular injuries or in stages of healing determined by the overall goals of the current rehabilitation and management phase.

#### NSAID and muscle

At a cellular level, NSAIDs probably have a negative effect on both muscle healing following injury and muscle hypertrophy after athletic training.<sup>281</sup> NSAIDs can inhibit protein synthesis<sup>282</sup> and reduce satellite cell activation, which is an essential step in muscle repair and regeneration.<sup>283, 284</sup> Inhibition of protein synthesis after resistance exercise may be limited to COX-1 NSAIDs, as selective COX-2 inhibitors have not been shown to induce similar reductions in protein synthesis.<sup>285</sup>

NSAIDs are often used by athletes in the treatment and prevention of DOMS, but scientific trials demonstrate very little evidence for a positive effect.

NSAIDs have been recommended for use in deep muscle contusions at risk of developing myositis ossificans.<sup>286</sup> Regular indomethacin for more than seven days is widely used by clinicians in this condition.

NSAIDs are not effective in the treatment of acute muscle tears and cannot be routinely recommended.<sup>287, 288</sup> They may have a short-term role to modulate an excessive early inflammatory response, but as this phase is necessary for appropriate satellite cell activation and initiation of regeneration, their use at this time may be detrimental to overall muscle repair.

#### NSAID and tendon

Basic science and animal-model studies of tendon tearing or surgical repair have consistently shown that NSAIDs reduce tenocyte proliferation and collagen formation, and therefore negatively affect tendon healing. However, in clinical studies of acute reactive tendinopathy, NSAIDs may facilitate short-term improvements in pain.<sup>289</sup> One small study also demonstrated improvements in leg stiffness and tendon function following treatment with a COX-2 inhibitor.<sup>290</sup>

It has been suggested that they may be useful in acute tendon overload despite (or perhaps because of) the potential negative effects on tenocyte activation.<sup>268</sup> However, clinicians should remember that basic science and clinical studies have shown that NSAIDs blunt exercise-induced collagen synthesis within tendon tissue.<sup>291</sup> Therefore, the prescribing of NSAIDs should, as with all medication, be considered within the overall treatment goals of the current rehabilitation phase. In Cook and Purdam's model of a continuum of tendon pathology (Chapter 4),<sup>268</sup> NSAIDs may be considered in the reactive tendinopathy phase, but are not recommended in the dysrepair or degenerative phases.

#### NSAID and ligament

NSAIDs have been shown to have a negative impact on collagen formation, fibroblast proliferation and healing in animal models of ligament injury.<sup>292-295</sup> Clinical studies of ligament injuries also do not support their use. One study of patients who underwent ACL reconstruction found increased joint laxity at six weeks in an NSAID-treated group compared with a group that had not been prescribed NSAIDs.<sup>296</sup> Another study demonstrated similar analgesic efficacy for paracetamol and NSAID (diclofenac) following acute ankle ligament injuries, but found increased oedema at day three in the NSAID group.<sup>297</sup>

#### NSAID and bone

Prostaglandins have an important role in bone metabolism, stimulating both osteoblasts and osteoclasts.<sup>298</sup> Numerous animal studies have reported a delay in bone healing with NSAID treatment.<sup>299</sup> It appears that COX-2 inhibition has the most negative impact due to inhibition of endochondral ossification.<sup>300-302</sup> Although high-quality clinical studies are lacking, a number of studies suggest a delay in bone healing with NSAID use.<sup>303, 304</sup>

### PRACTICE PEARL

NSAIDs could be considered a risk factor for fracture healing and cannot be recommended in fracture management.

### Adverse effects of NSAIDs

Adverse effects of NSAIDs may be associated with the gastrointestinal, cardiovascular and renal systems, and susceptibility increases with prolonged use and patient age.<sup>305</sup> The most common adverse effects are gastrointestinal with epigastric pain, nausea or reflux symptoms. The risk of experiencing these dyspeptic adverse effects can be lowered by using the minimum effective dose, taking the medication with food, using

gastroprotective formulations or the concomitant use of proton pump inhibitors (such as omeprazole or lansoprazole) or H2 antagonists (such as ranitidine). Occult gastrointestinal bleeding may contribute to iron depletion and therefore clinicians should enquire about NSAID self-prescribing in iron-deficient athletes.

Selective COX-2 inhibitors with reduced gastrointestinal side effects have been available since 1999. In 2004, a number of COX-2 inhibitors (valdecoxib and rofecoxib) were taken off the market, as they were specifically associated with a high number of adverse vascular events. COX-2 inhibitors, and some non-selective NSAIDs such as diclofenac, are associated with an increased risk of thrombotic events, and are contraindicated in ischaemic heart and cerebrovascular disease. They should be used with caution in patients with risk factors for cardiovascular events. However, they are often used in athletes with musculoskeletal injury due to their effective analgesic properties and low adverse effect profile.

### Medications for neuropathic pain and central sensitisation

Neuropathic pain is defined as pain arising from a lesion or disease affecting the somatosensory nervous system (Chapter 6).<sup>306, 307</sup> It is often characterised clinically by amplified pain responses following noxious or non-noxious stimuli and may be present in combination with true nociceptive pain arising from tissue damage. In patients with neuropathic pain, both peripheral and central neural sensitising mechanisms may be present.

Recent research has suggested that central sensitisation is a potentially important feature of a number of musculoskeletal presentations, including shoulder pain, lateral epicondylalgia and patellar tendinopathy.<sup>308, 309</sup> Central sensitisation is defined as 'an amplification of neural signalling within the central nervous system (CNS) that elicits pain sensitivity'.<sup>310</sup> It is an important feature for clinicians to detect and treat within the overall rehabilitation plan.

The management of neuropathic pain or central sensitisation in musculoskeletal injury should have a number of interdisciplinary elements and may incorporate therapeutic medication. In addition to the analgesic medication previously discussed, a number of other pharmaceuticals may have a therapeutic role. However, although these medications have demonstrated efficacy in RCTs and meta-analyses, there have been no clear predictors of treatment success in patients with neuropathic pain. The therapeutic approach is therefore usually a stepwise trial approach to identify which medication or combination provides the greatest pain relief with the fewest side effects.

### Tricyclic antidepressants

Tricyclic antidepressants inhibit serotonin and nor-adrenaline neurotransmitter re-uptake and block sodium channels. Nortriptyline is most widely used and is the active metabolite of amitriptyline. It is recommended in UK, European, US and Australian guidelines for the treatment of neuropathic pain, although not as a first-line treatment.<sup>311</sup> A dose of 10–25 mg is usually prescribed at night to avoid sedative effects during the day. A recent Cochrane review concluded that there was little evidence to support the use of nortriptyline in neuropathic pain, particularly when compared with duloxetine and pregabalin.<sup>311</sup>

### Serotonin reuptake inhibitors

Duloxetine is a serotonin re-uptake inhibitor with moderate to strong evidence for efficacy in the treatment of neuropathic pain.<sup>312, 313</sup> A starting dose of 30 mg is often increased to an efficacious treatment dose of 60 mg. Similar to other medications for neuropathic pain, fatigue may be a side effect.

### Gabapentin and pregabalin

Gabapentin and pregabalin are gamma-aminobutyric acid analogues that bind to calcium channels on afferent nociceptors and subsequently reduce neurotransmitter release. Pregabalin has a half-life of around six hours.<sup>314</sup> Starting dose of pregabalin is usually 75 mg twice daily and this may be titrated to a total daily dose of 300 mg over the course of one week. The most common adverse effect of these medications is fatigue or a mild sedative effect, and they are often not appropriate to take before training sessions. Gabapentin is also available in an extended-release preparation that may be more effective for neuropathic pain, but is more likely to impact on athlete's training programs.

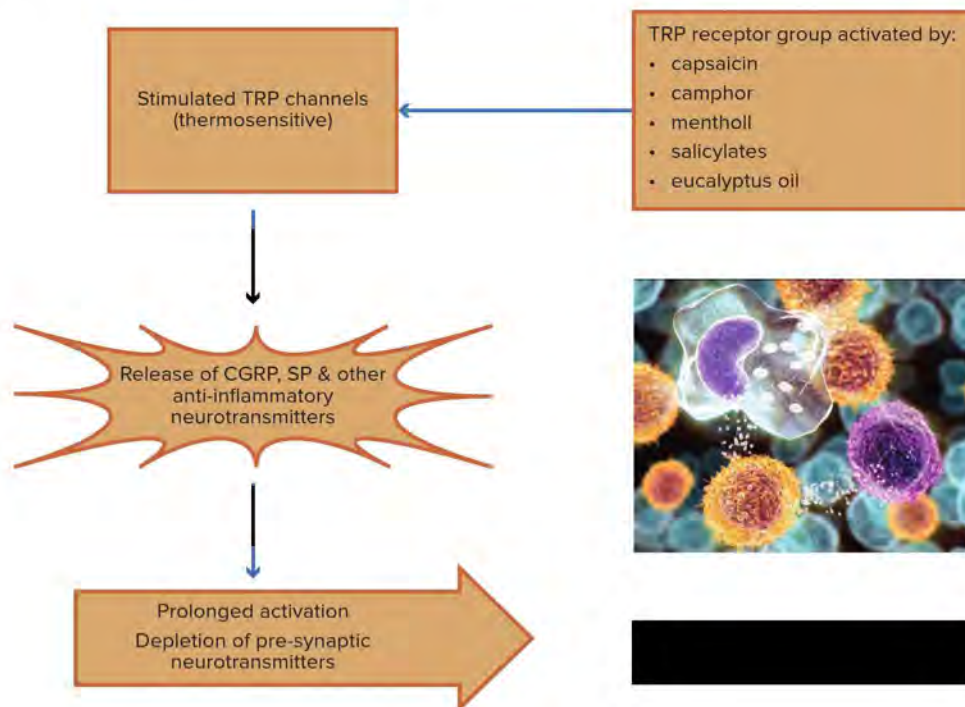

### Local anaesthetic patches

Topical lignocaine (lidocaine) patches have demonstrated positive effects in short-term studies on neuropathic pain<sup>312</sup> and may be helpful as a second-line treatment, although the quality of the evidence is weak.

### Counterirritants

Topical heat rubs are often used by athletes and mainly act as counterirritants. Their mechanism of action is probably related to their effect on transient receptor potential (TRP) channels (Fig. 17.22). These channels are sensitive to heat and initiate a local inflammatory response. Prolonged activation of the nociceptors may result in a depletion of local neurotransmitters, which may result in a reduction in pain and nociceptor transmission from the site of the more long-standing injury. Counterirritants, such as

**Figure 17.22** Mechanisms of action of counterirritants

### Injection therapy: should injections be performed under ultrasound guidance?

There is consistent high-quality evidence that ultrasound-guided injections are more accurate than landmark-guided injections.<sup>315</sup> There is moderate limited-quality evidence that ultrasound-guided injections are more efficacious than landmark-guided injections, particularly in large joints, subacromial bursal injections,<sup>316</sup> carpal tunnel and inflamed joints.<sup>317</sup> The interpretation of the research in this area is challenging, as corticosteroid injection is often studied. Not only may this be an inappropriate therapeutic choice for the particular pathology,<sup>318, 319</sup> but there are known systemic effects of corticosteroid injections that may affect outcome measures. It is also reasonable to assume that with the development of injectable therapeutic agents without systemic effects, such as hyaluronic acid, these would be unlikely to demonstrate maximal therapeutic efficacy unless accurately positioned. Therefore, we recommend that clinicians who regularly perform musculoskeletal injections undertake training in ultrasonography and perform injection therapy under ultrasound guidance.

**Figure 17.23** Ultrasound-guided injection  
USED WITH PERMISSION OF GE HEALTHCARE

capsaicin or camphor, may therefore have a use for mild analgesia before activity, but also potentially in a chronic injury that demonstrates increased neural sensitisation or elements of neuropathic pain.<sup>312</sup>

### Local anaesthetic injections

Local anaesthetic injections may be used in sports medicine for a number of reasons. They can be used in the treatment of musculoskeletal injury to reduce pain or

facilitate movement. Local anaesthesia may be performed on competition day to enable athletes to participate in sport despite injury. Local anaesthetic injections are also frequently used in conjunction with a corticosteroid injection to reduce needle pain.

Local anaesthetics cause a reversible block to conduction along nerve fibres by inhibiting sodium channels, particularly in small neurones. There is a wide variation in speed of onset, duration of action and potency. Lignocaine (lidocaine) and bupivacaine are the most commonly used preparations for musculoskeletal injection. Lignocaine 1% is a quick-acting local anaesthetic that is effectively absorbed from mucous membranes. The duration of anaesthesia is usually 60–120 minutes. Bupivacaine has a slower onset, taking up to 30 minutes for effect, and a longer duration of action, lasting for several hours.

### Local anaesthetic in competition

Anaesthetic injections are sometimes used to enable participation in elite sport despite the presence of AC joint injuries, finger and rib injuries, and iliac crest haematomas.<sup>320</sup> These injections appear to be relatively safe in the short and long term. We do not recommend intra-articular injections in weight-bearing joints or around tendons of the lower limb, due to the significant risk of further injury to these structures.

### Local anaesthetic in routine musculoskeletal injections

Clinicians have traditionally used local anaesthetic in most musculoskeletal injection protocols to reduce the pain of the procedure. However, as local anaesthetic has been shown to be myotoxic,<sup>321</sup> chondrotoxic<sup>322</sup> and tendon toxic,<sup>323, 324</sup> clinicians should reconsider their use of local anaesthesia during routine injection protocols.

### Traumeel

Traumeel is a herbal preparation of arnica, belladonna, calendula, heparin and echinacea that is reported to have an antioxidant and anti-inflammatory action. Some clinicians inject it in the treatment of muscle injuries<sup>325</sup> and it is also available as a topical anti-inflammatory. The topical application of traumeel has been demonstrated to be as efficacious as topical diclofenac for pain relief in low-grade acute ankle ligament injuries.<sup>326</sup> There are no clinical studies that evaluate its efficacy in the treatment of muscle injuries.

### Actovegin

Actovegin is a deproteinised ultrafiltrate of calf serum produced in Austria, a bovine spongiform encephalopathy-free country,<sup>327</sup> and a licensed drug in Europe, China and

Russia. It is reported to contain trace elements, amino acids, electrolytes, and carbohydrate and fat metabolites. The active ingredients have not been identified. Some basic science studies suggest Actovegin has a role in modulation of inflammatory processes, but no quality clinical evidence exists to support its use in muscle injury.

### Sclerosant

Early studies reported positive effects of sclerosing injections of polidocanol to areas of neovascularisation, just outside the Achilles tendon.<sup>328, 329</sup> However, more recent studies have not demonstrated positive effects<sup>330</sup> and it is currently not widely used in clinical practice.

### Prolotherapy

Prolotherapy is a collective term for the injection of an irritant, usually hyperosmolar dextrose, in the treatment of chronic painful musculoskeletal conditions.<sup>331</sup> The mechanisms of action are not fully understood, but it is claimed that prolotherapy stimulates inflammation and growth factor release, initiates a proliferative response and results in desensitisation through a denervating effect. There is conflicting evidence regarding its efficacy.<sup>332</sup>

### Mechanical and high-volume injections

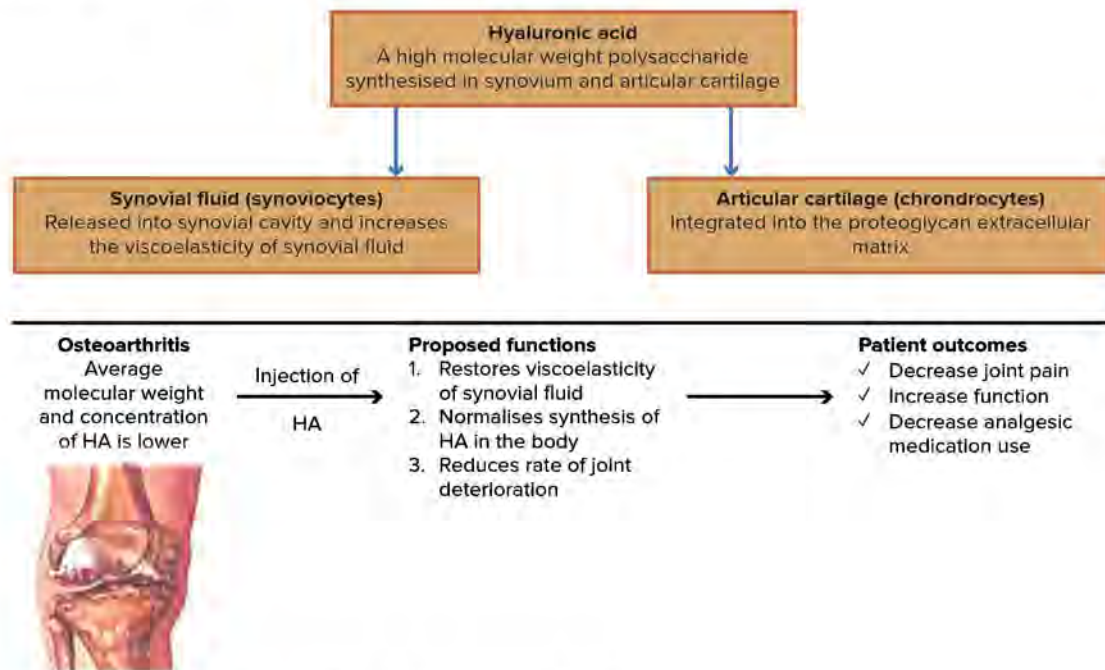

The pain and pathological processes involved in tendinopathy are not fully understood. Some theories suggest that tendon adherence to the adjacent fat pad or neurovascular in-growth from the fat pad are implicated in the pain and pathogenesis of Achilles and patellar tendinopathy. An injection protocol that infiltrates a high volume (up to 40 ml) of normal saline (with a small amount of local anaesthetic, hydrocortisone or aprotinin) to the interface between the tendon and the fat pad has been described.<sup>333–335</sup> While case series have demonstrated positive effects, further high-quality studies are needed.

### Hyaluronic acid

Chondrocytes and synovial cells produce hyaluronic acid, which is the major constituent of synovial fluid and a component of the extracellular matrix of cartilage. Hyaluronic acid maintains the structural integrity of cartilage and assists with joint mobility and shock absorption. It can also modulate the inflammatory response through inhibition of pro-inflammatory factors, such as arachidonic acid and Interleukin-1 (IL-1), which have a degradative effect on the cartilage matrix.

Hyaluronic injection can be useful in the treatment of chondropathy and may cause an initial reduction in pain due to this anti-inflammatory effect. However, it is generally most effective in the medium and long term,<sup>336</sup> probably through its stimulation of synovial cells to synthesise endogenous hyaluronic acid (Fig. 17.24). A meta-analysis

**Figure 17.24** Hyaluronic acid: mechanism of action in osteoarthritis

comparing hyaluronic acid injections to corticosteroid injections suggested greater pain relief following corticosteroid at two weeks but not at four weeks, and greater benefit of hyaluronic acid at 8–26 weeks.<sup>337</sup>

### Hyaluronic acid in tendons

Hyaluronic acid has been used in the field of hand surgery for several years to provide surface lubrication and enhance postoperative tendon mobility. With emerging evidence suggesting the importance of the Achilles or patellar tendon-fat pad interface in the development of tendon pathology, there have been some proposals for a role for hyaluronic acid injection in this interface<sup>338</sup>. Although there have been a number of case series publications,<sup>339, 340</sup> no high-level evidence currently exists to support this therapeutic approach.

### Corticosteroids

Corticosteroids are strong anti-inflammatory agents that reduce vascular permeability and leucocyte activation, and block inflammatory mediators. The proposed aim of corticosteroid injection is to reduce pain and inflammation to facilitate normal movement and allow therapeutic exercise. However, there are significant detrimental effects associated with the injection of corticosteroids. Therefore, clinicians should consider their use carefully in each case with specific regard to the current evidence, injured tissue, and the stage and goals of rehabilitation.

Peritendinous injection of corticosteroids is generally not recommended. Corticosteroids inhibit collagen synthesis and are detrimental to tendon healing. Biopsy studies have demonstrated an increase in the glutamate NMDA receptor following corticosteroid injection.<sup>341</sup> This receptor has been associated with chronic pain and tendinopathy.

Recent studies have demonstrated negative medium- and long-term outcomes from corticosteroid injection around elbow common extensor origin tendinopathy (tennis elbow) even compared with a 'wait and see' approach.<sup>318</sup> However, there is no doubt that they can provide effective pain relief in the short term and, in certain cases after informed discussions with the athlete and coach, this may be the main priority. Corticosteroid injection may be of value in inflammatory bursitis with healthy local tendon tissue. However, even in apparently isolated retrocalcaneal bursitis, caution is advised in elite athletes who place high demands on their Achilles tendons.

Intra-articular injections of corticosteroid for joint disease will reduce synovial inflammation and catabolic enzymes that are probably implicated in cartilage breakdown. However, there are negative joint consequences to be considered with respect to intra-articular corticosteroid injection. Cartilage matrix degradation and reduction in elasticity has been observed following intra-articular injections of corticosteroids to weight bearing joints.

Corticosteroid, particularly if combined with local anaesthetic, is known to be toxic to chondrocytes,<sup>342, 343</sup>

and repeated injections may limit cartilage repair and regeneration. The injection of corticosteroid followed by a quick return to running is thought to be more detrimental to the articular cartilage. Injection directed to the inflamed synovial tissue rather than the joint fluid may be considered to limit negative impact on the cartilage. In summary, corticosteroid injection into weight-bearing joints should be approached with caution and considered only in the presence of excessive inflammation. There may be a more appropriate and effective role for corticosteroid injection into smaller, nonweight-bearing joints or spinal, apophyseal joints or epidural injections.

### Other adverse effects of corticosteroids

The adverse effects of corticosteroids on tendons and cartilage have been presented above. However, there are other side effects that should be considered and discussed with the patient. Corticosteroid injection can commonly result in skin depigmentation, which may be permanent. Fat atrophy is also a possible effect, particularly in superficial injections. The risk of this can be minimised by accurate guided-needle placement and care to avoid steroid placement along the needle track during withdrawal.

Intra-articular injection may result in pericapsular calcification and severe adverse events such as avascular necrosis have been reported, usually following several injections within a short time frame. Joint infection is another significant serious adverse effect and appropriate sterilisation measures with a good injection technique are essential for these injections. The presence of an overlying skin infection is a contraindication to injection.

Corticosteroid injections commonly cause a short-term exacerbation in symptoms for several days after the injection. Patients are recommended to have a short period of rest and to modify athletic activity after a corticosteroid injection.

### Choice of corticosteroid

The most commonly used corticosteroids are triamcinolone, methylprednisolone, hydrocortisone and dexamethasone. They each have a different duration of action and solubility that should be considered when choosing an appropriate steroid for injection.

Triamcinolone and methylprednisolone are hydrophobic preparations and therefore form microcrystalline suspensions. As a result, they should have a longer duration of action than hydrophilic preparations, such as dexamethasone or hydrocortisone, which have a quicker onset of action but reduced duration of effect. Triamcinolone and methylprednisolone are particulate steroids that, according to recent guidelines in the USA, should be avoided in spinal injections. This is due to the risk of inadvertent arterial puncture and subsequent

particulate injection with severe vascular consequences. The debate on particulate versus non-particulate spinal injections continues, but there is some evidence to suggest that non-particulate steroids, such as dexamethasone, have an equivalent effect. Therefore, it may be prudent to choose this form of steroid for spinal injections.<sup>344, 345</sup>

## Other medications

### Sleep medication

Sleep is of great importance to the athlete in normal training to enable adaptation and recovery (Chapter 13). A lack of sleep is associated with an increased injury risk and impaired sporting performance. During injury rehabilitation, sleep can be disrupted due to pain and anxiety. For the injured athlete, good quality sleep is essential for many reasons, but particularly to enable optimal protein synthesis, for soft tissue healing and strengthening, and neuromotor learning to achieve the gait, running or skill re-education required during rehabilitation. The sleep strategy for an athlete in rehabilitation is a broad remit for the multidisciplinary team, but medication may have a useful short-term role.

There are several medications that can assist with sleep. The clinician should be aware of the dependence and tolerance that can occur with the use of hypnotics and should therefore reserve their use for short courses (of several days only). The use of sleep medication should be carefully documented in the patient's notes, particularly if there are a number of team physicians. Generally, short-acting hypnotics are the most appropriate for athletes with sleep disturbance associated with acute injury. These will assist with sleep onset and not have a sedative effect the following day.

Temazepam is a short acting benzodiazepine with little 'hangover' effect, although tolerance can develop quickly. Diazepam is a long-acting benzodiazepine that also reduces muscle spasm and can be of use if this is also a therapeutic goal, most commonly in the treatment of acute low back pain with muscle spasm. Non-benzodiazepine hypnotics, such as zolpidem or zopiclone, have a short duration of action without hangover effects.

### PRACTICE PEARL

Clinicians, as well as athletes, should always be aware of the dangers involved with the abuse of sleep medications. There have been multiple high-profile cases of such abuse across a multitude of sports. When athletes are prescribed sleep medications, they should always be warned of interactions with other drugs, including alcohol, which if taken in combination can cause enhanced central nervous system depression and lead to catastrophic consequences.

### Quinolone antibiotics

Unless there is no suitable antibiotic alternative, quinolone antibiotics (e.g. ciprofloxacin, ofloxacin) should not be prescribed to athletes. There is clear evidence linking quinolones with both acute tendon rupture and increased lifetime risk of tendon disease.<sup>346, 347</sup>

### Glyceryl trinitrate patches

Glyceryl trinitrate (GTN) patches have been proposed to modulate tendon healing by providing nitric oxide, which may stimulate collagen synthesis. There were some early studies that demonstrated improvements in tendon pain and function in patients with non-insertional Achilles, supraspinatus and elbow common extensor origin tendinopathies.<sup>348-350</sup> However, more recent RCTs fail to demonstrate clinical improvements compared with, or as an adjunct to, exercise rehabilitation.<sup>351-354</sup> There is a notable incidence of headache associated with initiation of treatment. Current evidence suggests that GTN patches do not appear to have an important therapeutic role in the management of tendinopathy.

### Bisphosphonates

Bisphosphonates inhibit osteoclastic function and therefore increase bone mass. They have been used for many years in the treatment of osteoporosis and decrease fracture risk in this population. The use of bisphosphonates in the prevention or treatment of stress fractures and one-off intravenous injections to reduce bone pain from pubic bone stress (osteitis pubis)<sup>355</sup> in athletes has been proposed.

One study found that bisphosphonates had no effect on stress fracture prevention in military recruits.<sup>356</sup> In stress fracture treatment, a small study suggested bisphosphonates could result in accelerated and safe return to sport.<sup>357</sup> Some clinicians also recommend the use of bisphosphonates for the treatment of athletes with osteitis pubis.

However, there are several significant concerns regarding the rationale and use for bisphosphonate treatment in athletes. Bisphosphonates have a half-life of 1–10 years, limit normal microdamage repair and suppress bone remodelling. This may be detrimental to an athlete in the long term, after recovery from the current injury, as normal bone remodelling is essential for adaptation and resilience to normal athletic training. Indeed, their short- and long-term use in an elderly osteoporotic population has demonstrated an increased risk of fatigue fractures.<sup>358, 359</sup> High-quality studies of the short- and long-term impact of bisphosphonate prescription in athletes are required.

The safety of bisphosphonates in women who may subsequently become pregnant has not been established. Animal studies have shown that bisphosphonates can cross the placenta and therefore affect foetal bone

mineralisation. While there have been no case reports of teratogenic effects in humans, it would seem prudent to avoid the use of bisphosphonates in female athletes.

In addition to the potential adverse effects above, there are side effects of bisphosphonates that should be recognised. Nausea, arthralgia and myalgia for 48 hours after intravenous treatment are common. Oral bisphosphonates can induce oesophageal inflammation and erosion. Osteonecrosis of the jaw has also been reported, usually in patients over 60 years with significant dental pathology. However, this risk should be discussed and a dental examination performed prior to bisphosphonate administration.

## NUTRACEUTICALS IN INJURY MANAGEMENT

with NOEL POLLOCK

In recent years there has been an increased focus on the potential role of dietary supplements and herbal products—often collectively referred to as nutraceuticals—in the treatment of sports injuries.

### Glucosamine, chondroitin and omega-3 fatty acids

Glucosamine has been advocated as a treatment for cartilage injury. The availability of glucosamine is a rate-limiting step in proteoglycan production.<sup>360</sup> Proteoglycans are large complex molecules which provide elasticity and integrity to cartilage tissue. There are numerous basic science studies that provide evidence for the important role of glucosamine in supporting joint health. In addition to its role in proteoglycan production, it may also have an anti-inflammatory role and limit chondrocyte apoptosis.

Some meta-analyses have concluded that long-term treatment with glucosamine can reduce pain and disease progression, and improve joint function and mobility in patients with osteoarthritis.<sup>361, 362</sup> Supplementation is often recommended in European and international guidelines on the treatment of osteoarthritis; however, while there is some rationale for its use in chondropathic conditions, the evidence is conflicting.<sup>363</sup> A daily oral dose of 1500 mg is most consistently recommended.

Chondroitin sulphate is a natural glycosaminoglycan and an important component of the extracellular matrix. Similarly to glucosamine, its use has been recommended in the treatment of inflammatory arthropathy including osteoarthritis and chondropathy.<sup>364</sup>

The role of glucosamine and chondroitin in the synthesis of large proteoglycans, such as aggrecan, has led some clinicians to consider their use in patients with tendinopathy.<sup>268</sup> Early tendon overload is characterised by tendon swelling and aggrecan production,<sup>365</sup> and therefore further increase in large molecule proteoglycan

synthesis may be detrimental. The role of glucosamine and chondroitin in proteoglycan synthesis suggest that it may be appropriate to avoid the use of these products in early, reactive tendinopathy.

Omega-3 polyunsaturated fatty acids have been used as dietary supplements in musculoskeletal injury, particularly joint injury, due to their anti-inflammatory and antioxidant effects. Reactive oxygen species are increased in arthritis and associated with cartilage degradation. Some low-level evidence suggests that omega-3 fatty acids may be helpful at reducing morning stiffness in patients with osteoarthritis.<sup>366</sup>

## Vitamin D

Vitamin D is a secosteroid hormone with a wide range of important physiological effects for health and athletic performance. Regarding musculoskeletal injury, Vitamin D has an essential role in the maintenance of muscle strength and mass, particularly for type II muscle fibres and in optimal bone health. Correction of vitamin D deficiency can improve muscle strength and reduce the risk of stress fractures.<sup>367, 368</sup> Vitamin D deficiency is prevalent in elite athletes, and screening and treatment of deficiency is recommended.<sup>369</sup>

## Green tea/polyphenols

Green tea and other polyphenol-rich foods such as cherry juice may have an important future role in the management of musculoskeletal injury. There have been some basic science and animal studies demonstrating a positive impact on tendon and cartilage healing.<sup>370, 371</sup> Clinical studies are required to determine the clinical impact of polyphenol supplements and nutrition.

## AUTOLOGOUS BLOOD, BLOOD PRODUCTS AND CELL THERAPY

with ROBERT-JAN DE VOS

Autologous blood, specific blood products, and cells are increasingly used in clinical trials in the field of musculoskeletal medicine. These autologous products secrete many growth factors that are thought to have a positive effect on healing of bone, cartilage, ligament, tendon and muscle injuries. This has been based on laboratory studies showing increased cell proliferation and collagen synthesis, and stimulation of a well-ordered angiogenesis.<sup>372-374</sup> The rationale, applications and efficacy of these treatments are summarised below.

### Autologous blood injections

The main rationale behind treatment with autologous blood injections is the presence of various growth factors

in blood with a potential healing effect. Blood is usually drawn from an arm vein and injected directly into the injured part. Ultrasound guidance can be helpful for improving delivery of autologous blood to the injury site, but in superficial injuries or in presence of clear anatomical landmarks, this is not always necessary. The amount of blood injected depends on the location and type of injury, but 3 mL or 6 mL are the most commonly used volumes.<sup>375</sup>

This procedure has been used mainly in tendinopathies; however, a systematic review did not show efficacy of this treatment for these injuries.<sup>375</sup> More recent randomised trials show efficacy of autologous blood injections in comparison with detrimental corticosteroid injections,<sup>376-378</sup> but not compared with placebo or standard physical therapy.<sup>379, 380</sup>

### Platelet-rich plasma

Platelet-rich plasma (PRP) is the product derived when autologous whole blood is centrifuged to separate out a preparation with a very high platelet content. The preparation is rich in both plasmatic and platelet  $\alpha$ -granule derived growth factors, as well as many thousands of other substances.<sup>372</sup>

With the preparation of a PRP injection, a larger amount of blood is withdrawn. The blood is then placed into a tube, which in turn is placed into a centrifuge, which spins many thousand times a minute, for various lengths of time depending on the protocol. At this point, the platelets have separated from the other blood components and can be aspirated for injection. Many different versions of PRP are described depending on the duration, force and number of spins. Several sub-classifications of PRP have been made, which can serve as a basis for evaluation of efficacy in clinical studies.<sup>381</sup>

Initially, many case series showed benefit of PRP injections in several clinical conditions.<sup>382</sup> In comparison with detrimental corticosteroid injections, it was found efficacious.<sup>383</sup> However, systematic reviews and more recent randomised studies with appropriate control groups receiving placebo injection therapies (e.g. saline) did not show efficacy of PRP in patients with Achilles tendon ruptures,<sup>384</sup> anterior cruciate ligament reconstruction,<sup>385</sup> arthroscopic rotator cuff repair,<sup>386</sup> Achilles tendinopathy,<sup>387</sup> lateral epicondylar tendinopathy,<sup>388</sup> patellar tendinopathy,<sup>389</sup> plantar fasciopathy<sup>390</sup> or acute hamstring injuries.<sup>391</sup> PRP injections showed limited to moderate evidence in a systematic review on efficacy in patients with knee osteoarthritis.<sup>392</sup> More high-quality randomised studies with low risk of bias are needed for this indication.

In conclusion, there is currently insufficient evidence to advise PRP injections as a routine part of management for musculoskeletal injuries.

## Cell therapy

Preclinical studies have shown the potential for cellular therapies to regenerate rather than repair the tissues. The cells can be harvested from embryos (embryonic stem cells–ESCs), bone marrow, adipose tissue (mesenchymal stem cells–MSCs) or differentiated cells from the preferred tissue (e.g. tenocytes or chondrocytes).<sup>393</sup> Cell lines such as ESCs have superior potency and proliferative properties, but their main disadvantages are ethical considerations and potential complications including tumorigenesis. MSCs offer promise in tissue engineering due to their proliferative capacity and the secretion of growth factors. Autologous cells can be harvested from the preferred tissue and expanded, prior to re-implantation. For example, healthy tendon cells (tenocytes) can be harvested from the patellar tendon (Fig. 17.25), expanded in a laboratory and injected into a tendinopathic tendon (e.g. Achilles). A disadvantage of this technique could be the donor site morbidity.

**Figure 17.25** Biopsy of patellar tendon for tenocyte harvesting

Clinical studies using cell therapy for the treatment of musculoskeletal conditions are currently increasing. Small case series in patients with lateral epicondylitis and rotator cuff tendinopathy treated with autologous tenocytes, bone-marrow-derived cells and skin-derived fibroblasts showed functional and structural improvement.<sup>394–396</sup> A recent randomised study in patients with patellar tendinopathy and Achilles tendinopathy showed efficacy of a local skin-derived fibroblast injection.<sup>397</sup> These conclusions are, however, hampered by several major shortcomings.

Effectiveness of cell therapy is also evaluated more frequently in cartilage defects. One systematic review did not demonstrate sufficient evidence for the use of bone-marrow-derived MSCs.<sup>398</sup> There is currently also insufficient evidence for surgical autologous chondrocyte implantation (ACI), the surgical implantation of healthy cartilage cells into the damaged areas.<sup>399</sup> While ACI has been suggested to provide better results in tissue quality and is increasingly performed in clinical practice, more high-quality studies with long-term follow-up are needed in this field.

There are no high-quality clinical studies available to support the use of cell therapy. We expect high-quality randomised clinical trials will be published in the coming years.

In conclusion, there is currently insufficient evidence to advise autologous blood injections, PRP or autologous tendon cell injections as a routine part of management for musculoskeletal injuries.

## SURGERY

Despite the many advances in the non-operative management of sports injuries, surgery has a major role to play in the management of both acute and overuse injuries. Surgery is used to remove, repair, reconstruct or realign damaged tissue. Sports surgery can be classified as arthroscopic surgery or open surgery.

### Arthroscopic surgery

Arthroscopy involves the introduction of a fibre-optic telescope into a joint space to provide diagnostic information and afford the opportunity to undertake minimally invasive surgery. It is a well-established procedure for the knee, shoulder, elbow, ankle and hip, and, more recently, the wrist.

Arthroscopy utilises a light source to illuminate the joint and a video camera to capture the image, which is then displayed on one or more screens. The arthroscope is introduced through a standard portal, while another portal or portals are used to introduce operating instruments. The location of portals is important to minimise the risk

of damage to vessels and nerves. A number of instruments are available for use in arthroscopic procedures.

Arthroscopy can be carried out under local, regional or, often, general anaesthesia as a day procedure. The main areas of interest to be viewed through the arthroscope are the articular surfaces, the synovium and intra-articular structures such as the meniscus and cruciate ligaments of the knee, the glenoid labrum and rotator cuff tendons of the shoulder, and the acetabular labrum of the hip. In most joints, the majority of the articular surfaces can be viewed. Assessment of stability can be aided by combining a direct view of the joint with manoeuvres that place the joint under stress.

Common procedures performed through the arthroscope include removal of loose bodies within the joint, separation of and removal of the torn part of a meniscus, repair of a torn structure such as a peripheral tear of the meniscus or a labral detachment in the shoulder, or dividing a tight structure such as the glenohumeral joint capsule in the shoulder or scar tissue in the knee. More complex reconstructive joint procedures (ACL reconstruction, rotator cuff repair) can be performed with the aid of an arthroscope.

Arthroscopy has a low complication rate. There is a small incidence of infection and delayed portal healing. Occasionally, arthroscopy can produce a persistent joint reaction manifesting as prolonged joint effusion, persistent pain and muscle wasting. Whether this is due to the arthroscopy itself or to the underlying joint pathology is sometimes difficult to determine. Complex regional pain syndrome type 1 may occasionally develop after arthroscopy.

### Open surgery

The open surgical treatment of sports-related problems includes surgery related to acute trauma and surgery for the treatment of overuse injuries. Surgery after an acute injury aims to recreate the pre-injury anatomy by the repair of damaged tissues. This may require internal bone fixation for an unstable fracture, or repair of torn ligaments or tendons. If repair of the damaged tissue is not possible, a reconstructive procedure may be performed; for example, ACL reconstruction.

Following an acute injury, the athlete may develop chronic problems, such as instability, that may require surgical repair or reconstruction. Chronic ligamentous or capsular inadequacy may develop following an injury or as a gradual process. Surgery may be required to tighten the stretched tissue, either by moving the attachment of the tissue or by a shortening procedure, such as plication, reefing or shifting.

Overuse injuries that have failed to respond to conservative measures are sometimes managed by surgical tissue release, division or excision. Excision may be performed if impingement is present or if degenerative change has led to tissue necrosis. In nerve compression, decompression or transposition of the nerve may be required. Stress fractures that fail to heal (non-union) are treated by fixation or bone graft.

With all surgical procedures, arthroscopic or open, the surgery must be considered as only a part of the treatment. Adequate post-surgical rehabilitation is as important as the procedure itself. Rehabilitation following injury and surgery is discussed in Chapter 18.

# Principles of sports injury rehabilitation

with HÅVARD MOKSNES and PHIL GLASGOW

*The pearl of long-term rehabilitation is to build a small team of core people who collaborate with other professions. Never walk alone!*

Kjetil Jansrud, alpine skiing gold medallist at the 2014 Sochi Winter Olympic Games, 13 months after rupturing his anterior cruciate ligament

Sports injury rehabilitation is a dynamic, structured process that aims to:

- restore the injured athlete's function and performance level
- return the athlete to sports participation in a safe and timely manner
- minimise the risk of re-injury.

As previous injury is a prominent risk factor for future injury,<sup>1-3</sup> rehabilitation is a critical aspect of our professions. In most cases, the goal should be to improve the athlete's physical function to above their pre-injury level.

The foundation of sports injury rehabilitation is a targeted exercise program that is progressed gradually. As outlined in previous chapters (including 6 and 17), exercise therapy acts at the local tissue level and in the central nervous system. It may be used as a direct injury treatment (mechanotherapy)<sup>4</sup> or to unload injured tissue via altered movement and muscle activation patterns. It is also important to maintain the athlete's condition as much as possible throughout the rehabilitation process. A model of the parallel priorities of exercise prescription during the rehabilitation process is shown in Figure 18.1.

Exercise prescription, progress and supervision is often performed by a physiotherapist (or similar health professional, for example sports rehabilitator, trainer, therapist). However, where possible, a broader multidisciplinary team including the sport and exercise medicine physician, orthopaedic surgeon and other sport scientists (such as strength and conditioning specialists)

should collaborate in rehabilitation planning. It is also critical to engage coaches in all phases of rehabilitation. In the early phases, coaches need to understand the plan and appreciate the functional milestones. In the later phases they should take an increasingly active role in implementing the program (Fig. 18.1).

Active rehabilitation is often supplemented with medical and manual therapies that may enhance the effects of exercise through pain management and improved tissue adaptations (Chapter 17). The success of rehabilitation depends on introducing the most effective intervention at the right time in an adequate dosage.<sup>5</sup>

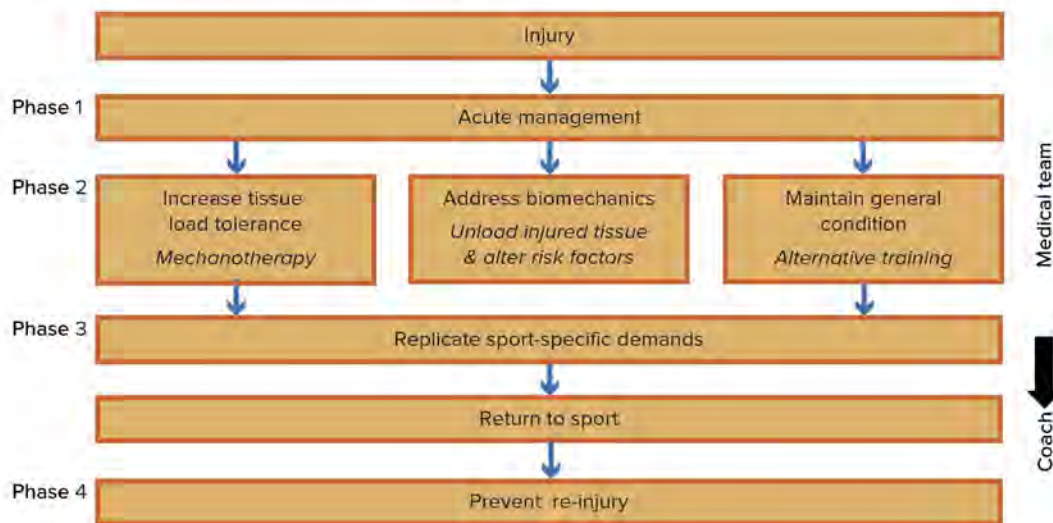

Modern sports injury rehabilitation is progressed through phases based on sound clinical reasoning, sequenced functional achievements and the completion of functional milestones. At the same time, knowledge of tissue-specific biological healing processes should be respected and will guide the rehabilitation timeline. Exercise prescription, communication and clinical reasoning are core skills for clinicians involved in rehabilitation of sports injuries. Although most experienced clinicians are probably subconsciously following a progression model through rehabilitation, few theoretical models have been published.<sup>5</sup>

This chapter outlines the general principles of sports injury rehabilitation and provides a framework for progression through phases.

## GENERAL PRINCIPLES

The primary aim of rehabilitation is to return the athlete to sport with appropriate function and fitness to participate at the desired level with a low risk of re-injury.

**Figure 18.1** A model of the parallel priorities of exercise prescription during sports injury rehabilitation. The responsibility for implementation of the program should be gradually transferred from the medical team to the coach throughout the later phases of rehabilitation

However, this is sometimes challenging due to the desire of the athlete, coach, parents, management and others to return athletes to competition prematurely. Regardless of the circumstance, the medical team is obliged to ensure that the athlete's long-term health is not compromised by a premature return to sport which may have serious consequences. Thus, all rehabilitation protocols should include a predefined sport-specific functional battery of tests to ensure that the athlete is fit to return to sport with minimal risk of re-injury.

The rehabilitation principles described in this chapter primarily apply to the treatment of acute sports injuries and post-operative musculoskeletal rehabilitation. These rehabilitation processes are usually relatively linear and, for the most part, predictable. The principles can also be applied to overuse injuries. However, because the symptoms of overuse injuries often fluctuate and athletes often continue to train and compete with pain/impaired function, athletes may present at different stages of the rehabilitation continuum.

Rehabilitation plans following sports injury are usually separated into distinct phases and include active interventions aimed at addressing body impairments and functional limitations, with the aim of facilitating the athlete's participation in his or her desired physical activity and sport.<sup>6</sup>

### An essential element—effective planning

Effective detailed planning is one of the most important aspects of rehabilitation. The plan should integrate

accurate anatomical, pathophysiological, biomechanical and sport-specific knowledge with physical training principles.

#### PRACTICE PEARL

When designing a rehabilitation program, the clinician should identify specifically how the injury affects or impairs the athlete's function—taking into account the sport and the player's role within it (e.g. their event, discipline or position).

For example, a professional athlete can devote more time to rehabilitation and to rest between exercise bouts than an amateur athlete with a demanding work schedule. This will influence the total volume of training that can be tolerated. Top athletes with day-to-day follow-up can usually progress more rapidly than recreational athletes who have less frequent encounters with their clinician. Hence, the clinician has to create a larger safety buffer when designing rehabilitation programs for non-professionals. Furthermore, physiological responses to rehabilitation stimuli vary between individuals, making the prediction of recuperation following an exercise more uncertain. Thus, the expected time to recovery differs depending on the injury, intrinsic personal and contextual factors, and the amount of stimuli that can be applied to facilitate tissue healing and recovery.

## GOAL SETTING AND TARGETED INTERVENTIONS

Early goal setting and an outline of the rehabilitation plan are important elements that should be addressed in collaboration with the athlete, coach, physiotherapist and other members of the clinical team.<sup>7</sup> In the first meeting between the medical team and the athlete, the key steps should include:

1. obtaining a thorough history, including the current injury, previous injuries and available resources
2. setting long-term goals
3. striving for an accurate diagnosis, which may be provisional and subject to supplementary investigations
4. identifying key impairments in body structure and function
5. raising potential physiological, psychological and logistical barriers
6. drafting a realistic progress plan that includes functional and measurable short-term goals.

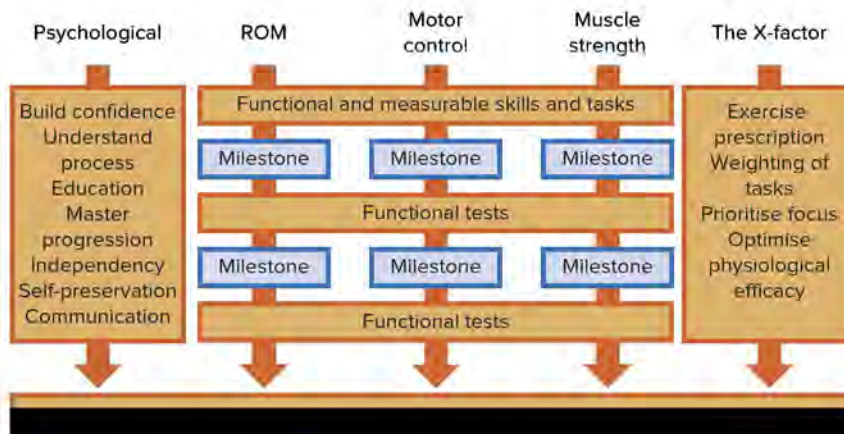

Identifying the athlete's ultimate goal is usually straightforward—most athletes want to return to participation in sport as quickly as possible. However, the expectations of a rapid return may sometimes be unrealistic, and misconceptions can undermine the collaboration and focus of the rehabilitation. Thus, giving the athlete an early outline of the expected progress with specific short-term goals accompanied by specific tasks will usually build a bond of confidence. Communicating the expected progress plan to coaches, team members, family and sometimes the media usually fosters a collaborative environment for focused rehabilitation.

Physical impairments and limitations are commonly subdivided into the areas of restricted range of motion (ROM), motor control and muscle strength. Different injuries will, in combination with previous injuries and fitness status, result in different impairments and limitations (Fig 18.2). The medical team should analyse the status of the injury and decide to what extent each of the impairments or limitations should be targeted during rehabilitation. The skill of prioritising exercise interventions throughout the rehabilitation has been designated as the 'X factor' in Figure 18.2. Prioritising rehabilitation interventions relies on the ability of the clinician and the broader team to effectively synthesise complex information (via skilled clinical assessment) and identify key limitations to performance as well as barriers to progression. While a large part of the 'X factor' will be based on sound clinical reasoning, it also involves the clinician's ability to relate to the athlete, to collaborate with other professions, to motivate and guide the athlete, and to educate key persons.

### PRACTICE PEARL

The clinician must clearly indicate that the rehabilitation plan is dynamic—the focus will change depending on the patient's response to the program.

Endurance and its specific subcomponents may also have to be integrated throughout the phases of rehabilitation. Examples are strength endurance for alpine skiers and speed endurance for footballers. The ability to

**Figure 18.2** A theoretical model of clinical focus throughout the sports injury rehabilitation process

continue to carry out a specific task or exercise for an extended period of time without a reduction in the quality or effort of the task is also an important component of the rehabilitation process. Fatigue has been identified as a risk factor for injury,<sup>8</sup> therefore, ensuring that the athlete is able to maintain good technique under fatigue is essential. Particular attention should be given to enhancing specific sub-qualities of endurance, such as skill execution under fatigue, as well as other strength and mobility parameters.

## PHASES OF REHABILITATION

A four-phase structure can guide the aims and content of the rehabilitation process (Fig. 18.3). Specific functional milestones and achievement goals are identified within each phase. Some goals will be primary in each phase; for example, achieving full knee extension and quadriceps activation after knee surgery in Phase 1. At the same time, preservation of gluteal muscle activation and ankle mobility will be important secondary areas of focus. Therapists with different backgrounds, knowledge and experience will choose different exercises and treatments to achieve rehabilitation aims. Although there is now consensus regarding the importance of individually tailored rehabilitation after injuries,<sup>9</sup> well-documented rehabilitation guidelines are scarce for most conditions in sports medicine. Also, treatment algorithms differ between cultures, countries and institutions.

Due to the multidimensional nature of sports rehabilitation, the clinician should be able to manage several parallel focus areas throughout the various phases of rehabilitation, each with different goals and milestones. The relative importance of each focus area will change throughout the rehabilitation process (Fig. 18.3). Progressing active rehabilitation requires continuous evaluation, which is necessary to guarantee a confident and timely return to training and competition.

## Phase 1: Acute

In line with the increased focus on active rehabilitation strategies, the traditional acronym PRICE (Protection, Rest, Ice, Compression and Elevation) for treatment of acute soft tissue injuries is increasingly replaced with POLICE (Protection, Optimal Loading, Ice, Compression and Elevation).<sup>10</sup> Optimal loading refers to the clinician evaluating the ability of the tissue to withstand and adapt to mechanical load.<sup>11</sup> The clinical challenge is not only to choose the most effective and safe exercise interventions, but also to apply the intervention in the appropriate dose. Immediate protection and relative rest after an acute injury still plays a role, but because of the detrimental effect of inactivity on biological tissues, leading clinicians look to have the athlete begin active movement (optimal loading) as soon as possible. For example, a player may begin hamstring activation exercises (loading) within 24 hours of a hamstring muscle strain depending on the severity of the injury and other factors.

Goal setting in the acute phase should be unidimensional and targeted toward impairments and limitations. For example, after knee ligament surgery the acute phase goals are for the athlete to regain voluntary quadriceps activation toward end-range extension (impairment) and to perform a straight-leg raise without extension lag (limitation). The combination of these two comprises the functional milestone of controlled active terminal knee extension, which allows the athlete to progress to walking without crutches for short distances.

The next goal could then be for the athlete to perform a step-up exercise with proper alignment and controlled loaded terminal extension (Fig. 18.4). When adequate step-up quality of movement is achieved, the use of crutches can be terminated for all distances. Blanchard and Glasgow have depicted the process for how to progress single exercises and this can be adapted to the rehabilitation process in general (Fig. 18.5).<sup>5</sup> The model describes how the clinician can build and manipulate the

	ROM	Motor control	Muscle strength	Exercise prescription
Phase 1	Regain active & passive range	Proprioception & motor output	Voluntary activation	Controlled
Phase 2	Cyclic, full-range loading	Joint stability	Hypertrophy	Extrinsic stimuli
Phase 3	Manual therapies if necessary	Speed & agility	Generate strength	Complex movements
Phase 4	Maintenance & recovery	Ingrain new patterns	Power & endurance	Sport-specific

**Figure 18.3** Model of rehabilitation through phases. Box outlines represent primary (green), secondary (orange) and tertiary (red) focus

**Figure 18.4** The ability to perform a high step-up with good control of terminal knee extension is a common functional goal during Phase 1 rehabilitation of acute knee injuries

exercises to gradually increase the demands on the athlete, while at the same time allow the healing tissue to adapt to the increase in mechanical load.

A variety of interventions are available to the clinician in Phase 1. Traditional low-load controlled exercises are at the core of interventions. However, adjunct modalities such as neuromuscular electrical stimulation (NMES) can help the athlete regain voluntary muscular control.<sup>12, 13</sup> Furthermore, manual therapies can be effective in the recovery of impairments during this phase (Chapter 17).

## Phase 2: Restore activities of daily living

The aim of the second phase of rehabilitation is to allow the athlete to return to daily activities and basic sport-specific technical movements. The clinician should gradually increase the complexity of movements from single joint controlled actions to more complex tasks including movements through several biomechanical planes. For example, the overhead athlete who has regained pain-free external rotation in the scapular plane with adequate scapular control in Phase 1 will typically progress to mimic the throwing motion at low velocity in Phase 2. While the throwing motion will be the primary focus of the rehabilitation program, the clinician must ensure that secondary functions such as contralateral hip stability and ankle range of motion are maintained.

Exercises can be progressed by increasing the number of repetitions, the velocity of the movement, or the frequency (rate) of the exercises. Further, adding external loads and increasing the complexity of movement will stimulate muscle strength and motor control. Thus, Phase 2 challenges the clinician to prioritise exercises successfully. Skilled clinicians are able to keep their eye on several parallel processes at the same time (the X-factor).

**Figure 18.5** Visual aid to demonstrate a complex rehabilitation progression with undulating tiers using lower limb injury as an example<sup>5</sup>. The horizontal axis represents time and the vertical axis represents difficulty. The clinician adds and subtracts elements of the rehabilitation to progressively challenge the athlete while keeping the overall workload appropriate

REPRODUCED FROM FIGURE 2 IN BLANCHARD S, GLASGOW P. A THEORETICAL MODEL TO DESCRIBE PROGRESSIONS AND REGRESSIONS FOR EXERCISE REHABILITATION. *PHYS THER SPORT*. 2014 AUG;15(3):131-5

Goal setting in the second phase will still focus on the remaining impairments, although the main goals are related to addressing functional limitations in activity and improving performance of semi-complex sport-specific movement patterns. Examples of Phase 2 functional milestones for an ACL-injured athlete can be jogging with good form, and the ability to perform single leg hops with full knee extension at take-off and high degrees of knee and hip flexion during landing.

The primary intervention throughout Phase 2 is to continue progressing the therapeutic exercise program. The program will mainly incorporate elements to improve motor control and muscle strength, with additional sessions of cardiovascular training. When determining the exact nature of cardiovascular training in rehabilitation, the clinician should ensure that the correct energy system is being trained and that adequate time is allowed for recovery and physiological adaptation. For athletes who are rehabilitating over longer periods of time (i.e. months after ACL reconstruction), the acute:chronic workload ratio should be considered (Chapter 12). The nature of training used should minimise stress on the injured tissues while simultaneously exercising muscle groups involved in the athlete's sport. Aerobic and anaerobic endurance can be effectively trained using pool-based conditioning or cardiovascular equipment such as a bicycle ergometer, cross-trainer, rowing ergometer and step machine.

#### PRACTICE PEARL

The nature, intensity, duration and work:rest ratio of individual training sessions should reflect sporting demands.

An example of a weekly schedule may consist of two muscle strength sessions, two motor control sessions, two cardiovascular sessions and one recovery day. The precise nature of the sessions and the order in which exercises are carried out will be dictated by the clinician's understanding of the sport to which the athlete must return, the effects of the specific impairments and an appreciation of how the prescribed exercise will influence restoration of function. The clinician must have a good understanding and ability to appropriately modify load and difficulty of the exercises, while still guarding the healing tissue from abrupt forces and overload. Efficient communication with specific cues that facilitate a move from an internal focus of attention to an external focus, in combination with careful explanation and involvement of the athlete can greatly increase the efficacy and adherence to interventions.<sup>14, 15</sup>

### Phase 3: Returning to sports activities

In the third phase of rehabilitation the clinician guides the athlete towards returning to participation in sports. More traditional strength and conditioning training can be incorporated in the weekly rehabilitation plan with increased focus on more complexity and velocity. Emphasis should be on a higher rate of force development and introduction of on-field sessions to bring in environmental adaptation. An athlete recovering from a knee injury can be brought to the field to perform sessions focused on higher speed running, cutting and turning tasks, and the inclusion of relevant equipment (ball, racquet, skis, etc.). Physical conditioning in the gym will be similar to pre-season training for the specific sport, although a majority of exercises should still be unilaterally focused to stimulate adaptation and reverse any remaining impairments.

Goal setting in Phase 3 will relate to all levels of function. Typically, muscle strength measurements (impairment) and single-leg hop tests (activity) are compared with the goal of 90% of the uninjured side.<sup>16, 17</sup> Participation goals can include completing specific parts of the team training sessions without symptoms during or after training. An important task for the clinician will be to monitor the overall load on the healing structures, which again calls for close collaboration and clear communication with coaches and strength and conditioning professionals.

Return-to-play decisions are perennially challenging and require a team approach that focuses on ensuring that function has been adequately restored. To facilitate safe return to sport, it is paramount that functional testing with valid and reliable outcome measures be performed. (See Chapter 16 for more on relevant outcome measures.) Multidimensional sets of tests that evaluate the different layers of function are best.<sup>18-21</sup> However, the scientific backing regarding content and cut-off limits for the test batteries are still lacking for most injuries. The return-to-play process is discussed in Chapter 19.

### Phase 4: Prevention of re-injury

All sports injuries with tissue disruption will render the athlete more susceptible to re-injury even though tissue structure and physical function may be restored after rehabilitation. In spite of the increased attention and knowledge on rehabilitation of sports injuries, the incidence of re-injury remains high in professional sports.<sup>22, 23</sup> The classical model on the aetiology of sports injuries published by Meeuwisse in 1994 (see Fig.12.1) points to the importance of recognising internal risk factors such as previous injuries in the prevention of sports injuries.<sup>24</sup>

**PRACTICE PEARL**

Every clinician involved in the rehabilitation of sports injuries must work diligently with the athlete, coach and conditioning professionals to continue targeted individualised prevention training after the athlete has returned to the competitive level.<sup>25</sup>

Interventions should be aimed at impairments and functional limitations known to exist as a result of injury such as altered muscle activation patterns and inadequate landing and cutting strategies.<sup>26-28</sup>

### WHEN REHABILITATION DOES NOT GO ACCORDING TO PLAN

Sports injury rehabilitation seems like a straightforward linear process when presented in this chapter (Fig. 18.6a). However, as every clinician has experienced, progression does not always go according to plan (Fig. 18.6b). Longstanding pain, recurrent effusion, persistent range of motion deficits and muscle inhibition are a few of the most common obstacles. What to do when progression fails?

A thorough look at the content and volume of the rehabilitation program is usually indicated. Are the interventions targeting the impairments they were intended to target? It is often prudent to follow the athlete through a full session to ensure proper technique and understanding

is present. Experienced clinicians will often state that 'less is more' and that splitting the original rehabilitation program into two parts is often a wise decision.

**PRACTICE PEARL**

It may be necessary to revisit the diagnosis and the functional assessment.

Symptoms tend to change over time—and not always in a predictable fashion. A step back to address the basic functional impairments is often necessary.

Sit down with the athlete and analyse the total load during the week. Is there enough time to recover between sessions? How much load is placed on the healing structures between training sessions? Are there any environmental challenges related to family, friends, facilities or motivation? Collaborate with the athlete to resolve underlying challenges. Ask open questions and probe their psychological status. A few days off rehabilitation may be a relief to many athletes.

Ask a colleague! A referral back to the physician or orthopaedic surgeon may be indicated. A second opinion from another clinician within the field can often open new doors. Additionally, a multidisciplinary meeting with all involved parties can adjust and streamline the expectations and responsibilities of each member of the rehabilitation team.

**Figure 18.6** It can be helpful to share a map of the rehabilitation journey with your patient (a) Most patients believe rehabilitation should be straightforward and speedy (b) Sports physiotherapist Adam Meakins has added his own take to the traditional 'winding road'. Patients can feel they are travelling backwards in time on occasions. The expert clinician anticipates this in his or her discussion while planning rehabilitation

# Return to play

with IAN SHRIER

*Perhaps the most common question for every active but injured patient is  
'When can I return to play?'*

Return-to-play (RTP) decisions can be difficult and complex.<sup>1</sup> The clinician is expected to provide an opinion based on a large number of factors including the history of the injury, physical examination, type of injury, rehabilitation, type of activity, psychological state, competitive level and ability to protect the injury. Further, these decisions do not occur in a vacuum. The athlete may receive advice from family, friends, coaches, other clinicians and, in the case of elite athletes, agents.

Because determining prognosis is difficult and frequently subjective, some disagreements regarding RTP will always occur.<sup>2</sup> Differing sociocultural and clinical perspectives of the medical doctor, coach, athlete and others lead to a high potential for conflict. Apart from being challenging and an unpleasant experience, such conflicts are believed to lead to a number of negative scenarios including:

1. miscommunication
2. loss of trust
3. potential litigation
4. declines in sport participation rates—some individuals never 'get back in the game' due to fear of re-injury (despite acceptable levels of risk)
5. serious medical complications—some athletes return to activity while still at unacceptable levels of risk for subsequent sport-related injury.<sup>3-6</sup>

Two important factors may minimise development of such conflict: a formal structure or process outlining how an actual RTP decision should be made and a formal process to guide the interactions between individuals who contribute in any way to the RTP process. It is important to note that in some cultures the clinician is

expected to determine the reasonable course of action for a seemingly independent third party—the athlete—who is otherwise capable of making autonomous decisions. In other cultures shared decision making may be promoted by the medical community in general, but the clinician is usually still considered legally responsible for any consequences of the decision. Regardless of the cultural context in which one is situated, having a transparent framework for arriving at RTP decisions should help minimise any conflict that might arise.

The purpose of this chapter is to provide such a framework. In 2010, we published a 3-Step framework<sup>7</sup> developed specifically for RTP decision making. The framework is consistent with clinicians' beliefs independent of country of practice or clinician specialty,<sup>8</sup> and represents a framework to help organise complex information; it should not be interpreted as proscriptive. After feedback from clinicians, this has now evolved into a revised framework called the Strategic Assessment of Risk and Risk Tolerance (StARRT).<sup>9</sup>

The StARRT framework is based on causal relationships and considers that differences in RTP decisions are partly due to differences in (1) risk assessment and (2) risk tolerance. Differences in risk assessment could be decreased through the application of research and knowledge dissemination leading to improved evidence-based practice. Differences in risk tolerance are based on societal and personal values, which are independent of research and evidence-based practice. This may be part of the reason why different participants presented with the same information come to different RTP decisions.<sup>10</sup> Finally, the framework's general approach means that it can be applied by whoever represents the decision-making

authority: a clinician, non-clinician or a multidisciplinary team.

## STRATEGIC ASSESSMENT OF RISK AND RISK TOLERANCE FRAMEWORK FOR RTP DECISION MAKING

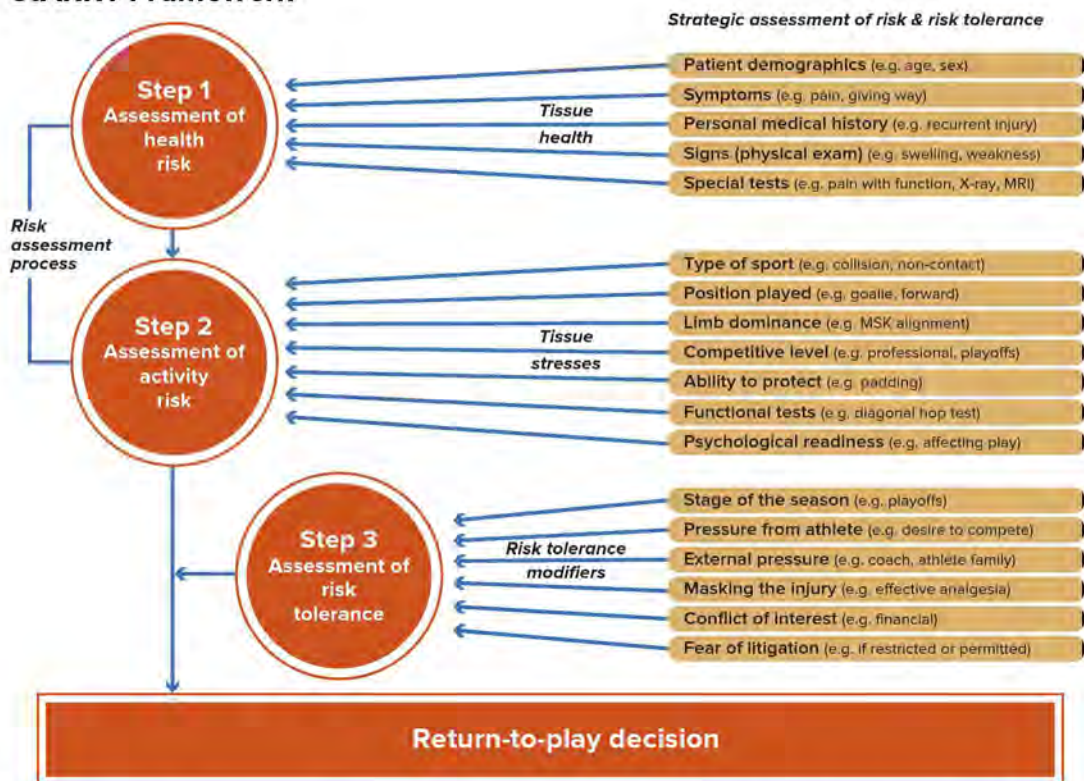

The StARRT framework for RTP decisions is illustrated in Figure 19.1. Rational decision making requires weighing the benefits and risks of different alternatives.<sup>11-13</sup> For RTP decisions, the clinician is generally concerned with managing risk of re-injury, but may at times be concerned with risk of any injury, death or illness.

The foundation of the framework is that an injury or re-injury will occur whenever the stress applied to a tissue is greater than the stress the tissue can absorb (tissue health).

### Step 1—Tissue health

The first step in the StARRT framework is to assess the stress the tissue can absorb before becoming damaged. This is a function of the health of the tissue. For the same level of activity, the risk of re-injury increases with increasing damage to the tissue that is generally evaluated through the presence of symptoms (e.g. pain), signs

### StARRT Framework

**Figure 19.1** The Strategic Assessment of Risk and Risk Tolerance (StARRT) framework for return-to-play (RTP) decisions. This framework illustrates that athletes should be allowed to return to play when the risk assessment (Steps 1 and 2) is below the acceptable risk tolerance threshold (Step 3) and not allowed to return to play if the risk assessment is above the threshold. The StARRT framework groups factors according to their causal relationships with the two components of risk assessment (tissue health, stresses applied to tissue) and risk tolerance, as opposed to the 3-Step framework that groups factors according to the sociological source (medical culture, sport culture, decision maker) of the information. In some cases, an apparently single factor can have more than one causal connection and would be repeated. For example, playoffs will increase the competitive level of play and therefore increase tissue stresses and increase risk. However, playoffs are also expected to affect an athlete's desire to compete (i.e. mood, risk of depression if not allowed to RTP) and could affect financial benefit as well. These causal effects would lead to increased risk tolerance. In this framework, each outcome is evaluated for RTP, and the overall decision is based on the most restricted activity across all outcomes (see text and Table 19.1)

(e.g. swelling) and diagnostic tests (e.g. muscle strength). As this information comes from health professionals, the factors were originally considered 'medical'.

### Step 2—Tissue stresses

The second step of the framework is to assess the stress that will be applied to the tissue. This is directly related to the planned activity, as opposed to the status of the original injury and is therefore considered sport-related. Using the frequency, intensity, time and type (FITT) training principle, one can modify activity through frequency (e.g. 3 days per week), intensity (e.g. running fast or climbing hills), timing (e.g. 20 minutes per session) and type. For the type of activity, one can think in general terms such as running or swimming.

However, for re-injury risk, the most salient detail is the required biomechanics that increase stress (i.e. the causes of injury), and the categories 'type of sport' and 'position played' are meant to capture this information. For example, the biomechanics of freestyle swimming are very different from those of breaststroke (analogous to different positions in other sports). Therefore, trying to assess the risk of re-injury in 'swimming' is likely not the best clinical approach. Rather, clinicians should focus on the activities that cause the underlying stresses on the musculoskeletal system to increase. If these can be modified to reduce stress to the injured area (e.g. switch from crawl to breaststroke for some types of shoulder injuries or from whip kick to flutter kick for some types of knee injuries), then the injury risk is decreased.

Psychological factors are listed in Step 2 because, as noted above, they affect risk of re-injury via the way the athlete plays the game and therefore the potential stresses applied to the body. Similarly, functional capacity such as endurance, range of motion and proprioception also describe factors that increase or decrease stresses applied to the injured area and are included here. For example, tight hamstrings mean that forward flexion must come more from the back, which increases lumbar and thoracic stress. Limitations in scapular rotation lead to a decrease in the subacromial space during abduction (increasing the risk of impingement syndrome) as more motion must come from the glenohumeral joint.

### Step 3—Risk tolerance modifiers

Step 3 is designed to account for the reasons why two clinicians (or two athletes) presented with the same risk assessment, may come to different RTP decisions. Because the risk is the same, the different RTP decisions reflect differences in risk tolerance. If the competition is the Olympics, a clinician's risk tolerance for the worsening of

a sprained ankle may be greater than if the athlete is a 14-year-old male playing high school basketball. A factor is included as a risk tolerance modifier if there is any context where changing the factor would change one's threshold of an acceptable risk (e.g. for the Olympian) even if it does not affect the decision under other contexts (e.g. high school basketball player).

### Return-to-play decision making—beyond risk for injury

The StARRT framework is about arriving at a decision based on whether the assessment of risk exceeds one's risk tolerance. Most clinicians likely think that the framework is about risk for re-injury. Although we are certainly concerned about the risk of re-injury, our focus should be on the overall health or wellbeing of the athlete.<sup>14</sup> How do we define wellbeing or health? Should this be restricted to pathology of muscle, tendon or bone (as for re-injury)? Should we also consider mental health or socioeconomic health?

In a series of studies, we found that sports and exercise medicine clinicians from various fields and regions considered many factors unrelated to risk as important factors in their decisions.<sup>8</sup> These included several psychological-related factors (desire to compete, psychological impact of not returning to play, loss of competitive standing) as well as potential financial loss, timing of the season, competitive level and fear of litigation. Most interesting was that the pattern of responses in one study that included both clinicians and non-clinicians found very little difference between these two groups.<sup>14</sup>

In summary, the StARRT framework organises the information available into risk assessment (Steps 1 and 2) for a particular outcome and information related to other factors that affect one's risk tolerance for that outcome (Step 3) because they may affect other aspects of the athlete's overall wellbeing. In the next section, we discuss how the framework can be applied in some challenging situations.

### APPLYING THE StARRT FRAMEWORK

The application of the framework to most clinical situations is straightforward. Consider a case that we used in one of our validation studies where a collegiate American football linebacker (lots of contact at high speed) injured his acromioclavicular joint (Fig. 19.2).<sup>10</sup>

As the severity of signs and symptoms increases (from Example 1 through Example 6 in Fig. 19.2), most would agree that the stress the tissue could absorb prior to re-injury would decrease. In our study, as the health of the tissue decreased in the vignettes, clinicians became

**Figure 19.2** The proportion of respondents who would allow activity without restriction is plotted for the different acromioclavicular injury severity levels (increasing severity from Example 1 to 6) described in clinical vignettes.<sup>10</sup> The solid line presents the results for the base case when the athlete is an American football linebacker. The dashed line presents the results when we decreased the likelihood of excessive stress by considering the player to be a field goal kicker instead of a linebacker (tissue stresses). The dotted line presents the results when the linebacker (base case) was being evaluated for a multi-million dollar bonus (risk tolerance modifiers)<sup>9</sup> REPRODUCED WITH PERMISSION FROM BRITISH JOURNAL OF SPORTS MEDICINE<sup>9</sup>

less likely to allow the athlete to full RTP. We then changed the scenario so that the athlete was a field goal kicker (very low risk of contact) instead of a linebacker. By decreasing the risk of applying excessive stress to the tissue (i.e. contact), the risk of re-injury decreases and this explains why more clinicians allowed full RTP than when the athlete had been a linebacker. Finally, returning to the context of a linebacker, we changed the vignette and said the athlete was being evaluated for a million dollar signing bonus. Given the potential benefit to his economic condition and overall wellbeing, the risk tolerance of many clinicians changed and these clinicians now allowed the athlete to RTP even though the risk of re-injury remained unchanged.

The StARRT framework may appear to discuss RTP decisions as if they are all or none. In clinical practice, RTP may refer to 'full return without restrictions', 'partial return', 'allowed to practice' and so forth. In fact, StARRT is a general framework for any decision-making process and will work equally well when one is trying to decide about return to training, return to practice or any level of activity.

## Assessing across outcomes and probabilities

Steps 1 and 2 of StARRT evaluate only a single risk at a time. Yet, RTP decisions usually need to account for many outcomes (e.g. both in the short and long term) simultaneously. In the short term, clinicians and athletes might focus on risk of re-injury or decreased performance (leading to decreased competitive standing). With respect to long-term outcomes, one might focus on risk of osteoarthritis from joint injuries or long-term cognitive deficits following concussions. Each of these represents a different outcome that could be assessed through StARRT. An example of the process for a hypothetical case is shown in Table 19.1. For simplicity, Table 19.1 shows only the overall risk tolerance and omits the particular factors that affect it.

In Table 19.1, Clinician A is the decision maker and evaluates the risk for each outcome. In this hypothetical example, Clinician A considered the risks acceptable and allowed RTP for 6/7 outcomes (column 3), but unacceptable for short-term disability. The *overall RTP decision* must represent the most restricted decision in the table and the athlete is not allowed to RTP. The process is in fact, the same as that which occurs when there is more than one injury (e.g. assessing overall restrictions for an athlete with a knee injury and an ankle injury).

An ankle injury might result in an athlete only partially participating, but a concurrent knee injury might cause the clinician to restrict the athlete's activity to only weight training. The decision-making process for considering five outcomes on one injury in an athlete is the same as that for two outcomes on two injuries in an athlete: evaluate

**Table 19.1** Applying the StARRT framework for RTP across different short-term and long-term outcomes. The final decision is the one that imposes the most limiting restrictions of all the outcomes (no RTP in this example)<sup>9</sup>

Outcome	Risk assessment	Risk tolerance	Decision
<i>Short term</i>			
Re-injury	<10%	Acceptable	RTP
Pain	50–70%	Acceptable	RTP
Work disability	20–30%	Not acceptable	No RTP
Performance	20–40%	Acceptable	RTP
<i>Long term</i>			
Osteoarthritis	2%	Acceptable	RTP
Disability	2%	Acceptable	RTP
Cost prohibitive	1%	Acceptable	RTP

across all outcomes and the highest level of restriction becomes the overall restriction.

Risk tolerance modifiers reflect contexts where risk tolerance is affected. These modifiers themselves have particular values (e.g. yes/no or a numerical value if a continuous scale) but are not necessarily risks themselves. For example, timing of the season is pre-season, regular season, finals/playoffs, off-season. In the finals/playoffs, athletes are often playing at higher intensities and more aggressively, leading to increased risk of injury. This is captured in Step 2 under 'competitive level'. In addition, finals/playoffs also have effects on financial compensation, ego and prestige, which are likely to affect risk tolerance in many contexts. Therefore, there may be contexts where timing of the season has minimal effect on risk assessment (Table 19.1, column 2), but large effects on risk tolerance (Table 19.1, column 3) or vice versa.

Baseline risk tolerance simply refers to one's risk tolerance under some arbitrary set of values for the risk tolerance modifying factors. In the case of a knee injury, we might consider a 15% increased risk of re-injury (compared to the uninjured knee) as acceptable. If we believe an athlete's mental health state might be affected by not playing, we might raise the acceptable risk for a knee injury from 15% to 25%. Risk tolerance modifiers are defined by this interaction. Contrast this with the risk of osteoarthritis. If the risk of osteoarthritis is high (or low), we might prevent (or allow) RTP because of the risk of knee osteoarthritis, but it does not change our risk tolerance for the risk of knee re-injury *per se*.

### Additional perspectives

The StARRT framework is a simplified version of a more complex process that can lead to decision-tree analysis. When evaluating any action, there must be a comparison with a different action, which may or may not be 'no action'. Table 19.2 illustrates the process for comparing action A (Allow RTP) with action B (Do not allow RTP).

In making a decision, we are hoping for a particular outcome.

Let us consider re-injury as our outcome of interest. If we allow RTP, the athlete may get injured or not get injured. The mental health of the athlete will likely be healthy because they are doing what they want to do. If we do not allow RTP, they cannot get injured. In this context, the mental health of the athlete may be unhealthy (if we are correct that preventing RTP is damaging to the psyche) or may be healthy (if we are not correct that preventing RTP is damaging to the psyche).

In a full decision-tree analysis, one attaches probabilities to the results defined in each row of Table 19.2 (i.e. combination of physical and mental health). Preferably, the probabilities would be based on actual risk scores developed from surveillance or intervention studies (similar to Framingham risk score for cardiovascular disease<sup>15</sup>). One could also include the severity of the outcome in terms of disability or decreased capacity. If we assume equal probabilities for each row (25%), one still has to make a value judgment whether being injured with a healthy mental state is better or worse than being uninjured with an unhealthy mental state.

This is a value judgment and there are no algorithms or statistical analyses that can provide the best answer for an individual athlete. Statistically, one multiplies the probability by the value, but this calculation is based on several assumptions that may or may not be true. Regardless, the optimal choice will obviously depend on the disability and long-term consequences of the injury, the disability and long-term consequences associated with the poor mental health and the personal values of whoever is the decision maker.

In reality, the probabilities will not be equal. But the question remains the same and only the proportions change. Is a 20% risk of injury with 10% risk of poor mental health a better choice than 0% chance of being injured with an 80% risk of poor mental health?

**Table 19.2 Hypothetical example for an RTP decision-tree analysis approach to RTP. Each action leads to a particular physical state and cognitive state. The probability for the combined physical and cognitive state is estimated, and the 'value' associated with the combined state is given a number between 0 (no value) and 100 (maximum value). The value associated with the state is multiplied by its probability of occurring to provide a total score. The total scores for each row associated with a particular action are summed and the decision is the action that provides the highest decision value**

Action	Physical state	Mental state	Probability	Value	Total score (prob*value)	Decision value
Allow RTP	Not injured	Healthy	25%	100	25	37.5
Allow RTP	Injured	Healthy	25%	50	12.5	
No RTP	Not injured	Healthy	25%	60	15	
No RTP	Not Injured	Unhealthy	25%	30	7.5	

## WHO SHOULD BE THE DECISION MAKER?

Within society at large, most people have the authority to make decisions about their own risks for health unless otherwise restricted by law (e.g. helmets while driving motorcycles in many countries). In the context of returning to play or work after an injury, the decision-making power is often shifted from the individual athlete to the healthcare clinician. For many people, this loss of autonomy can be challenging.

In this section, we discuss different approaches to deciding who should have the authority to make the decision and when and why. A fairly complete list of possible options are: the athlete (or designated representative such as parent or power of attorney), any one of the clinicians (e.g. medical doctor, physiotherapist, athletic trainer, chiropractor, nurse, nutritionist), coach, management (e.g. sport association, team employer), athlete's family, agent or some multidisciplinary team made up of a combination of the above stakeholders. Some of these may be clearly inappropriate in some contexts, but the list is provided to highlight the different factors that need to be considered.

Although power relationships within society are commonly studied in medical sociology,<sup>16</sup> this has not occurred within the context of RTP decisions. The interactions between the athlete, family, friends, agents, coaches, clinicians, and institutional or corporate managers are often complex and confusing. Although clinicians and athletes may 'negotiate' approaches to treatment,<sup>17</sup> the clinician usually has ultimate decision-making power. When athletes avoid interaction with clinicians,<sup>17</sup> they retain power over the decision-making process by default except where the clinician's approval is expressly required.

The first two steps of the StARRT framework require the capacity to evaluate risk. To our knowledge, there is no evidence examining if clinicians are actually better than non-clinicians at evaluating risk of sport injury or whether certain types of clinicians (e.g. medical doctors) are better at evaluating risk compared to other types of clinicians (e.g. physiotherapists).

In one study,<sup>14</sup> we asked members of different Canadian sports medicine professional groups as well as athletes, coaches and sport associations to rank which professional group members might be best to answer such questions. First, most participants felt that medical doctors were the most capable of assessing the health of the tissue. However, when asked who was best to assess the risk of re-injury, short-term and long-term consequences, the members of each of the main clinical professions (medical doctors, physiotherapists, athletic therapists, chiropractors) generally felt that their own professional members had the greatest capacity to evaluate these risks

(e.g. physiotherapists believed physiotherapists were best, chiropractors believed chiropractors were best).

On the other hand, official sport association members generally believed medical doctors were best, athletes believed physiotherapists were often equal to or better than medical doctors, and coaches believed physiotherapists and medical doctors were generally equal but medical doctors were better at assessing long-term consequences. When the same respondents were asked which group had the greatest capacity to assess the importance of risk tolerance modifiers, the athletes and coaches were generally considered the best.

Although these results do not directly speak to who should have the authority to make the RTP decision, they do suggest that an informed decision requires information from several sources. Most importantly, the decision maker needs to act in the best interests of the athlete, which means they have to understand the best interests of the athlete. A coach might have the athlete's best interests at heart, but may not have the experience of watching people suffer with severe osteoarthritis and cannot evaluate the magnitude of disability. A medical doctor may have only limited contact with an athlete and not understand their wishes, dreams or psychological stability.

In addition, as we have seen, there may be differences in opinion about how to weigh all the benefits and risks, but factors that benefit or harm others (i.e. not the athlete) should generally not be included in the decision-making process. Such factors can occur when there are power imbalances. For example, if a clinician is worried about losing his or her status as team doctor or physiotherapist as a result of restricting a player from playing, there may be an unconscious or conscious bias to allow the athlete to RTP even though the risk assessment suggests a risk higher than the decision maker's risk tolerance level in the absence of this fear. Similarly, a coach's performance is based on winning, which might (inappropriately) affect the risk tolerance level even though it is unrelated to the athlete's wellbeing. Table 19.3 summarises some major strengths and weaknesses of each of the stakeholders. The rest of this section discusses some particular points in more detail.

## Clinicians

In the workers' compensation injury context, a medical doctor's opinion is generally required to return to work following an injury. This is to protect the worker from unreasonable pressure by the employer. Because the medical doctor is independent, the assumption is that the medical doctor's opinion will be free of bias. This is also the current framework model for most of sports medicine.

However, the external pressures in sport are different from the traditional work environment. In sport, the medical

**Table 19.3 Strengths and weaknesses when the decision maker is a particular stakeholder**

Stakeholder	Strengths	Weaknesses
<i>Clinicians</i>		
Medical doctor	Knowledge about injury risk and consequences of injury. More often not an employee of management so lower probability of coercion	Less personal contact with individual athletes and may not understand them as well
Team therapist*	Knowledge about injury risk and consequences of injury. Generally know athletes better than medical doctors	Usually an employee of management and may have less perceived power than medical doctor. This might mean more likely subject to coercion
Other (e.g. nutritionist, psychologist)	Similar to medical doctors and usually knowledgeable about injury/illness risk and consequences of injury/illness within their field of expertise	Usually a paid consultant to management. If perceived power is less than that of a medical doctor, then more subject to coercion
<i>Non-clinicians</i>		
Athlete	Knowledge of the athlete's global needs is near complete (but not complete). By definition, provides the best source for information about athlete's needs and values	Only has personal experience about injuries incurred so knowledge base is limited. Difficulty assessing risk. During heightened emotion of competition, may not be able to weigh the risks and benefits properly, even if given information. For injuries affecting cognition (e.g. concussion), informed consent is not possible
Coach	Often aware of athletes' strengths, desires and values. On occasion, will have a more complete view of athlete's benefits such as sport career potential	Limited experience to evaluate risk. During heightened emotion of competition, may be difficult to evaluate risks properly. Potential conflict if athlete may be important to win the game
Family / friends	Often strong knowledge of athlete's global needs, desires and values	Least experience to evaluate risk. On occasion, could be motivated by own personal gains if athlete RTP
Management (sport association / team)	Often aware of career potential and the benefits (or lack thereof) that can occur with RTP	Objective to win may increase risk tolerance even though athlete would not benefit

\* The term 'team therapist' is used to refer to a professional who is not a medical doctor and has clinical training to evaluate and treat sport injuries and illnesses. In some cases, the term used to represent a recognised clinical profession in one country represents a completely different (and unrecognised) profession in another country. Team therapists include physiotherapists, athletic therapists, sports therapists, sports rehabilitators, athletic trainers, chiropractors and massage therapists

doctor is usually hired by the team and experiences dual allegiances. Although professional athletes may have access to non-team medical doctors when major conflicts arise, the team medical doctor usually retains the final decision-making power unless legal proceedings ensue. Therefore, unlike the workers' compensation context, medical doctors may indeed be subject to coercion. The same principle is true for all clinicians working for a team. Although financial remuneration will differ with each individual profession, team and region, one should not underestimate the power of social status even when clinical staff are unpaid.

When several health professionals are involved in caring for an athlete, the lines of communication and

authority must be clearly defined.<sup>1</sup> Otherwise, what is already a complex situation for RTP is likely to become even more problematic. According to one consensus document, the essential elements for RTP decisions are the safety of the injured athlete and other athletes, as well as compliance with any rules or regulations.<sup>1</sup> Although some have mentioned that social and economic factors may create pressure for the clinician, the role such factors play in RTP has not been explicitly studied.<sup>18</sup> Because of the absence of clear recommendations, individual treating clinicians have been described as using their own value and belief systems which often include issues other than safety.<sup>17</sup>

## Athletes

Making RTP decisions requires informed consent. The short-term and long-term consequences of any decision must be evaluated. Therefore, when an athlete's mental status is impaired, he or she would not normally be able to process the information. Although this is obviously the case in certain injuries like concussion, one could also argue that it is the norm in any game or competition context. Simply put, the lack of time available during a competition, accompanied by the emotions that occur during the event, would be expected to affect the ability of almost anyone to process the complex interactions of factors and possible consequences of RTP. However, outside the context of a competition or game, the athlete would normally have the time available to become informed and to evaluate the different consequences with respect to all aspects of health.

What motivates an athlete to want to RTP as soon as possible? In general, the internal factors include (1) that injury may represent a form of body-betrayal and a source of self-resentment,<sup>19</sup> and (2) psychological needs such as the desire to compete or 'love of the game'.<sup>20</sup> In addition, the external factors<sup>21</sup> include sociocultural influences, as well as greater status among peers and fans.<sup>2,19</sup> Not playing when injured can lead to identity crises, feelings of guilt and shame, or experiences of alienation from the team.<sup>20-22</sup> All of these factors can lead to low self-esteem and depression.<sup>2</sup>

In some countries, there is a push towards medical care based on shared decision making for medical conditions.<sup>23</sup> The general concept is that clinicians are sources of information, and help patients through the maze of complex issues and values to achieve greater insight, and therefore participate in the decision-making process. This is in contrast to the traditional model where medical doctors are the authority and patients simply comply. Although some athletes would like to be more involved in RTP decisions themselves,<sup>20</sup> others indicate they have learned to trust medical doctors and trainers to make decisions for them,<sup>22</sup> and believe it is important for medical personnel to prevent them from returning to sport prematurely.<sup>21</sup> Conversely, some athletes have reported being pressured into returning to sport too early by the medical doctor, trainer or coach.<sup>21</sup>

## The coach

The primary role of the coach is to maximise athletic performance. Some coaches believe athletes can be caught in a 'risk-pain-injury paradox' and that one of the coach's functions is to push athletes to their limits without taking excessive risks.<sup>24</sup> This may include competing while injured. Further, some coaches have suggested that medical personnel do not appreciate a need for an individualised approach or that delaying RTP can harm

the athlete psychologically. Coaches also see their role as managing unrealistic athlete expectations about progress following an injury and return to sport.<sup>21</sup>

## Family, friends, agents

Family, friends, agents, and institutional or corporate managers all have interests in RTP decisions and their interactions are often complex and confusing. Although it is often believed these persons will place 'non-health issues' above 'health issues', it is apparent that when 'health' is defined very narrowly, it may not represent the best interests of the athlete.

## Management

It is clear that management's objective is to win and there is a strong possibility of conflict of interest. That said, management may have important information and perspectives to offer with respect to career potential.

## A multidisciplinary approach

If we assume that the RTP decision should be based on the best interests of the athlete, then each of the stakeholders represents a source of information about a different aspect of the athlete. With different personal and societal values, there is clearly not going to be one 'correct' answer for the vast majority of injuries in the vast majority of athletes. In this framework, the key component is to ensure the decision is being based on some combination of the athletes' needs, desires and interests, and that there is no coercion or misrepresentation of information. Could a multidisciplinary model achieve this?

All stakeholders have a potential conflict of interest. Whether this manifests as a real conflict of interest depends on the individuals involved. Although a team approach does not eliminate this risk, its strength is that each team member can help ensure that others' (and their own) potential conflicts of interest are made transparent and documented. This may temper the enthusiasm of some to inappropriately argue in favour of a decision that is mostly for their own self-benefit, as opposed to the wellbeing of the athlete.

There remain significant challenges with a team approach. First, when decisions have to be made very quickly (e.g. during competition), a team approach is not always feasible. Second, a team approach does not eliminate contradicting values, but only brings them together in a transparent fashion. Decisions about risk assessment and risk tolerance can elicit strong emotions and there is a risk that systematising such decisions within a team approach may create interpersonal conflicts that would otherwise be avoided when there is one clear decision maker. Third, when there are conflicting opinions, a mechanism must be available to resolve the issue and come to a decision:

either the athlete returns to activity or does not return to activity.

Should there be a democratic vote with each member having one vote, or should some members' votes have greater weight than others to account for their different capacities and potential conflict of interests? Such a method seems difficult to operationalise, but would have the advantage of providing a significant voice to aspects of athletes' wellbeing that may otherwise go ignored. Exploring solutions to these challenges could be helpful in transforming the current model into one that maximises the chances for athletes' wellbeing to be the focus of the decision.

## SUMMARY

In this chapter, we describe the StARRT framework for RTP decision making. The first two steps focus on risk assessment and the third step focuses on factors that alter the decision maker's risk tolerance. If the risk of the outcome is less than the risk tolerance after all factors are

considered, the decision should be to RTP. Otherwise, the decision should be not to RTP.

The current decision-making process is embedded within a social context reflected principally by the values, beliefs and attitudes of a single decision maker. The steps in the process are not always transparent and can lead to confusion and unnecessary conflict. Although the medical doctor is often the ultimate decision maker, many organised sports do not have team doctors and other clinicians make these decisions. Theoretically, each of the stakeholders has information that might be helpful in understanding the best interests of the athlete, and each of the stakeholders is in a potential conflict of interest where their own interests may benefit from one decision or the other.

Finding a solution is likely to be difficult. To borrow a thought from Winston Churchill, at the current time, our current process seems to be the worst form of decision making, 'except for all those other forms that have been tried from time to time'.<sup>25</sup> But that doesn't mean we should stop trying yet.

PART B

# Regional problems

# Sports concussion

with PAUL McCrORY, MICHAEL MAKDISSI, GAVIN DAVIS and MICHAEL TURNER

*I've been knocked out a few times in there, but I have no idea  
how many concussions I've ever had.*

Hulk Hogan

Although head injuries are common in all contact sports, the vast majority are minor. Sports in which minor head injuries are commonly observed include equestrian sports, various codes of football, boxing, gymnastics and martial arts. The incidence ranges from 0.25–9 per 1000 player hours of exposure in professional team sports. Amateur point-to-point (cross-country) jockeys have the highest concussion rate of any sport (95 concussions per 1000 player hours of exposure), followed by professional jumps and flat jockeys. With increasing media awareness, more concussions are being reported; however, direct epidemiological comparisons between sports are limited by methodological issues.

Head injuries of all levels are a medical emergency because they can prove fatal if misdiagnosed or incorrectly managed. The clinician's role in the management of acute head injuries is to (i) recognise the problem, (ii) ensure immediate resuscitation (if required) and (iii) transfer the injured athlete to the appropriate facility.

In this chapter we cover the following topics:

- definition
- prevention of concussion
- clinically relevant pathophysiology
- management of the concussed athlete
- complications of concussion
- return to play issues.

The chapter helps the reader to learn to diagnose and manage concussions in sport using the Sport Concussion Assessment Tool 3 (SCAT3<sup>TM</sup>)<sup>1</sup> (Fig. 20.2), the Pocket Concussion Recognition Tool<sup>TM</sup> (Pocket CRT)<sup>2</sup> (Fig. 20.3) and Child SCAT3<sup>TM</sup> (Fig. 20.6).

We emphasise that the SCAT3 tools and the Pocket CRT are critical aspects of concussion management, as they are the result of more than 10 years of global collaboration and development by experts, at the 4th International Consensus Conference on Concussion in Sport held in Zurich in November 2012 (Fig. 20.1). These tools are designed to standardise the medical assessment and create a framework for the diagnosis of an acute concussion.

### PRACTICE PEARL

The SCAT3, (Fig. 20.2) Child SCAT3 (Fig. 20.6) and Pocket CRT (Fig. 20.3) are derived from international conferences on concussion in sport and have been used internationally to assist clinicians and athletes reach 'quality decisions' about return to play (RTP) following concussion.

### DEFINITION

'Concussion' is the term commonly used to describe a subtype of head injury. It is worth noting that the terms concussion and 'mild traumatic brain injury' (MTBI) refer to entirely different injury constructs and the terms cannot be used interchangeably. While concussion is a subset of mild traumatic brain injury, the converse is not true. A term often used in Europe is *commotio cerebri*, which has the same meaning as *concussion* in this setting.

Some publications on concussion refer to the Glasgow Coma Scale (GCS) as a means of classifying traumatic brain

**Figure 20.1** The Concussion in Sport Group met in Berlin in October 2016. Their updated consensus statement and systematic reviews will be available in peer-reviewed journals including the *British Journal of Sports Medicine* (BJSM) by May 2017

COVER REPRODUCED WITH PERMISSION FROM BMJ GROUP AND CONCUSSION IN SPORT GROUP

injury (TBI). This is a validated and widely used measure of conscious state used in the assessment of TBI. Its primary role is in the monitoring of serial change in neurological status post-injury, which is critical in determining the need for further intervention. It also has a secondary role in determining the prognosis of TBI by subdividing the spectrum of injury into mild, moderate and severe TBI based on an assessment at 6 hours post injury. The scale, however, does not encompass sport concussion due to the mild nature of the symptoms involved and the fact that many concussion symptoms affecting the conscious state are well and truly resolved by 6 hours.

The 4th International Consensus Conference on Concussion in Sport re-affirmed the clinical definition of sports concussion reached previously by experts at earlier meetings (see box below).<sup>3-6</sup>

### PREVENTION OF CONCUSSION

There is no good clinical evidence that currently available protective equipment will prevent concussion, although mouth guards have a clear role in preventing dental and oro-facial injury.<sup>7-10</sup> Biomechanical studies have shown a small reduction in impact forces to the brain with the use of commercially available helmets, but these findings have not been translated to show a reduction in concussion incidence in published RCTs. For skiing and snowboarding there are a number of studies to suggest that helmets provide protection against head and facial injury and hence should be recommended for participants in alpine sports. In specific sports such as cycling, motor and equestrian sports, protective helmets may prevent other forms of head injury (e.g. skull fracture) that are related to falling on hard road surfaces and these may be an important injury prevention issue for those sports.<sup>7</sup>

### Definition of concussion

Concussion is defined as a complex pathophysiological process affecting the brain, induced by traumatic biomechanical forces. Several common features that incorporate clinical, pathologic and biomechanical injury constructs that may be utilised in defining the nature of a concussive head injury include:

1. Concussion may be caused either by a direct blow to the head, face, neck, or elsewhere on the body with an 'impulsive' force transmitted to the head.
2. Concussion typically results in the rapid onset of short-lived impairment of neurologic function that resolves spontaneously. However, in some cases symptoms and signs may evolve over a number of minutes to hours.
3. Concussion may result in neuropathological changes, but the acute clinical symptoms largely reflect a functional disturbance rather than a structural injury and, as such, no abnormality is seen on standard structural neuroimaging studies.
4. Concussion results in a graded set of clinical symptoms that may or may not involve loss of consciousness. Resolution of the clinical and cognitive symptoms typically follows a sequential course. However, it is important to note that in some cases symptoms may be prolonged.

It is expected that future evolution of the definition of concussion will encompass clinical features, imaging changes, biomarkers, proteomics, epigenetic changes and genotype in a more comprehensive matrix of post-injury changes.

The major concern with the recommendation for helmet use in sport is the phenomenon known as 'risk compensation', whereby helmeted athletes change their playing behaviour in the misguided belief that the protective equipment will stop all injury. This is where the use of protective equipment results in behavioural change such as the adoption of more dangerous playing techniques, which can result in a paradoxical increase in injury rates. This may be a particular concern in child and adolescent athletes where head injury rates are often higher than in adult athletes.<sup>11</sup>

Consideration of rule changes to reduce the head injury incidence or severity may be appropriate where a definite mechanism is implicated in a particular sport. An example of this is in soccer where research studies demonstrated that upper limb to head contact in heading contests accounted for approximately 50% of concussions.<sup>12</sup> Rule changes have recently been introduced in certain sports (e.g. rugby) to allow an effective off-field medical assessment to occur without compromising the athlete's welfare, affecting the flow of the game or unduly penalising the player's team. It is important to note that rule enforcement is a critical aspect of modifying injury risk in these settings and referees play an important role in this regard.

The competitive/aggressive nature of sport, which makes it fun to play and watch, should not be discouraged. However, sporting organisations should be encouraged to address violent conduct that may increase concussion risk. Fair play and respect should be supported as key elements of sport.<sup>13</sup>

## THE INITIAL IMPACT: APPLIED PATHOPHYSIOLOGY

In a concussion, the athlete has sustained a significant impact to the brain. Although the pathophysiology of concussion remains poorly understood, the current consensus is that it reflects a disturbance of brain function rather than a structural injury. The impact sets in train a number of physiological mechanisms including a neurochemical metabolic cascade, lipid peroxidation, tau phosphorylation and amyloid folding, in addition to membrane gene-expression changes. Unlike more severe brain injury, these changes are not related to structural or neuropathological damage.

The concussed athlete, although conscious and without obvious focal neurological signs, may have impaired higher cortical function, for example, impaired short-term memory and speed of information processes. These subtle cognitive changes may only be detected by neuropsychological testing (discussed later in this chapter). While there are no gross structural changes on traditional imaging, newer imaging techniques (such as functional MRI or

connectomics) demonstrate transient alterations in brain function following concussion. The clinical significance of these results remains unclear. Subtle functional deficits are also suggested by recent work on eye movement abnormalities in the setting of TBI. These have been used as markers in other neurological diseases (e.g. Huntington's disease) and can be measured relatively easily.

Following a blow to the head, the athlete's conscious state may be altered. This may vary from simply being stunned to a significant loss of consciousness. Memory is typically affected in a concussive episode. A period of retrograde amnesia, that is, loss of memory of events prior to the incident, or anterograde amnesia, that is, loss of memory of events after the incident, may follow minor head injury.

The ability to think clearly, concentrate on tasks and process information may also be affected. Concussive symptoms such as headache, dizziness, blurred vision and nausea, as well as reduced reaction times, may place the athlete at risk of injury if they return to sport before symptoms have resolved.

Frequently, in episodes of mild concussion ('bell ringers'), the athlete will be dazed or stunned for a period of seconds only and continue playing. The other players and coaches may be unaware that a concussive episode has occurred. Any visual clues or signs and symptoms, as highlighted on the Pocket CRT, can be indicative of concussive injury. As such, it is recommended that alert medical and training staff should closely observe the actions of a player who has received a knock to the head for signs or symptoms of concussion.

It is a key aspect of concussion management that athletes are educated regarding the significance of concussion injuries and the importance of reporting symptoms to medical staff. While athletes may try to minimise problems to avoid removal from play, they may increase their risk of short and long-term problems related to the concussion.

## MANAGEMENT OF THE CONCUSSED ATHLETE

Patient management is discussed in the on-field setting and with respect to return to play.

### On-field management

Every athlete who sustains a head injury is at risk of having a structural brain or neck injury (e.g. brain contusion or cervical spine fracture). One of the critical roles of the initial medical assessment is to examine the player neurologically for such injuries. Having said that, it is not possible on the sidelines to absolutely exclude structural brain injury especially when a player may have ongoing cognitive impairment that limits examination or

where structural injury (e.g. subdural haematomas) may take time to develop post injury.

Clinical features that may raise concerns of structural injury include:

- the mechanism of injury, particularly if there is a high velocity of impact or collision with an unyielding body part (e.g. head to knee impact) or where the injury involves a vertical fall (e.g. fall from a horse, spear tackle in rugby)
- immediate and/or prolonged loss of consciousness
- evidence of a skull fracture and/or bleeding or cerebrospinal fluid (CSF) leak from ears/nose
- examination finding of a focal neurological deficit
- seizure
- progression of any clinical features over time.

Any deterioration in clinical state, in particular worsening headache, nausea or vomiting, or deterioration in conscious state, should raise suspicion of a structural head injury and warrant urgent investigation. Similarly, structural head injury should be kept in mind in any case where symptoms persist beyond 10 days.

A player with a suspected structural head injury requires immediate transport to a hospital with a neurosurgical unit and urgent computerised tomography (CT) brain scan to exclude intracranial pathology (e.g. haemorrhage, swelling) and to exclude/manage any associated cervical spine injury.

It is essential that all team physicians who have an on-field injury management role in their sport have formal training and certification in both first aid and trauma management. Depending upon the country concerned, there may be regional differences in certification and accreditation courses; some of the best known include Advanced Trauma Life Support (ATLS); Emergency Management of Severe Trauma (EMST); Pre-Hospital Emergency Care Course (PHECC); Pre-Hospital Trauma Life Support (PHTLS) and the British Association of Immediate Care Course (BASICS). This list is not exhaustive; all these courses deliver the skill-set required to appropriately and safely manage acute injuries. A medical degree alone is insufficient training in this regard.

The initial priorities when confronted by an acutely injured athlete are the basic principles of first aid. The simple mnemonic DRABC may be a useful aide-memoire.

- |          |               |  |
|----------|---------------|--|
| <b>D</b> | <b>Danger</b> | Ensure that there are no immediate environmental dangers that may potentially injure the patient or treatment team. This may involve stopping play in a football match or marshalling cars on a motor racetrack. |
|----------|---------------|--|

- |          |                    |  |
|----------|--------------------|--|
| <b>R</b> | <b>Response</b>    | Is the patient conscious? Can he/she talk?   |
| <b>A</b> | <b>Airway</b>      | Ensure a clear and unobstructed airway. Remove any mouth guard or dental device that may be present. |
| <b>B</b> | <b>Breathing</b>   | Ensure the patient is breathing adequately.  |
| <b>C</b> | <b>Circulation</b> | Ensure an adequate circulation.  |

Once the basic first aid aspects of care have been achieved and the patient is stabilised, consideration of removal of the patient from the field to an appropriate facility for further assessment is necessary. At this time, careful assessment for the presence of a cervical spinal cord or other injury is necessary. If an alert patient complains of neck pain, has evidence of neck tenderness or deformity, or has neurological signs suggestive of a spinal injury, then neck bracing and transport on a suitable spinal frame is required. If the patient is unconscious, then a cervical injury should be assumed until proven otherwise. Airway protection takes precedence over any potential spinal injury. In this situation, the removal of helmets or other head protectors should only be performed by individuals trained in this aspect of trauma management.

The clinical management of a concussed athlete may involve the treatment of a disorientated, confused, unconscious, uncooperative or convulsing patient (see Table 20.1 for other symptoms and signs of concussion). The immediate treatment priorities remain the basic first aid principles outlined above. Once this has been established and the patient stabilised, a full medical and neurological assessment exam should follow. On site physicians are in an ideal position to initiate the critical early steps in an athlete's care to ensure optimal recovery from a head injury. Typically, with a medical doctor present on the sidelines the more detailed assessment of the injured athlete would occur in the medical rooms where a quiet and unhurried environment exists. This would be the normal situation in the case of an athlete that is conscious and without a spinal cord injury. In some situations, where no doctor is present, safe removal to a hospital emergency department is the correct approach.

When examining a concussed athlete, a full neurological examination is important. Because the major management priorities at this stage are to establish an accurate diagnosis and exclude a potentially catastrophic intracranial injury, this part of the examination should be particularly thorough. Having determined the presence of a concussive injury, the patient needs to be serially monitored until full recovery ensues. In the acute situation following a traumatic brain injury of any severity,

**Table 20.1 Symptoms and signs of concussion**

Symptoms	Signs
<ul style="list-style-type: none"> <li>• Headache</li> <li>• Dizziness</li> <li>• Nausea or vomiting</li> <li>• Unsteadiness or loss of balance</li> <li>• Confusion</li> <li>• Unaware of period, opposition, score of game</li> <li>• Feeling 'dinged', stunned or 'dazed'</li> <li>• Seeing stars or flashing lights</li> <li>• Ringing in the ears</li> <li>• Double vision or blurred vision</li> </ul>	<ul style="list-style-type: none"> <li>• Loss of consciousness or impaired conscious state</li> <li>• Poor coordination or balance</li> <li>• Convulsive convulsion or impact seizure</li> <li>• Unsteady gait or loss of balance</li> <li>• Slow to answer questions or follow directions</li> <li>• Easily distracted, poor concentration</li> <li>• Displaying unusual or inappropriate emotions</li> <li>• Vacant stare or glassy eyed</li> <li>• Slurred speech</li> <li>• Personality changes</li> <li>• Inappropriate playing behaviour</li> <li>• Significantly decreased playing ability</li> <li>• Double vision or blurred vision</li> </ul>

conscious state is the key element to assess initially. This is measured in the GCS which is included in the SCAT3.

Once severe brain or cervical spine injury has been excluded, the most important components of concussion management include:

- confirming the diagnosis (includes differentiating from other pathologies, e.g. post-traumatic headaches)
- determining when the player has fully recovered so that he/she can safely return to competition.

### Confirming the diagnosis

Common symptoms of concussion include headache, nausea, dizziness and balance problems, blurred vision or other visual disturbance, confusion, memory loss and a feeling of slowness or fatigue (Table 20.1). Many of these symptoms are not specific to concussion. Nevertheless, concussion should be suspected in any player who presents with any of these symptoms following a collision or direct trauma to the head. When performing an on-field assessment it is suggested that the CRT (Fig. 20.3) be utilised as a rapid means of making such assessment.

Clinical features that are more likely to suggest a diagnosis of concussion include loss of consciousness (LOC), convulsive convulsions, confusion or attention deficit, memory disturbance and balance disturbance.

#### PRACTICE PEARL

If a concussion is suspected, the player should be removed from the playing environment, with appropriate care of the cervical spine and evaluated in a place free from distraction (e.g. medical room).

These may not be present in all cases and in some cases may present in a delayed fashion. The assessment as per the SCAT3 (Fig 20.2) form should be used and focus on:

- symptom checklist
- tests of cognitive function (e.g. Maddocks' questions, Standardised Assessment of Concussion [SAC])
- tests of balance function
- neurological examination.

One of the critical aspects of the SCAT3 is that it should be used after 10 minutes have passed following the injury. In that time, the clinician should ensure that the first aid priorities have been completed, a GCS recorded, spinal and other injuries excluded and the opportunity to review any video of the incident (if available) completed. This delay in the concussion assessment is important as, in many cases, the concussion injury is an evolving one and many athletes only begin to exhibit symptoms and signs several minutes after injury. If the SCAT3 is done too early following the injury, then the critical concussion features may be missed.

Any player with symptoms and/or evidence of a disturbance of cognitive function (e.g. LOC, balance disturbance, disorientation or cognitive deficit) can be considered to have a concussive injury. Once concussion is medically diagnosed then the player should be removed from the game or training and not return to play on that day (Fig 20.4). As a general rule, even in cases where the diagnosis is not entirely clear, a conservative approach should be adopted (*'If in doubt sit them out'*).

For practical purposes, the CRT (Fig. 20.3) can be utilised on-field or on the sideline to screen for concussion and once concussion is diagnosed, the player removed to the medical room and the full SCAT3

## Sport Concussion Assessment Tool – 3rd Edition

For use by medical professionals only

Name \_\_\_\_\_

Date/Time of Injury  
Date of Assessment \_\_\_\_\_

Examiner \_\_\_\_\_

### What is the SCAT3?

The SCAT3 is a standardized tool for evaluating injured athletes for concussion and can be used in athletes aged from 13 years and older. It supersedes the original SCAT and the SCAT2 published in 2005 and 2009, respectively. For younger persons, ages 12 and under, please use the Child SCAT3. The SCAT3 is designed for use by medical professionals. If you are not qualified, please use the Sport Concussion Recognition Tool. Preseason baseline testing with the SCAT3 can be helpful for interpreting post-injury test scores.

Specific instructions for use of the SCAT3 are provided on page 3. If you are not familiar with the SCAT3, please read through these instructions carefully. This tool may be freely copied in its current form for distribution to individuals, teams, groups and organizations. Any revision or any reproduction in a digital form requires approval by the Concussion in Sport Group.

**NOTE:** The diagnosis of a concussion is a clinical judgment, ideally made by a medical professional. The SCAT3 should not be used solely to make, or exclude, the diagnosis of concussion in the absence of clinical judgement. An athlete may have a concussion even if their SCAT3 is "normal".

### What is a concussion?

A concussion is a disturbance in brain function caused by a direct or indirect force to the head. It results in a variety of non-specific signs and/or symptoms (some examples listed below) and most often does not involve loss of consciousness. Concussion should be suspected in the presence of **any one or more** of the following:

- Symptoms (e.g., headache), or
- Physical signs (e.g., unsteadiness), or
- Impaired brain function (e.g., confusion) or
- Abnormal behaviour (e.g., change in personality)

### SIDELINE ASSESSMENT

#### Indications for Emergency Management

**NOTE:** A hit to the head can sometimes be associated with a more serious brain injury. Any of the following warrants consideration of activating emergency procedures and urgent transportation to the nearest hospital:

- Glasgow Coma score less than 15
- Deteriorating mental status
- Potential spinal injury
- Progressive, worsening symptoms or new neurologic signs

#### Potential signs of concussion?

If any of the following signs are observed after a direct or indirect blow to the head, the athlete should stop participation, be evaluated by a medical professional and **should not be permitted to return to sport the same day** if a concussion is suspected.

Any loss of consciousness?	Y	N	
"If so, how long?"			
Balance or motor incoordination ( <i>stumbles, slow/laboured movements, etc.</i> )?	Y	N	
Disorientation or confusion ( <i>inability to respond appropriately to questions</i> )?	Y	N	
Loss of memory	Y	N	
"If so, how long?"			
"Before or after the injury?"			
Blank or vacant look:	Y	N	
Visible facial injury in combination with any of the above:	Y	N	

### 1 Glasgow coma scale (GCS)

**Best eye response (E)**

No eye opening	1
Eye opening in response to pain	2
Eye opening to speech	3
Eyes opening spontaneously	4

**Best verbal response (V)**

No verbal response	1
Incomprehensible sounds	2
Inappropriate words	3
Confused	4
Oriented	5

**Best motor response (M)**

No motor response	1
Extension to pain	2
Abnormal flexion to pain	3
Flexion/Withdrawal to pain	4
Localizes to pain	5
Obeys commands	6

**Glasgow Coma score (E + V + M)** 15

GCS should be recorded for all athletes at time of subsequent deterioration.

### 2 Maddocks Score<sup>2</sup>

"I am going to ask you a few questions, please listen carefully and give your best effort."

Modified Maddocks questions (1 point for each correct answer)

What venue are we at today?	0	1
Which half is it now?	0	1
Who scored last in this match?	0	1
What team did you play last week/game?	0	1
Did your team win the last game?	0	1

**Maddocks score** 0/5

Maddocks score is validated for sideline diagnosis of non-severe injury and is not specific for visual injury.

**Notes:** Mechanism of Injury ("tell me what happened?")

**Any athlete with a suspected concussion should be REMOVED FROM PLAY, medically assessed, monitored for deterioration (i.e., should not be left alone) and should not drive a motor vehicle until cleared to do so by a medical professional. No athlete diagnosed with concussion should be returned to sports participation on the day of injury.**

## BACKGROUND

Name: \_\_\_\_\_ Date: \_\_\_\_\_

Examiner: \_\_\_\_\_

Sport/team/school: \_\_\_\_\_ Date/time of injury: \_\_\_\_\_

Age: \_\_\_\_\_ Gender: ☐ M ☐ F

Years of education completed: \_\_\_\_\_

Dominant hand: ☐ right ☐ left ☐ neither

How many concussions do you think you have had in the past? \_\_\_\_\_

When was the most recent concussion? \_\_\_\_\_

How long was your recovery from the most recent concussion? \_\_\_\_\_

Have you ever been hospitalized or had medical imaging done for a head injury? ☐ Y ☐ N

Have you ever been diagnosed with headaches or migraines? ☐ Y ☐ N

Do you have a learning disability, dyslexia, ADD/ADHD? ☐ Y ☐ N

Have you ever been diagnosed with depression, anxiety or other psychiatric disorder? ☐ Y ☐ N

Has anyone in your family ever been diagnosed with any of these problems? ☐ Y ☐ N

Are you on any medications? If yes, please list: ☐ Y ☐ N

SCAT3 to be done in resting state. Best done 10 or more minutes post exercise.

## SYMPTOM EVALUATION

3

## How do you feel?

"You should score yourself on the following symptoms, based on how you feel now".

	none	mild	moderate	severe			
Headache	0	1	2	3	4	5	6
"Pressure in head"	0	1	2	3	4	5	6
Neck Pain	0	1	2	3	4	5	6
Nausea or vomiting	0	1	2	3	4	5	6
Dizziness	0	1	2	3	4	5	6
Blurred vision	0	1	2	3	4	5	6
Balance problems	0	1	2	3	4	5	6
Sensitivity to light	0	1	2	3	4	5	6
Sensitivity to noise	0	1	2	3	4	5	6
Feeling slowed down	0	1	2	3	4	5	6
Feeling like "in a fog"	0	1	2	3	4	5	6
"Don't feel right"	0	1	2	3	4	5	6
Difficulty concentrating	0	1	2	3	4	5	6
Difficulty remembering	0	1	2	3	4	5	6
Fatigue or low energy	0	1	2	3	4	5	6
Confusion	0	1	2	3	4	5	6
Drowsiness	0	1	2	3	4	5	6
Trouble falling asleep	0	1	2	3	4	5	6
More emotional	0	1	2	3	4	5	6
Irritability	0	1	2	3	4	5	6
Sadness	0	1	2	3	4	5	6
Nervous or Anxious	0	1	2	3	4	5	6

Total number of symptoms (Maximum possible 22) \_\_\_\_\_

Symptom severity score (Maximum possible 132) \_\_\_\_\_

Do the symptoms get worse with physical activity? ☐ Y ☐ N

Do the symptoms get worse with mental activity? ☐ Y ☐ N

☐ self rated ☐ self rated and clinician monitored

☐ clinician interview ☐ self rated with parent input

**Overall rating:** If you know the athlete well prior to the injury, how different is the athlete acting compared to his/her usual self?

Please circle one response:

☐ no different ☐ very different ☐ unsure ☐ N/A

Scoring on the SCAT3 should not be used as a stand alone method to diagnose concussion, measure recovery or make decisions about an athlete's readiness to return to competition after concussion. Since signs and symptoms may evolve over time, it is important to consider repeat evaluation in the acute assessment of concussion.

Delayed recall score \_\_\_\_\_

## INSTRUCTIONS

Words in *italics* throughout the SCAT3 are the instructions given to the athlete by the tester.

### Symptom Scale

*"You should score yourself on the following symptoms, based on how you feel now."*

To be completed by the athlete. In situations where the symptom scale is being completed after exercise, it should still be done in a resting state, at least 10 minutes post exercise.

For total number of symptoms, maximum possible is 22.

For Symptom severity score, add all scores in table, maximum possible is  $22 \times 6 = 132$ .

### SAC<sup>4</sup>

#### Immediate Memory

*"I am going to test your memory. I will read you a list of words and when I am done, repeat back as many words as you can remember, in any order."*

#### Trials 2 & 3:

*"I am going to repeat the same list again. Repeat back as many words as you can remember in any order, even if you said the word before."*

Complete all 3 trials regardless of score on trial 1 & 2. Read the words at a rate of one per second. **Score 1 pt. for each correct response.** Total score equals sum across all 3 trials. Do not inform the athlete that delayed recall will be tested.

#### Concentration

##### Digits backward

*"I am going to read you a string of numbers and when I am done, you repeat them back to me backwards, in reverse order of how I read them to you. For example, if I say 7-1-9, you would say 9-1-7."*

If correct, go to next string length. If incorrect, read trial 2. **One point possible for each string length.** Stop after incorrect on both trials. The digits should be read at the rate of one per second.

#### Months in reverse order

*"Now tell me the months of the year in reverse order. Start with the last month and go backward. So you'll say December, November ... Go ahead."*

**1 pt. for entire sequence correct**

#### Delayed Recall

The delayed recall should be performed after completion of the Balance and Coordination Examination.

*"Do you remember that list of words I read a few times earlier? Tell me as many words from the list as you can remember in any order."*

**Score 1 pt. for each correct response**

### Balance Examination

#### Modified Balance Error Scoring System (BESS) testing<sup>3</sup>

This balance testing is based on a modified version of the Balance Error Scoring System (BESS)<sup>3</sup>. A stopwatch or watch with a second hand is required for this testing.

*"I am now going to test your balance. Please take your shoes off, roll up your pant legs above ankle (if applicable), and remove any ankle taping (if applicable). This test will consist of three twenty-second tests with different stances."*

##### (a) Double leg stance:

*"The first stance is standing with your feet together with your hands on your hips and with your eyes closed. You should try to maintain stability in that position for 20 seconds. I will be counting the number of times you move out of this position. I will start timing when you are set and have closed your eyes."*

##### (b) Single leg stance:

*"If you were to kick a ball, which foot would you use? [This will be the dominant foot] Now stand on your non-dominant foot. The dominant leg should be held in approximately 30 degrees of hip flexion and 45 degrees of knee flexion. Again, you should try to maintain stability for 20 seconds with your hands on your hips and your eyes closed. I will be counting the number of times you move out of this position. If you stumble out of this position, open your eyes and return to the start position and continue balancing. I will start timing when you are set and have closed your eyes."*

##### (c) Tandem stance:

*"Now stand heel-to-toe with your non-dominant foot in back. Your weight should be evenly distributed across both feet. Again, you should try to maintain stability for 20 seconds with your hands on your hips and your eyes closed. I will be counting the number of times you move out of this position. If you stumble out of this position, open your eyes and return to the start position and continue balancing. I will start timing when you are set and have closed your eyes."*

(c)

#### Balance testing – types of errors

1. Hands lifted off iliac crest
2. Opening eyes
3. Step, stumble, or fall
4. Moving hip into > 30 degrees abduction
5. Lifting forefoot or heel
6. Remaining out of test position > 5 sec.

Each of the 20-second trials is scored by counting the errors, or deviations from the proper stance, accumulated by the athlete. The examiner will begin counting errors only after the individual has assumed the proper start position. **The modified BESS is calculated by adding one error point for each error during the three 20-second tests. The maximum total number of errors for any single condition is 10.** If a athlete commits multiple errors simultaneously, only one error is recorded but the athlete should quickly return to the testing position, and counting should resume once subject is set. Subjects that are unable to maintain the testing procedure for a minimum of **five seconds** at the start are assigned the highest possible score, ten, for that testing condition.

**OPTION:** For further assessment, the same 3 stances can be performed on a surface of medium density foam (e.g., approximately 50 cm x 40 cm x 6 cm).

#### Tandem Gait<sup>4,5</sup>

Participants are instructed to stand with their feet together behind a starting line (the left is best done with footwear removed). Then, they walk in a forward direction as quickly and as accurately as possible using a 30mm wide (about 1 1/2 inch) meter line with an alternate foot behind the gait ensuring that they approximate their heel and toe on each step. Once they cross the end of the 3m line, they turn 180 degrees and return to the starting point, using the same gait. A total of 4 times are done and the best time is retained. Athletes should complete the test in 14 seconds. Athletes fail the test if they step off the line, have a separation between their heel and toe, or if they touch or grab the examiner or an object. In this case, the time is not recorded and the test repeated, if appropriate.

### Coordination Examination

#### Upper limb coordination

##### Finger-to-nose (FTN) task:

*"I am going to test your coordination now. Please sit comfortably on the chair with your eyes open and your arm (either right or left) outstretched (shoulder flexed to 90 degrees and elbow and fingers extended), pointing in front of you. When I give a start signal, I would like you to perform five successive finger to nose repetitions using your index finger to touch the tip of the nose, and then return to the starting position, as quickly and as accurately as possible."*

**Scoring: 5 correct repetitions in < 4 seconds = 1**

**Note for testers: Athletes fail the test if they do not touch their nose, do not fully extend their elbow or do not perform five repetitions. Failure should be scored as 0.**

### References & Footnotes

## ATHLETE INFORMATION

Any athlete suspected of having a concussion should be removed from play, and then seek medical evaluation.

### Signs to watch for

Problems could arise over the first 24–48 hours. The athlete should not be left alone and must go to a hospital at once if they:

- Have a headache that gets worse
- Are very drowsy or can't be awakened
- Can't recognize people or places
- Have repeated vomiting
- Behave unusually or seem confused; are very irritable
- Have seizures (arms and legs jerk uncontrollably)
- Have weak or numb arms or legs
- Are unsteady on their feet, have slurred speech

**Remember, it is better to be safe.**

**Consult your doctor after a suspected concussion.**

### Return to play

Athletes should not be returned to play the same day of injury.

When returning athletes to play, they should be **medically cleared** and then follow a **stepwise supervised program**, with stages of progression

For example:

Rehabilitation stage	Functional exercise at each stage of rehabilitation	Objective of each stage
Inactivity	Physical and cognitive rest	Recovery
Light aerobic exercise	Walking, swimming or stationary cycling, keeping intensity <70% max, symptom-provoked heart rate. No resistance training	Increase heart rate
Sport-specific exercise	Skating drills on ice hockey, running drills on soccer. No head impact activities	Add movement
Non-contact training drills	Progression to injury (complex) training drills, eg passing drills in football and ice hockey. May start progressing resistance training	Formal, non-contact, skill, cognitive load
Full contact practice	Following medical clearance participate in normal training activities	Restore confidence and assess functional skills by coaching staff
Return to play	Normal game play	

There should be at least 24 hours (or longer) for each stage and if symptoms recur the athlete should rest until they resolve once again and then resume the program at the previous asymptomatic stage. Resistance training should only be added in the later stages

If the athlete is symptomatic for more than 10 days, then consultation by a medical practitioner who is expert in the management of concussion, is recommended.

**Medical clearance should be given before return to play.**

### Scoring Summary:

Test/Domain	Score
Date: _____	_____
Number of Symptoms of 22	_____
Symptom Severity Score of 132	_____
Orientation of 5	_____
Immediate Memory of 15	_____
Concentration of 5	_____
Delayed Recall of 5	_____
<b>SAC Total</b>	_____
BESS (total errors)	_____
Tandem Gait (seconds)	_____
Coordination of 1	_____

Notes:

## CONCUSSION INJURY ADVICE

(To be given to the **person monitoring** the concussed athlete)

This patient has received an injury to the head. A careful medical examination has been carried out and no sign of any serious complications has been found. Recovery time is variable across individuals and the patient will need monitoring for a further period by a responsible adult. Your treating physician will provide guidance as to this timeframe.

**If you notice any change in behaviour, vomiting, dizziness, worsening headache, double vision or excessive drowsiness, please contact your doctor or the nearest hospital emergency department immediately.**

### Other important points:

- Rest (physically and mentally), including training or playing sports until symptoms resolve and you are medically cleared
- No alcohol
- No prescription or non-prescription drugs without medical supervision. Specifically:
  - No sleeping tablets
  - Do not use aspirin, anti-inflammatory medication or sedating pain killers
- Do not drive until medically cleared
- Do not train or play sport until medically cleared

## Pocket CONCUSSION RECOGNITION TOOL™

To help identify concussion in children, youth and adults

### RECOGNIZE & REMOVE

Concussion should be suspected **if one or more** of the following visible clues, signs, symptoms or errors in memory questions are present.

#### 1. Visible clues of suspected concussion

Any one or more of the following visual clues can indicate a possible concussion:

- Loss of consciousness or responsiveness
- Lying motionless on ground/Slow to get up
- Unsteady on feet / Balance problems or falling over / Incoordination
- Grabbing/Clutching of head
- Dazed, blank or vacant look
- Confused/Not aware of plays or events

#### 2. Signs and symptoms of suspected concussion

Presence of any one or more of the following signs & symptoms may suggest a concussion:

- |                          |                            |
|--------------------------|----------------------------|
| - Loss of consciousness  | - Headache                 |
| - Seizure or convulsion  | - Dizziness                |
| - Balance problems       | - Confusion                |
| - Nausea or vomiting     | - Feeling slowed down      |
| - Drowsiness             | - "Pressure in head"       |
| - More emotional         | - Blurred vision           |
| - Irritability           | - Sensitivity to light     |
| - Sadness                | - Amnesia                  |
| - Fatigue or low energy  | - Feeling like "in a fog"  |
| - Nervous or anxious     | - Neck Pain                |
| - "Don't feel right"     | - Sensitivity to noise     |
| - Difficulty remembering | - Difficulty concentrating |

© 2013 Concussion in Sport Group

### 3. Memory function

Failure to answer any of these questions correctly may suggest a concussion.

- "What venue are we at today?"
- "Which half is it now?"
- "Who scored last in this game?"
- "What team did you play last week / game?"
- "Did your team win the last game?"

**Any athlete with a suspected concussion should be IMMEDIATELY REMOVED FROM PLAY, and should not be returned to activity until they are assessed medically. Athletes with a suspected concussion should not be left alone and should not drive a motor vehicle.**

It is recommended that, in all cases of suspected concussion, the player is referred to a medical professional for diagnosis and guidance as well as return to play decisions, even if the symptoms resolve.

### RED FLAGS

**If ANY of the following are reported then the player should be safely and immediately removed from the field. If no qualified medical professional is available, consider transporting by ambulance for urgent medical assessment:**

- |  |                                 |
|--|---------------------------------|
| - Athlete complains of neck pain               | - Deteriorating conscious state |
| - Increasing confusion or irritability         | - Severe or increasing headache |
| - Repeated vomiting                            | - Unusual behaviour change      |
| - Seizure or convulsion                        | - Double vision                 |
| - Weakness or tingling/burning in arms or legs |                                 |

### Remember:

- In all cases, the basic principles of first aid (danger, response, airway, breathing, circulation) should be followed.
- Do not attempt to move the player (other than required for airway support) unless trained to do so.
- Do not remove helmet (if present) unless trained to do so.

**Figure 20.3** Pocket Concussion Recognition Tool™ (CRT)<sup>2</sup>  
REPRODUCED WITH PERMISSION FROM *BRITISH JOURNAL OF SPORTS MEDICINE*

assessment tool used by the attending physician. If the diagnosis of concussion is confirmed following the medical assessment, the player should not be returned to play on the day and serial monitoring should be commenced immediately. New portable technologies are continually being incorporated into acute sports concussion assessment; however, research is yet to establish how effective and clinically applicable these new methods are.<sup>14</sup>

In addition to post-injury assessment, it is recommended that the SCAT3 be used by medical staff for pre-season baseline testing. This may be helpful for interpreting post-concussion test scores as it provides an objective record of possible change. More importantly, it provides an educative opportunity for the physician to highlight the importance of reporting all concussive injuries.

### Does amnesia associate with injury severity?

There is renewed interest in post-traumatic amnesia and its role as a surrogate measure of injury severity.

**Figure 20.4** Recognition of concussion, removal from play, and review and assessment of the athlete are the key steps in management

Post-traumatic amnesia can be separated into retrograde amnesia (loss of memory prior to injury) and anterograde amnesia (loss of memory post injury). Virtually all concussed athletes will have periods of amnesia, however brief, whether they were unconscious or not.

## PRACTICE PEARL

In broad terms, the duration of post-traumatic amnesia does not reflect the severity of concussion or mild TBI. This contrasts with moderate to severe traumatic brain injury where post-traumatic amnesia is a prognostic factor and should be assessed in all cases.

Note that retrograde amnesia varies depending on when it is measured after injury; thus, it is a particularly poor indicator of injury severity.

The number and duration of the clinical post-concussive symptoms may be more important than the presence or duration of amnesia alone. The overall clinical management and return to play depends on the presence and recovery of all symptoms and signs.

### Does an acutely concussed athlete need to go to hospital or have urgent neuroimaging?

The treating clinician may face the decision of whether the athlete should be referred on to a hospital emergency facility or for urgent neuroimaging. In general terms, an uncomplicated concussion does not need routine neuroimaging. Imaging, however, has a role in the exclusion of suspected intracranial injury and the indications are listed in the box. Apart from 'cookbook' type approaches, referral to such a centre depends on the experience, ability and competency of the physician at hand. If the team physician happens to be an SEM physician, neurologist or neurosurgeon experienced in concussion management, the clinical referral pathways will be different to a family practitioner called to assist at a football match after an injury has occurred.

## PRACTICE PEARL

The overall approach should be 'when in doubt, refer'.

Other diagnostic tests such as biomarkers, EEG and functional MRI brain scanning do not have a role in the early diagnosis and management of a concussion injury, except in an experimental or research context.<sup>15</sup> Structural neuroimaging such as CT and MRI does not clinically add to a diagnosis of concussion; however, these have an important role in excluding more significant injuries.

### How should acute concussion be graded?

There is no reliable or scientifically validated system of grading the severity of sports-related concussion. At the present time, there are at least 45 published anecdotal

### Indications for urgent imaging or hospital referral

Any player who has or develops the following:

- fractured skull
- penetrating skull trauma
- deterioration in conscious state following injury
- focal neurological signs
- confusion or impairment of consciousness >30 minutes
- loss of consciousness >1 minute
- persistent vomiting or increasing headache post injury
- any convulsive movements
- more than one episode of concussive injury in a match or training session
- where there is assessment difficulty (e.g. an intoxicated patient)
- all children with head injuries
- high-risk patients (e.g. haemophilia, anticoagulant use)
- inadequate post injury supervision
- high-risk injury mechanism (e.g. high velocity impact, missile injury).

severity scales. The danger is that athletes and/or their coaches may 'shop around' for a scale that is not in their best medical interests. At the end of the day, good clinical judgment should prevail over written guidelines. At all four international conferences on concussion in sport to date, the expert committee has strongly recommended that combined measures of recovery should be used to assess injury severity and guide individual decisions on return to play.<sup>5</sup> Individual assessment was strongly re-endorsed at the 2012 Zurich meeting.<sup>6</sup>

### Determining when the player can return safely to competition

Return-to-play decisions remain difficult. Expert consensus guidelines recommend that players should **not** return to competition until they have recovered **completely** from their concussive injury. The majority (80-90%) of clinical symptoms and cognitive deficits resolve in a relatively short 7-10 day period. MRI diffusion or connectomic radiological changes may still be present for longer; however, the significance of such changes is unknown.<sup>16-18</sup> Children and adolescents may take longer to recover from concussive injuries.<sup>19</sup>

Currently, there is no single gold standard measure of brain disturbance and recovery following concussion. It should be noted that most athletes wanting to return to play will report 'feeling fine'. Therefore, clinicians should incorporate both subjective and objective measures to determine readiness to return to play (RTP). In practical

terms, this can involve a multifaceted and multidisciplinary clinical approach, which includes assessment of symptoms, signs (such as balance) and cognitive function.

### Return to play on the day of injury

#### PRACTICE PEARL

The Zurich consensus group reaffirmed the previous general management principle that no return to play on the day should be contemplated for a concussed athlete.

There is published evidence in high school and college athletes that RTP on the day of injury resulted in delayed and prolonged cognitive deterioration. It is not within the scope or expertise of a physiotherapist, trainer or other non-medical person to manage a concussive injury or determine the timing of return to play. A player should never RTP while symptomatic: 'When in doubt, sit them out!'

### Return to play during the subsequent week(s)

Whether or not to allow the concussed athlete to return to training and then competition is one of the most difficult decisions the SEM physician must make. In minor cases of concussion, where all symptoms resolve quickly and there is no sign of cortical dysfunction, or evidence of impairment of short-term memory or information processing, the player may be allowed to return once recovered. Neuropsychological testing may be used to confirm full recovery. A player permitted to return to play should be closely observed for any signs of impaired function. A multifaceted clinical approach is used to manage players following injury (Fig. 20.5). In practical terms, this involves five sequential steps:

1. a brief period of cognitive and physical rest to facilitate recovery
2. monitoring for recovery of post-concussion symptoms and signs
3. the use of neuropsychological tests to estimate recovery of cognitive function
4. a graduated return to activity with monitoring for recurrence of symptoms
5. a final medical clearance before resuming full contact training and/or playing.

#### Period of cognitive and physical rest to facilitate recovery

Early rest is important to allow recovery following a concussive injury; however, prolonged rest may be counterproductive.<sup>20, 21</sup> In the immediate post-concussion stage (24–48 hours), physical activity, physiological stress (e.g. altitude and flying) and

Figure 20.5 Multimodality concussion assessment

cognitive loads (e.g. studying, video games or computer work) can all worsen symptoms and possibly delay recovery. Players should be advised to rest from these activities in the early stages after a concussive injury, especially while symptomatic (see 'Concussion injury advice', p. 4 of the SCAT3). Similarly, the use of alcohol, narcotic analgesics, anti-inflammatory medication or sedatives can exacerbate symptoms following head trauma, delay recovery or mask deterioration, and should also be avoided. Specific advice should also be given on avoidance of activities that place the individual at risk of further injury (e.g. driving).

The recovery and outcome of concussion may be modified by a number of factors that may require more sophisticated management strategies. The Zurich consensus panel agreed that a range of 'modifying' factors may influence the investigation and management of concussion and, in some cases, may predict the potential for prolonged or persistent symptoms.<sup>6, 22</sup> These modifiers would also be important to consider in a detailed concussion history and are outlined in Table 20.2.

When these modifying influences are present, simple RTP advice may be inappropriate. It may be wise to consider additional investigations including: formal neuropsychological testing, balance assessment and neuroimaging. It is envisioned that athletes with such modifying features would be managed in a multidisciplinary manner coordinated by a physician with specific expertise in the management of concussive injury.

**Table 20.2 Factors that influence whether investigation or more sophisticated management (e.g. referral to a physician with expertise in concussion management) is indicated**

Factors	Modifier
Symptoms	Number
	Duration (>10 days)
	Severity
Signs	Prolonged LOC (>1 min), amnesia
Sequelae	Concussive convulsions
Temporal	Frequency—repeated concussions over time
	Timing—injuries close together in time
	'Recency'—recent concussion or TBI
Threshold	Repeated concussions occurring with progressively less impact force or slower recovery after each successive concussion.
Age	Child and adolescent (<18 years old)
Co- and pre-morbidities	Migraine, depression or other mental health disorders, attention deficit hyperactivity disorder (ADHD), learning disabilities (LD), sleep disorders
Medication	Psychoactive drugs, anticoagulants
Behaviour	Dangerous style of play
Sport	High-risk activity, contact and collision sport, high sporting level

### Monitoring for recovery of post-concussion symptoms and signs

The symptoms of concussion are dynamic and evolve over time. It is important that players who are suspected of having a concussion be monitored over time to assess for delayed symptom onset. Monitoring of post-concussion symptoms and signs can be facilitated by the use of the SCAT3.

### Use of neuropsychological tests to estimate recovery of cognitive function

Cognitive deficits associated with concussion are typically subtle and may exist in a number of domains. Common

deficits that follow concussion in sport include reduced attention and ability to process information, slowed reaction times and impaired memory.

The use of neuropsychological tests in the management of concussion overcomes the reliance on subjective symptoms, which are known to be poorly recognised and variably reported. It allows detection of cognitive deficits, which have been observed to outlast symptoms in many cases of concussion.

There are a number of levels of complexity of cognitive testing, including:

- formal neuropsychological testing
- screening computerised cognitive test batteries
- basic paper-and-pencil evaluation (i.e. SCAT3).

Formal neuropsychological testing performed by trained neuropsychologists remains the clinical best practice standard for the assessment of cognitive function.<sup>23</sup> Formal testing is logistically impractical for routine use following all concussive injuries, but is recommended in any case where there is uncertainty about recovery or in difficult cases (e.g. prolonged recovery).

Screening computerised cognitive tests provide a practical alternative for the assessment of cognitive recovery. Ideally, the tests should be compared to the individual's own pre-injury baseline. A number of screening computerised cognitive test batteries have been validated for use following concussion in sport and are readily available. These include test platforms such as CogState Sport/Axon Sports ([www.cogstate.com/go/Sport](http://www.cogstate.com/go/Sport)), ImPACT ([www.impacttest.com](http://www.impacttest.com)) and the US military-developed tool Automated Neuropsychological Assessment Metrics (ANAM).

Computerised tests provide a quick, valid and reliable measure of cognitive recovery following a concussive injury. Furthermore, routine use of computerised screening tests in the pre-season facilitates screening of players for cognitive deterioration over time.

Basic paper-and-pencil cognitive tests (e.g. SCAT3, Fig. 20.2) are the quickest and simplest of the cognitive screening tests; however, they are the least sensitive to the subtle cognitive changes that accompany concussion. In cases where the concussion has resulted in brief symptoms and clinically the player has recovered well, basic paper-and-pencil cognitive tests can be used to provide an estimate of cognitive function. The use of a basic paper-and-pencil evaluation should be combined with a conservative return to play approach and careful monitoring of symptoms as the player progresses through a graduated RTP program.

Overall, it is important to remember that neuropsychological testing is only one component of assessment and therefore should not be the sole basis of management decisions. Neuropsychological testing

does not replace the need for a full history and clinical/neurological assessment.

#### Graduated return to activity

Following a concussive injury, players should be returned to play in a graduated fashion once clinical features have resolved and cognitive function returned to 'baseline'. When considering RTP the athlete should be off any medications prescribed in the management of the concussion at the time of considering commencement of the rehabilitation phase or at the final medical assessment.

In accordance with current consensus guidelines, there is no mandatory period of time that a player must be withheld from play following a concussion. However, at minimum, a player must be symptom free at rest and with exertion and determined to have returned to baseline level of cognitive performance.

The Zurich consensus statement recommends a stepwise Graduated Return to Play Protocol (Table 20.3). If a player remains asymptomatic for 24 hours at level 1, they may progress to level 2. They are allowed to advance provided that they remain asymptomatic. Using this protocol, an athlete should take approximately 1 week before returning to normal game play. If any symptoms surface during the progression, players should drop back to the previous level in which they were asymptomatic for a further 24 hours before attempting to progress again.

#### A final medical clearance before resuming full contact training and/or playing

A player who has suffered from a concussive injury must not be allowed to return to play before having a medical

clearance. In every case, the decision regarding the timing of return to training should be made by a medical doctor with experience in concussive injuries. This assessment is multidimensional and based on evidence of resolution of the athlete's symptoms, physical signs and cognitive deficit. Ideally, concussed players should be examined by an experienced medical practitioner with the decision about RTP based on the clinical findings and, if possible, neuropsychological testing. In general, a more conservative approach (i.e. longer time to return to sport) is used in cases where there is any uncertainty about the player's recovery ('If in doubt, sit them out').

In a number of contact sports, such as boxing and rugby (previously), authorities have legislated for a mandatory exclusion period from competition for concussed players. While the intent of such a policy is praiseworthy, an arbitrary exclusion period is hard to justify scientifically as each episode of concussion requires individual evaluation. For some players, the period of exclusion will be too long and for other players not long enough. More importantly, the assumption that a player has recovered simply because a prescribed period of time has passed has the potential to lead to premature return to play and resultant problems.

#### The risk of premature return to play and concussion sequelae

There are several risks associated with premature RTP.

#### Risk of further injury

The principal concern of premature RTP of a concussed athlete is that due to the impaired cognitive function (e.g. slowed information processing, reduced attention) the

**Table 20.3 Graduated Return to Play Protocol**

Rehabilitation stage	Functional exercise at each stage of rehabilitation	Objective at each stage
1. No activity	Complete physical (no training, playing, exercise, weights etc.) and cognitive rest (no television, extensive reading, video games etc.)	Recovery* <i>Beware of exertion with activities of daily living and caution regarding daytime sleep</i>
2. Light aerobic exercise	Walking, swimming or stationary cycling keeping intensity <70% HR max. No resistance training	Increase heart rate
3. Sport-specific exercise	Skating drills in ice hockey, running drills in soccer. No head-impact activities	Add movement
4. Non-contact training drills	Progression to more complex training drills, e.g. passing drills in hockey and football	Exercise, coordination and cognitive load
5. Full contact practice	Following medical clearance participate in normal training activities	Restore confidence and assess functional skills by coaching staff
6. Return to play	Normal game play	

Reproduced with permission from Table 1: Zurich consensus statement in BJSM<sup>3</sup>

athlete will sustain further injury (both concussive and other) when returning to a dangerous playing environment.

### Second impact syndrome

Second impact syndrome (SIS) is frequently mentioned in the concussion literature, but surprisingly, has little scientific evidence for its existence. It is a term used to describe the potential catastrophic consequences resulting from a second concussive blow to the head before an individual has fully recovered from the symptoms of a previous concussion. The second head injury is believed to result in loss of cerebrovascular auto-regulation, which in turn leads to brain swelling secondary to increased cerebral blood flow. Mortality in this condition approaches 100%. The evidence that repeated concussion was a risk factor for SIS has been critically reviewed and published cases of SIS were classified as definite, probable, possible or not SIS according to four criteria.<sup>24</sup>

Seventeen published cases of SIS were identified from the literature. None were classified as 'definite' SIS, five were considered to be 'probable' SIS cases and 12 were classified as 'not' SIS primarily because there was an absence of a witnessed second impact. In addition, the veracity of teammate recall of concussive episodes, which is often the basis of a 'first impact' in such cases, was shown to be unreliable. Based on these results, the investigators concluded that there is a lack of evidence to support the claim that the second impact is a risk factor for diffuse cerebral swelling.

In the review paper,<sup>24</sup> the central issue is whether repeated concussion was a risk factor for cerebral swelling which is the putative definition of SIS. There is published evidence that acute (and delayed) brain swelling may occur following a single blow to the head, in association with a structural injury such as a subdural haematoma and in disorders of calcium channels, suggesting a possible genetic basis for some of these cases. Such events are virtually only seen in children and adolescents.

### Concussive convulsions

A variety of immediate motor phenomena (e.g. tonic posturing) or convulsive movements may accompany a concussion. Although dramatic, these clinical features are generally benign and require no specific management beyond the standard treatment of the underlying concussive injury. These dramatic phenomena are a non-epileptic manifestation of concussion.<sup>25</sup>

### Prolongation of symptoms

If a player recommences playing while symptomatic, post-concussive symptoms may be prolonged. It is important to be aware that studies have demonstrated measurable cognitive deficits in individuals even after the

symptoms have resolved, which argues for an increasingly conservative RTP strategy.<sup>17</sup> Premature RTP may also increase the chance of developing the 'post-concussive syndrome', in which fatigue, difficulty in concentration and headaches persist for some time, often months, following the original injury. This syndrome is uncommon in sport. These patients should undergo formal neuropsychological testing as well as an MRI brain scan and be evaluated by a physician experienced in concussion management. Other potential contributing factors should be assessed and treated where appropriate, for example vestibular system disturbance.

### Chronic traumatic encephalopathy (CTE)

Recent publications have suggested that US footballers may suffer similar neuropathological risks to boxers. Pathological case reports and cross-sectional studies have suggested that retired NFL footballers, who have had recurrent concussions during their sporting careers, disproportionately suffer from mild cognitive impairment, depression and other mental health problems. What is becoming increasingly clear from a number of diverse lines of research is that a percentage of footballers seem to suffer chronic or long-term sequelae.<sup>26</sup> While there has been an association demonstrated between recurrent head trauma and appearance of abnormal Tau protein in post-mortem assessment of brains, whether this is a consequence of head injury, the effect of brain injury on ageing, or the development of neurodegenerative disease unrelated to sports participation is unclear. At this time, very little is known about what type, frequency or amount of trauma is necessary to induce the accumulation of pathological proteins in the brain and more importantly why only a small number of athletes are at risk of CTE.<sup>18</sup> Nevertheless, until these issues are resolved, it is recommended that conservative management strategies are used to ensure player welfare.

### Mental health issues

Mental health issues (e.g. depression) have been reported as a long-term consequence of traumatic brain injury including sports-related concussion. Neuroimaging studies using functional MRI (fMRI) suggest that a depressed mood following concussion may reflect an underlying pathophysiological abnormality consistent with a limbic-frontal model of depression. All players with ongoing symptoms or a prolonged clinical course should be screened for depression.

### THE 'DIFFICULT' CONCUSSION

A 'difficult' concussion can be defined as one in which clinical recovery falls outside the expected window (i.e. 10-14 days).<sup>17</sup> The incidence of persistent symptoms

following sports-related concussion varies from about 10–30% depending on the cohort being investigated and definitions used.

### Clinical assessment

Common persistent symptoms include headache, dizziness, mood changes (e.g. depression/anxiety), 'difficulty concentrating', irritability, 'fatigue or low energy', 'difficulty sleeping' or 'feeling not quite right, in a fog or slowed down'. The symptoms are non-specific and overlap with other conditions such as structural head injury, cervicogenic headaches and anxiety/depression. Clinical assessment, therefore, requires careful history and a detailed, multimodal examination (including neurological, cognitive function, cervical spine, balance and vestibular function).

### Role of investigations

Formal neuropsychological testing is useful to identify persistent cognitive deficits, monitor recovery and help guide return to school or work plans.

Conventional neuroimaging (CT or MRI) should be considered in any athlete with persistent symptoms where there is any suspicion of an underlying structural brain injury. Advanced neuroimaging and other investigation techniques (e.g. diffusion tensor imaging, fMRI, magnetic resonance spectroscopy, electroencephalography) have demonstrated changes in cohorts of patients with persistent symptoms. Changes have also been observed in subjects well after clinical recovery following sports-related concussion. At present, the clinical significance of these changes remains unclear. Consequently, the use of advanced investigation techniques is currently not recommended in the routine management of athletes with concussion.

### Treatment

A brief period of rest is important in the acute period following sports-related concussion. There is no evidence, however, that prolonged rest is beneficial for athletes with persistent symptoms. Preliminary studies demonstrate that an active rehabilitation program ('sub-symptom threshold activity') may be useful for the management of cases where symptoms are prolonged.<sup>27–28</sup> Cervicovestibular rehabilitation may also be useful to facilitate recovery in cases with persistent symptoms.<sup>29</sup>

Other treatments may be used to manage specific symptoms. For example, manual or physical therapy may be used to treat myofascial pain or neck trigger points contributing to headaches; cognitive therapy may be useful for some patients with persistent cognitive

symptoms; and meditation, biofeedback or psychological therapy may benefit those who have problems with psychological symptoms.

Medications are often used to treat specific symptoms (e.g. analgesics for headache, anti-depressants), although there is limited evidence for their use in the setting of persistent post-concussive symptoms.

Overall, the difficult concussion should be managed in a multi-disciplinary manner. Ideally, this is in the setting of a concussion clinic with access to expertise in a wide range of areas.

### CHILDREN AND CONCUSSION IN SPORT

The CRT (Fig. 20.3) aims to identify concussion in children, youth and adults. It is simple to use and is designed so that anyone can use it. This tool is particularly useful at children's sports events that may not have a recognised health professional present. If a concussive injury is suspected, the child should be removed from play and sent urgently for medical evaluation.<sup>16</sup> It is never appropriate for a child or adolescent athlete with concussion to return to play on the same day as the injury regardless of the level of athletic performance.

For medical assessments in this setting, the SCAT3 (Fig. 20.2) is appropriate for use in children and adolescents older than 13 years of age and the Child SCAT3 (Fig. 20.6) for 12 years and under. An additional consideration in assessing the child or adolescent athlete with a concussion is the need to include parent input as well as teacher and school input when appropriate.

The decision to use neuropsychological testing is broadly the same as the adult assessment paradigm. However, timing of testing may differ in order to assist planning in school and home management (and may be performed while the child is still symptomatic). If cognitive testing is performed then it must be developmentally sensitive until late teen years due to the ongoing cognitive maturation that occurs during this period which, in turn, makes the utility of comparison to either the person's own baseline or to population norms limited. In this age group it is more important to consider the use of trained neuropsychologists to interpret assessment data, particularly in children with learning disorders and/or ADHD who may need more sophisticated assessment strategies.

Children should not be returned to practice or play until clinically completely symptom free, which may require a longer time frame than for adults. In addition, the concept of 'cognitive rest' is highlighted with special reference to a child's need to limit exertion with activities of daily living and to limit scholastic and other cognitive stressors (e.g. text messaging, video games) while symptomatic.

### What is childSCAT3?

The ChildSCAT3 is a standardized tool for evaluating injured children for concussion and can be used in children aged from 5 to 12 years. It supersedes the original SCAT and the SCAT2 published in 2005 and 2009, respectively. For older persons, ages 13 years and over, please use the SCAT3. The ChildSCAT3 is designed for use by medical professionals. If you are not qualified, please use the Sport Concussion Recognition Tool. Pre-season baseline testing with the ChildSCAT3 can be helpful for interpreting post-injury test scores.

Specific instructions for use of the ChildSCAT3 are provided on page 3. If you are not familiar with the ChildSCAT3, please read through these instructions carefully. This tool may be freely copied in its current form for distribution to individuals, teams, groups and organizations. Any revision and any reproduction in a digital form require approval by the Concussion in Sport Group.

**NOTE:** The diagnosis of a concussion is a clinical judgment, ideally made by a medical professional. The ChildSCAT3 should not be used solely to make, or exclude, the diagnosis of concussion in the absence of clinical judgment. An athlete may have a concussion even if their ChildSCAT3 is "normal".

### What is a concussion?

A concussion is a disturbance in brain function caused by a direct or indirect force to the head. It results in a variety of non-specific signs and/or symptoms (like those listed below) and most often does not involve loss of consciousness. Concussion should be suspected in the presence of any one or more of the following:

- Symptoms (e.g., headache), or
- Physical signs (e.g., unsteadiness), or
- Impaired brain function (e.g., confusion) or
- Abnormal behaviour (e.g., change in personality).

## SIDELINE ASSESSMENT

### Indications for Emergency Management

**NOTE:** A hit to the head can sometimes be associated with a more severe brain injury. If the concussed child displays any of the following, then do not proceed with the ChildSCAT3; instead activate emergency procedures and urgent transportation to the nearest hospital.

- Glasgow Coma score less than 15
- Deteriorating mental status
- Potential spinal injury
- Progressive, worsening symptoms or new neurologic signs
- Persistent vomiting
- Evidence of skull fracture
- Post-traumatic seizures
- Coagulopathy
- History of Neurosurgery (eg Shunt)
- Multiple injuries

**1 Glasgow coma scale (GCS)**

<b>Best eye response (E)</b>	
No eye opening	1
Eye opening in response to pain	2
Eye opening to speech	3
Eyes opening spontaneously	4
<b>Best verbal response (V)</b>	
No verbal response	1
Incomprehensible sounds	2
Inappropriate words	3
Confused	4
Oriented	5
<b>Best motor response (M)</b>	
No motor response	1
Extension to pain	2
Abnormal flexion to pain	3
Flexion/Withdrawal to pain	4
Localizes to pain	5
Obeys commands	6
<b>Glasgow Coma score (E + V + M)</b>	<b>15</b>

GCS should be recorded for all athletes in case of subsequent deterioration.

(a)

Figure 20.6 Child SCAT3™

REPRODUCED WITH PERMISSION FROM BRITISH JOURNAL OF SPORTS MEDICINE

### Potential signs of concussion?

If any of the following signs are observed after a direct or indirect blow to the head, the child should stop participation, be evaluated by a medical professional and **should not be permitted to return to sport the same day** if a concussion is suspected.

Any loss of consciousness?	Y	N
"If so, how long?"		
Balance or motor incoordination (stumbles, slow/laboured movements, etc.)?	Y	N
Disorientation or confusion (inability to respond appropriately to questions)?	Y	N
Loss of memory	Y	N
"If so, how long?"		
"Before or after the injury?"		
Blank or vacant look	Y	N
Visible facial injury in combination with any of the above	Y	N

### 2 Sideline Assessment – child-Maddocks Score<sup>3</sup>

"I am going to ask you a few questions, please listen carefully and give your best effort."

(Modified Maddocks questions (1 point for each correct answer))

Where are you at now?	0	1
Is it before or after lunch?	0	1
What did you have last lesson/class?	0	1
What is your teacher's name?	0	1
<b>child-Maddocks score</b>	<b>0</b>	<b>4</b>

Child-Maddocks score is for sideline diagnosis of concussion only and is not used for serial testing.

**Any child with a suspected concussion should be REMOVED FROM PLAY, medically assessed and monitored for deterioration (i.e., should not be left alone). No child diagnosed with concussion should be returned to sports participation on the day of injury.**

## BACKGROUND

Name:	Date/Time of Injury:
Examiner:	Date of Assessment:
Sport/team/school:	
Age:	Gender: M F
Current school year/grade:	
Dominant hand:	right left neither
Mechanism of Injury ("tell me what happened"):	

### For Parent/carer to complete:

How many concussions has the child had in the past?	
When was the most recent concussion?	
How long was the recovery from the most recent concussion?	
Has the child ever been hospitalized or had medical imaging done (CT or MRI) for a head injury?	Y N
Has the child ever been diagnosed with headaches or migraines?	Y N
Does the child have a learning disability, dyslexia, ADD/ADHD, seizure disorder?	Y N
Has the child ever been diagnosed with depression, anxiety or other psychiatric disorder?	Y N
Has anyone in the family ever been diagnosed with any of these problems?	Y N
Is the child on any medications? If yes, please list:	Y N

## SYMPTOM EVALUATION

**3 Child report**

Name: \_\_\_\_\_

	never	rarely	sometimes	often
I have trouble paying attention	0	1	2	3
I get distracted easily	0	1	2	3
I have a hard time concentrating	0	1	2	3
I have problems remembering what people tell me	0	1	2	3
I have problems following directions	0	1	2	3
I daydream too much	0	1	2	3
I get confused	0	1	2	3
I forget things	0	1	2	3
I have problems finishing things	0	1	2	3
I have trouble figuring things out	0	1	2	3
It's hard for me to learn new things	0	1	2	3
I have headaches	0	1	2	3
I feel dizzy	0	1	2	3
I feel like the room is spinning	0	1	2	3
I feel like I'm going to faint	0	1	2	3
Things are blurry when I look at them	0	1	2	3
I see double	0	1	2	3
I feel sick to my stomach	0	1	2	3
I get tired a lot	0	1	2	3
I get tired easily	0	1	2	3

Total number of symptoms (Maximum possible 20) \_\_\_\_\_

Symptom severity score (Maximum possible 20 x 3 = 60) \_\_\_\_\_

☐ self rated ☐ clinician interview ☐ self rated and clinician monitored

**4 Parent report**

The child

	never	rarely	sometimes	often
has trouble sustaining attention	0	1	2	3
is easily distracted	0	1	2	3
has difficulty concentrating	0	1	2	3
has problems remembering what he/she is told	0	1	2	3
has difficulty following directions	0	1	2	3
tends to daydream	0	1	2	3
gets confused	0	1	2	3
is forgetful	0	1	2	3
has difficulty completing tasks	0	1	2	3
has poor problem solving skills	0	1	2	3
has problems learning	0	1	2	3
has headaches	0	1	2	3
feels dizzy	0	1	2	3
has a feeling that the room is spinning	0	1	2	3
feels faint	0	1	2	3
has blurred vision	0	1	2	3
has double vision	0	1	2	3
experiences nausea	0	1	2	3
gets tired a lot	0	1	2	3
gets tired easily	0	1	2	3

Total number of symptoms (Maximum possible 20) \_\_\_\_\_

Symptom severity score (Maximum possible 20 x 3 = 60) \_\_\_\_\_

Do the symptoms get worse with physical activity? ☐ Y ☐ N

Do the symptoms get worse with mental activity? ☐ Y ☐ N

☐ parent self rated ☐ clinician interview ☐ parent self rated and clinician monitored

**Overall rating** for parent/teacher/coach/carer to answer:  
How different is the child acting compared to his/her usual self?

Please circle one response:

☐ no different ☐ very different ☐ unsure ☐ N/A

Name of person completing Parent-report: \_\_\_\_\_

Relationship to child of person completing Parent-report: \_\_\_\_\_

Scoring on the ChildSCAT3 should not be used as a stand-alone method to diagnose concussion, measure recovery or make decisions about an athlete's readiness to return to competition after concussion.

**7 Balance examination**

Do one or both of the following tests.

Footwear (shoes, barefoot, braces, tape, etc.) \_\_\_\_\_

**Modified Balance Error Scoring System (BESS) testing<sup>1</sup>**

Which foot was tested (i.e. which is the non-dominant foot) ☐ Left ☐ Right

Testing surface (hard floor, field, etc.) \_\_\_\_\_

**Condition**

Double leg stance: \_\_\_\_\_ Errors \_\_\_\_\_

Tandem stance (non-dominant foot at back): \_\_\_\_\_ Errors \_\_\_\_\_

**Tandem gait<sup>4,7</sup>**

Time taken to complete (best of 4 trials): \_\_\_\_\_ seconds

If child attempted, but unable to complete tandem gait, mark here ☐

**8 Coordination examination**

**Upper limb coordination**

Which arm was tested: ☐ Left ☐ Right

Coordination score \_\_\_\_\_ of 1

**9 SAC Delayed Recall<sup>4</sup>**

Delayed recall score \_\_\_\_\_ of 5

Since signs and symptoms may evolve over time, it is important to consider repeat evaluation in the acute assessment of concussion.

## INSTRUCTIONS

Words in *italics* throughout the ChildSCAT3 are the instructions given to the child by the tester.

### Sideline Assessment – child-Maddocks Score

To be completed on the sideline/in the playground, immediately following concussion. There is no requirement to repeat these questions at follow-up.

### Symptom Scale<sup>a</sup>

In situations where the symptom scale is being completed after exercise, it should still be done in a resting state, at least 10 minutes post exercise.

#### On the day of injury

- the child is to complete the Child Report, according to how he/she feels now

#### On all subsequent days

- the child is to complete the Child Report, according to how he/she feels today, **and**  
- the parent/carer is to complete the Parent Report according to how the child has been over the previous 24 hours.

### Standardized Assessment of Concussion – Child Version (SAC-C)<sup>a</sup>

#### Orientation

Ask each question on the score sheet. A correct answer for each question scores 1 point. If the child does not understand the question, gives an incorrect answer, or no answer, then the score for that question is 0 points.

#### Immediate memory

*"I am going to read you a string of words. I will read you a list of words and when I am done, repeat back as many words as you can remember, in any order."*

#### Trials 2 & 3:

*"I am going to repeat the same list again. Repeat back as many words as you can remember in any order, even if you said the word before."*

Complete all 3 trials regardless of score on trial 1 & 2. Read the words at a rate of one per second. **Score 1 pt. for each correct response.** Total score equals sum across all 3 trials. Do not inform the child that delayed recall will be tested.

#### Concentration

##### Digits Backward:

*"I am going to read you a string of numbers and when I am done, you repeat them back to me backwards, in reverse order of how I read them to you. For example, if I say 7-1, you would say 1-7."*

If correct, go to next string length. If incorrect, read trial 2. **One point possible for each string length.** Stop after incorrect on both trials. The digits should be read at the rate of one per second.

#### Days in Reverse Order:

*"Now tell me the days of the week in reverse order. Start with Sunday and go backward. So you'll say Sunday, Saturday... Go ahead."*

**1 pt. for entire sequence correct**

#### Delayed recall

The delayed recall should be performed after completion of the Balance and Coordination Examination.

*"Do you remember that list of words I read a few times earlier? Tell me as many words from the list as you can remember in any order."*

Circle each word correctly recalled. **Total score equals number of words recalled.**

### Balance examination

These instructions are to be read by the person administering the ChildSCAT3, and each balance task should be **demonstrated to the child**. The child should then be asked to copy what the examiner demonstrated.

#### Modified Balance Error Scoring System (BESS) testing<sup>3</sup>

This balance testing is based on a modified version of the Balance Error Scoring System (BESS)<sup>3</sup>. A stopwatch or watch with a second hand is required for this testing.

*"I am now going to test your balance. Please take your shoes off, roll up your pant legs above ankle (if applicable), and remove any ankle taping (if applicable). The test will consist of two different parts."*

##### (a) Double leg stance:

*The first stance is standing with the feet together with hands on hips and with eyes closed. The child should try to maintain stability in that position for 20 seconds. You should inform the child that you will be counting the number of times the child moves out of this position. You should start timing when the child is set and the eyes are closed.*

##### (b) Tandem stance:

*Instruct the child to stand heel-to-toe with the non-dominant foot in the back. Weight should be evenly distributed across both feet. Again, the child should try to maintain stability for 20 seconds with hands on hips and eyes closed. You should inform the child that you will be counting the number of times the child moves out of this position. If the child stumbles out of the position, instruct him/her to open the eyes and return to the start position and continue balancing. You should start timing when the child is set and the eyes are closed.*

#### (c)

### Balance testing – types of errors – Parts (a) and (b)

1. Hands lifted off iliac crest
2. Opening eyes
3. Step, stumble, or fall
4. Moving hip into > 30 degrees abduction
5. Lifting forefoot or heel
6. Remaining out of test position > 5 sec.

Each of the 20-second trials is scored by counting the errors, or deviations from the proper stance, accumulated by the child. The examiner will begin counting errors only after the child has assumed the proper start position. **The modified BESS is calculated by adding one error point for each error during the two 20-second tests. The maximum total number of errors for any single condition is 10.** If a child commits multiple errors simultaneously, only one error is recorded but the child should quickly return to the testing position, and counting should resume once subject is set. Children who are unable to maintain the testing procedure for a minimum of **five seconds** at the start are assigned the highest possible score, ten, for that testing condition.

**OPTION:** For further assessment, the same 2 stances can be performed on a surface of medium density foam (e.g., approximately 50cm x 40cm x 6cm).

### Tandem Gait<sup>4,5</sup>

Use a clock (with a second hand) or stopwatch to measure the time taken to complete this task. *Instruction for the examiner – Demonstrate the following to the child*

*The child is instructed to stand with their feet together behind a starting line (the line is kept about 1m from the examiner). Then, they walk in a forward direction as quickly and as accurately as possible along a 30m line (approximately 30m is marked on the ground). The child is instructed to walk in a forward direction, ensuring that they approximate their heel and toe on each step. Once they cross the end of the 30 m line, they turn 180 degrees and return to the starting point using the same gait. A total of 4 trials are done and the best time is retained. The examiner has the post if they step off the line, have a separator between their feet and toes, or if they touch or grab the examiner or an object. In this case, the time is not recorded and the trial repeated, if appropriate.*

*Explain to the child that you will time how long it takes them to walk to the end of the line and back.*

### Coordination examination

#### Upper limb coordination

##### Finger-to-nose (FTN) task:

The tester should **demonstrate it to the child**.

*"I am going to test your coordination now. Please sit comfortably on the chair with your eyes open and your arm (either right or left) outstretched (shoulder flexed to 90 degrees and elbow and fingers extended). When I give a start signal, I would like you to perform five successive finger to nose repetitions using your index finger to touch the tip of the nose as quickly and as accurately as possible."*

**Score: 5 correct repetitions in < 4 seconds = 1**

**Note for testers:** Children fail the test if they do not touch their nose, do not fully extend their elbow or do not perform five repetitions. **Failure should be scored as 0.**

Figure 20.6 (cont.) Child SCAT3<sup>™</sup>

## CHILD ATHLETE INFORMATION

Any child suspected of having a concussion should be removed from play, and then seek medical evaluation. The child must NOT return to play or sport on the same day as the suspected concussion.

### Signs to watch for

Problems could arise over the first 24–48 hours. The child should not be left alone and must go to a hospital at once if they develop any of the following:

- New Headache, or Headache gets worse
- Persistent or increasing neck pain
- Becomes drowsy or can't be woken up
- Can not recognise people or places
- Has Nausea or Vomiting
- Behaves unusually, seems confused, or is irritable
- Has any seizures (arms and/or legs jerk uncontrollably)
- Has weakness, numbness or tingling (arms, legs or face)
- Is unsteady walking or standing
- Has slurred speech
- Has difficulty understanding speech or directions

**Remember, it is better to be safe.**

**Always consult your doctor after a suspected concussion.**

### Return to school

Concussion may impact on the child's cognitive ability to learn at school. This must be considered, and medical clearance is required before the child may return to school. **It is reasonable for a child to miss a day or two of school after concussion, but extended absence is uncommon.** In some children, a graduated return to school program will need to be developed for the child. The child will progress through the return to school program provided that there is no worsening of symptoms. If any particular activity worsens symptoms, the child will abstain from that activity until it no longer causes symptom worsening. Use of computers and internet should follow a similar graduated program, provided that it does not worsen symptoms. This program should include communication between the parents, teachers, and health professionals and will vary from child to child. The return to school program should consider:

- Extra time to complete assignments/tests
- Quiet room to complete assignments/tests
- Avoidance of noisy areas such as cafeterias, assembly halls, sporting events, music class, shop class, etc
- Frequent breaks during class, homework, tests
- No more than one exam/day
- Shorter assignments
- Repetition/memory cues
- Use of peer helper/tutor
- Reassurance from teachers that student will be supported through recovery through accommodations, workload reduction, alternate forms of testing
- Later start times, half days, only certain classes

The child is not to return to play or sport until he/she has successfully returned to school/learning, without worsening of symptoms. **Medical clearance should be given before return to play.**

If there are any doubts, management should be referred to a qualified health practitioner, expert in the management of concussion in children.

### Return to sport

There should be no return to play until the child has successfully returned to school/learning, without worsening of symptoms.

**Children must not be returned to play the same day of injury.**

When returning children to play, they should **medically cleared and then follow a stepwise supervised program**, with stages of progression:

For example:

Rehabilitation stage	Functional exercise at each stage of rehabilitation	Objective of each stage
No activity	Physical and cognitive rest	Recovery
Light aerobic exercise	Walking, swimming or stationary cycling keeping intensity, 70% maximum predicted heart rate. No resistance training	Increase heart rate
Sport-specific exercise	Skating drills in ice hockey, running drills in soccer. No head impact activities	Add movement
Non-contact training drills	Progression to more complex training drills, eg passing drills in football and ice hockey. May start progressive resistance training	Exercise, coordination, and cognitive load
Full contact practice	Following medical clearance participate in normal training activities	Restore confidence and assess functional skills by coaching staff
Return to play	Normal game play	

There should be approximately 24 hours (or longer) for each stage and the child should drop back to the previous asymptomatic level if any post-concussive symptoms recur. Resistance training should only be added in the later stages.

If the child is symptomatic for more than 10 days, then review by a health practitioner, expert in the management of concussion, is recommended.

**Medical clearance should be given before return to play.**

### Notes:

## CONCUSSION INJURY ADVICE FOR THE CHILD AND PARENTS / CARERS

(To be given to the **person monitoring** the concussed child)

This child has received an injury to the head. A careful medical examination has been carried out and no sign of any serious complications has been found. It is expected that recovery will be rapid, but the child will need monitoring for the next 24 hours by a responsible adult.

**If you notice any change in behavior, vomiting, dizziness, worsening headache, double vision or excessive drowsiness, please call an ambulance to transport the child to hospital immediately.**

### Other important points:

- Following concussion, the child should rest for at least 24 hours.
- The child should avoid any computer, internet or electronic gaming activity if these activities make symptoms worse.
- The child should not be given any medications, including pain killers, unless prescribed by a medical practitioner.
- The child must not return to school until medically cleared.
- The child must not return to sport or play until medically cleared.

Clinic phone number

(d)

Figure 20.6 (cont.) Child SCAT3™

School attendance and activities should be considered and modified as appropriate to avoid provocation of symptoms.

Due to the different physiological response and longer recovery after concussion, and specific risks (e.g. diffuse cerebral swelling) related to head impact during childhood and adolescence, a more conservative RTP

approach is recommended.<sup>22</sup> It is appropriate to extend the amount of time of asymptomatic rest and/or the length of the graded exertion in children and adolescents. In the management paradigm of children post concussion, return to school should be achieved prior to consideration of return to sport.

# Headache

with TOBY HALL

*In the beginner's mind there are many possibilities, in the expert's mind there are few.*

Shunryu Suzuki, *Zen Mind, Beginner's Mind*

Headache is one of the most prevalent pain conditions present at all stages of life. It affects the majority of the global population and is among the top 10 causes of disability.<sup>1</sup> Despite this, the burden of headache has been largely underestimated, with headache disorders often dismissed as minor and undeserving of medical care.<sup>1, 2</sup> Although athletes suffer from the same causes of headache as non-athletes, there are several key causes of headache that relate directly to exercise or to the sport itself. An additional factor to consider is that headache can impair both training and sports performance.

The International Headache Society (IHS) classifies headache into a range of disorders comprising three broad categories with more than 300 underlying headache forms.<sup>3</sup> The majority of these disorders are not particularly relevant to an athletic population or the IHS definitions do not adequately cover the symptoms experienced by athletes.<sup>4</sup> Figure 21.1 lists the broad classification according to the IHS and the common headache disorders seen in sport.

## HEADACHE IN SPORT

The prevalence of headache directly related to sport has been poorly investigated or reported, although there is increasing attention in contact sport on concussion or trauma-related headache.<sup>5</sup> In a New Zealand university setting, 35% of athletes surveyed reported headaches, both traumatic and non-traumatic.<sup>6</sup> Importantly, 54% of people who reported headache associated with sport or exercise gave up their activity.<sup>7</sup> In some codes of football, more than 50% of athletes experience regular headaches from matches and training.<sup>4</sup>

While the latest edition of the IHS headache classification is comprehensive, it is not aimed specifically at a sporting

**Figure 21.1** Classification of headache

setting. Williams and Nukada proposed a simple framework for specific sporting headaches.<sup>8</sup> This included:

- effort-exertional headache
- effort migraine
- trauma-triggered migraine
- post-traumatic headache.

An alternative sports-specific headache organisational framework has been proposed that incorporates the non-sporting as well as sporting headaches.<sup>9</sup> Headaches are categorised as follows:

- a recognised headache syndrome (migraine, tension-type headache, cluster headache) coincidental to sporting activity

- headache arising from mechanisms that occur during exertion; these can be primary (mechanism unknown) or secondary where a causal factor can be demonstrated, such as a headache:
  - related to changes in cardiovascular parameters
  - related to trauma
  - arising from structures in the neck
  - arising from mechanisms that are specific to an individual sport.

## CLINICAL APPROACH TO THE PATIENT WITH HEADACHE

Headache is an unusual condition being both a symptom and a disease, which can make diagnosis and management challenging. Of primary importance is identifying when headache is a symptom of serious pathology such as a tumour, aneurysm, meningitis, subdural haemorrhage or space-occupying lesion. These are life-threatening events that the clinician must be vigilant for, and if suspected require urgent medical evaluation. Hence, a good knowledge of the following warning signals, or red flags, is essential:

- new, unaccustomed or atypical headache
- stiff neck or meningeal signs
- systemic symptoms (e.g. fever, weight loss, malaise)
- neurological symptoms (e.g. drowsiness, weakness, numbness of limbs)
- local extracranial symptoms (e.g. ear, sinus, teeth)
- changes in the pattern of headache
- headache increasing over a few days
- sudden onset of severe headache or headaches that wake the patient
- headache triggered by cough or Valsalva.

The majority of headaches are benign and do not require such intensive medical assessment.

### PRACTICE PEARL

*In each case, the clinician should seek a potential underlying cause for the headache, as this will influence management.*

Common illnesses that may provoke headache include respiratory tract infection, sinusitis and influenza. Drug-induced headaches are also common. The most common are alcohol and caffeine, but many other commonly used drugs can also provoke headache including analgesics, antibiotics, antifungals and antihypertensives. Of particular importance is the frequency of analgesic use. Analgesic medication used on more than 15 days per month may

sensitise the trigeminocervical nucleus, and is defined as medication overuse headache.<sup>10</sup> A thorough knowledge of the patient's drug history is therefore important.

Following the exclusion of headaches associated with red flags, drugs and infections, the clinician aims to differentiate between the more common headache categories: either primary or secondary headache. Primary headache includes migraine, exertional headache and tension-type headache. Secondary headache includes cervicogenic headache, temporomandibular dysfunction headache and concussion headache arising from musculoskeletal dysfunction around the neck and orofacial region.

Exertional headache follows exercise, and concussion post-traumatic headache follows a history of trauma. Tension-type headache typically presents without features of migraine or cervicogenic headache, and tends to be of a low-grade frequent bilateral headache described as pressing or squeezing. In contrast, differentiating cervicogenic headache from migraine is more challenging.

Although a comprehensive large-scale survey of people with 'pure' migraine and cervicogenic headache found that each has distinctive features (Table 21.1),<sup>11, 12</sup> in many cases features coexist, which makes a definitive diagnosis difficult.

## History

Headache location is unilateral in cervicogenic headache,<sup>13</sup> but is less so in migraine, often starting on one side of the head and spreading to the opposite side during a migraine attack. The presence of associated neck and arm symptoms should also be noted. Cervicogenic headache usually starts in the neck before spreading to the head, whereas migraine starts in the head and spreads to the neck.

The nature of onset can be informative. A sudden onset of severe, unfamiliar headache, with altered consciousness or cognition, may indicate a cerebral haemorrhage or other intracerebral pathology.<sup>14</sup> Cervicogenic headache typically has a more gradual onset. A recent history of a head and neck trauma, with or without concussion, is also relevant.

The intensity and temporal pattern is helpful in diagnosis. Migraine is episodic and more severe than cervicogenic headache, building up to a crescendo in a set time period (24–48 hours), unless early preventive analgesic medication is taken. Cervicogenic headache is typically less severe, does not have a set time period and does not progressively increase in intensity unless the provocative stimulus is maintained.

The relationship between exercise and headache onset is informative. Although exercise usually aggravates headaches of all types, brief episodes of headache brought

**Table 21.1** Summary of subjective diagnostic criteria contrasting migraine and cervicogenic headache<sup>9,10</sup>

	Migraine	Cervicogenic headache
Gender ratio	1.7 female/male	0.7 female/male
Age at onset	18 years	33 years
Headache onset	Anterior head	Posterior head/neck
Pain area	50% unilateral	Predominantly unilateral
Nausea	Frequent	Infrequent
Photo/phonophobia	Very frequent	Infrequent
Throbbing pain	Frequent	Infrequent
Pain on trunk forward bend	Very frequent	Infrequent
Migraine medication	Usually helpful	Not helpful
Neck position pain	Rare	Universal

on by exercise may indicate exertional headache. More prolonged headache brought on by exercise might indicate cervicogenic headache or exertional migraine. Hence, a cyclist who develops headache while riding could have exertional headache, but equally if they have an inadequately set-up bike and associated poor posture this might be causing stress on the neck and hence cervicogenic headache. Once migraine has started, exercise is usually provocative. Conversely, aerobic exercise may be helpful in reducing the frequency of headache attacks.<sup>15</sup>

#### PRACTICE PEARL

Headache aggravated by specific neck movements or postures in sport may indicate cervicogenic headache, and identifying provocative movement is usually helpful for planning manual therapy.

Rest usually helps alleviate all headache forms during an attack. For example, migraine is usually relieved by sleep, but this might not always be the case for cervicogenic headache, particularly if the sleeping position, mattress or pillow is not suitable.

Prior to the onset of migraine headache, there may be associated visual or sensory symptoms (migraine with aura). Photophobia, phonophobia, nausea and vomiting are also commonly associated with migraine headache and usually occur concurrently with the headache episode. The presence of neurological symptoms or systemic symptoms such as weight loss and malaise is a 'red flag' and may indicate a more serious cause of headache (e.g. tumour).

Common forms of secondary headache are associated with symptoms in the upper or lower respiratory tract, sinuses and temporomandibular joints (jaw clicking or painful limitation of mouth opening), or influenza-like symptoms. These features should be looked for to enable differentiation from primary headache.

A past history of head trauma, even if relatively minor, may be significant as subdural haematoma may present well after the trauma, even weeks later. Previous problems such as encephalitis or major systemic illnesses should also be recorded.

Psychological comorbidities are factors in cases where headache becomes long lasting, such as in chronic migraine where headache persists for more than 3 months.<sup>16</sup> An assessment of life stresses is an important part of the history. These include personal relationships, work pressures and problems related to the athlete's sporting activity. Identified problems require management as part of an overall care package.

#### Clinical measurement of headache

Headache is a complex multidimensional problem, which needs to be assessed using a range of different measurement tools including diaries and questionnaires. There are specific instruments that measure headache burden and severity.<sup>17</sup> Primary measures of headache include attack frequency or headache days per month, which can be combined with headache severity and duration to form an index.<sup>18</sup> Additional parameters include measures of disability and quality of life such as the headache disability inventory,<sup>19</sup> as well as medication consumption, psychiatric symptoms, stress and coping, and treatment satisfaction. Simply measuring headache frequency, intensity and duration as an outcome measure may be problematic as people tend

**Figure 21.2** Factors to consider in a headache evaluation

to either underestimate or overestimate their symptoms depending on how they feel at the time they are asked.<sup>17</sup> Hence evaluating a range of headache parameters is likely to give a clearer, bias-free estimate of change. Figure 21.2 illustrates typical measurements taken during evaluation.

## Examination

In all patients presenting with headache, a full neurological examination is required, and the skull, cervical spine and orofacial region must always be carefully examined. The examination should consist of some or all of the following components depending on the presence or absence of specific symptoms in the history:

- general appearance
- mental state
- speech
- skull examination
- cervical spine examination
- temporomandibular joint
- gait and stance
- pupils and fundi
- special senses (e.g. smell, vision, hearing)
- other cranial nerves
- motor system
- sensory system
- general examination.

## PRIMARY HEADACHE

Primary headache includes migraine, tension-type headache, medication overuse headache, exercise-related headache and some types of post-traumatic headache.

In the general population, the 1-year prevalence rate for primary headache is 62%.<sup>20</sup> By survey, approximately 40% of migraine sufferers experience migraine precipitated by exercise, and 34% of Australian rules football players suffered migraine according to IHS criteria, a rate higher than population controls.<sup>7</sup> In that study, almost 60% of subjects experienced regular headaches related to sport.<sup>4</sup>

## Migraine

Previously primary headache, in particular migraine, was thought to be a vascular disorder, or due to cortical spreading depression. More recent evidence points to abnormality of brain function leading to a chain of events in the periphery.<sup>21-23</sup> In simple terms, migraine pain can be thought of as an altered perception of normality, such that normal sensory input is misinterpreted as pain.<sup>24</sup> This concept of the variable modulation of sensory input is explained in Lorimer Moseley's YouTube video 'Why things hurt' (<http://ow.ly/S9n0h>). (See also Chapters 5 and 6.)

The neuroanatomical basis for migraine is the trigeminocervical nucleus. The migraine pain process is likely to be a combination of direct factors, that is, activation of the trigeminal nociceptors, in concert with a reduction in the normal functioning of the centrally mediated endogenous pain control pathways that normally gate that pain.<sup>25</sup> Thus there are both central and peripheral mechanisms involved.

Migraine is broadly categorised into migraine with and without aura. An aura is a specific set of neurological symptoms that typically precede the headache which include visual disturbances (e.g. scotomas), paraesthesia, vertigo, hemiplegia and ophthalmoplegia. Although most people think of migraine as headache alone, the true migraine sufferer usually notices a spectrum of symptoms, including nausea, vomiting, diarrhoea and weight gain. The important point for sports clinicians is that there does not have to be an aura. The IHS criteria for the diagnosis of migraine without aura are shown in Table 21.2.<sup>3</sup>

## Clinical features

The typical features of migraine are precipitation by a change in homeostasis such as tiredness, temperature, altitude, thirst, hunger or stress. Ensuing headache pain is described as sharp and intense, throbbing or beating in time with their pulse. Commonly, it begins in the temple or forehead on both sides. When it starts on one side, it may spread to the other side. Occasionally, the headache begins at the back of the head and moves forwards.

The common neurological accompaniments to migraine with aura are visual. Patients speak of bright or dark objects often to one side of the visual field. These objects may shine or flicker and typically move across the visual field. The visual symptoms usually last about 20 minutes

**Table 21.2 Diagnostic criteria for migraine without aura<sup>3</sup>**

- A. At least five attacks fulfilling criteria B–D below
- B. Headache attacks lasting 4–72 hours
- C. Headache has at least two of the following four characteristics:
1. unilateral location
  2. pulsating quality
  3. moderate or severe pain intensity
  4. aggravation by or causing avoidance of routine physical activity (e.g. walking or climbing stairs)
- D. During headache at least one of the following:
1. nausea and/or vomiting
  2. photophobia and phonophobia
- E. Not better accounted for by another diagnosis

and most often clear before the sensory, cognitive or headache symptoms begin. Sensory symptoms are usually described as tingling, pricking or pins and needles. These commonly commence in the face or fingers and gradually spread up the limb or over the same side of the body. Nausea, vomiting and dizziness are common during or after the attack.

### Precipitating factors in migraine

A number of precipitating factors in addition to a change in homeostasis are commonly found in association with migraine headaches. These are:

- endocrine changes (e.g. premenstrual or menstrual, oral contraceptive pills, pregnancy, puberty, menopause, hyperthyroidism)
- metabolic changes (e.g. anaemia, thyroid disease)
- infective causes (e.g. fever, rhinitis)
- change in activity including extreme exercise
- alcohol
- drugs (e.g. glyceryl trinitrate [nitroglycerine], nitrates, indomethacin).

Chocolate and cheese are anecdotally reported triggers of migraine, but this is not confirmed in trials.<sup>26</sup>

### Treatment

Although sleep and resting quietly in a dark room often helps alleviate a migraine attack, the primary method of active treatment is typically pharmacological. High-dose aspirin (ASA) (900 to 1200 mg), often combined with an antiemetic, is the drug of choice in the acute phase. Other acute agents such as oral, intranasal or parenteral triptans may be used as rescue medications if the initial therapy is unsuccessful. Determining the best drug option depends on a number of patient factors as well as the nature of the headache and timing of treatment. This is best done by a medical practitioner experienced in this area. A person experiencing frequent or disabling migraine episodes,

**Figure 21.3** Management of migraine

especially when he or she is losing considerable time off work or school, may find prophylactic therapy necessary.

The long-term management of migraine should be multifactorial (Fig. 21.3). An important part of this plan is to identify and avoid precipitating factors. Central to this is the patient's understanding of homeostasis, maintaining equilibrium through adequate diet, hydration and sleep, as well as reducing stress and anxiety.<sup>27</sup> Neuroscience education may also be valuable in this regard, and involves the careful explanation of pain mechanisms and central sensitisation. Other options include traditional herbal remedies such as 'feverfew'.

Exercise can induce and exacerbate migraine, but exercise can also activate a pain modulatory mechanism, ideal in the management of migraine.<sup>28</sup> The prophylactic effects of exercise in migraine were shown in a randomised controlled

trial.<sup>29</sup> Intervention comprised three arms: home relaxation; controlled aerobic exercise on a static bike; or the oral medication topiramate. The study included an extended follow-up period. Exercise was equally effective as medication in reducing episodes of migraine. A second pilot study evaluated the effects of an 8-week running program and also found positive benefits compared to a control group.<sup>15</sup>

It is critical in the management of migraine and other forms of headache that the use of repeated doses of analgesia alone be avoided. One of the consequences of the overuse of analgesic medication is medication overuse headache, which becomes a self-generating headache. The underlying mechanisms of medication overuse headache appear similar to migraine with alteration in cortical neuronal excitability and central sensitisation. The diagnosis is based on the presence of chronic headache on 15 days per month for 3 months, with simple analgesic medication taken on 15 days per month.<sup>3</sup> The condition can be managed with variable success with a structured management program.<sup>30</sup> For this reason, the use of simple analgesics in headache treatment should be limited to a maximum of 3 days per week. Drug management should be directed at the cause of the problem, not simply short-term pain relief.

### Primary exercise headache

Primary exercise headache is precipitated by exercise in the absence of any intracranial disorder. It has been reported in association with weightlifting, cycling, running and other sporting activities. The IHS criteria include that the headache:

- is specifically brought on by sustained strenuous physical exercise
- has a pulsating quality that lasts from 5 minutes to 48 hours
- is prevented by avoiding excessive exertion
- occurs particularly in hot weather or at high altitude.<sup>3</sup>

The onset of the headache can be with straining and Valsalva manoeuvres such as those seen in weightlifting and competitive swimming. The prevalence may be high, as headache consistent with primary exercise headache was reported in 26% of 4000 competitors in a tough cycling event in Holland, and was particularly associated with extreme exertion, low fluid intake and warm weather.<sup>31</sup> In the Vaga study in Norway, 12% of a sample of 1646 people were reported to have primary exercise headache.<sup>32</sup> Patients with this form of headache have significantly higher prevalence of internal jugular venous valve incompetence, which suggests that intracranial venous congestion caused by retrograde jugular venous flow may play a role in the pathophysiology of this disorder.<sup>33</sup> The major differential diagnoses are subarachnoid haemorrhage, cervical arterial dissection and reversible

cerebral vasoconstriction syndrome, which need to be excluded by the appropriate investigations.

It has been postulated that primary exercise headache is due to dilatation of the pain-sensitive venous sinuses at the base of the brain as a result of increased cerebral arterial pressure due to exertion.<sup>34</sup> In weight lifters, systolic blood pressure may reach levels above 400 mmHg and diastolic pressures above 300 mmHg with maximal lifts.

The management of this condition involves either avoiding the precipitating activity or drug treatment, for example, indomethacin (25 mg three times a day). In practice, the headaches tend to recur over weeks to months and then slowly resolve, although in some cases they may be lifelong.

Exertion may also be a triggering factor in migraine. In this case, the presentation shows the typical pattern of migraine with exertion as the precipitating factor. Most patients with this condition describe the migraine beginning immediately after exercise, more frequently when the exercise has been vigorous. Exertional migraine is often severe and like primary exercise headache may be worse in hot weather. Modulation of exercise programs including adequate warm up, particularly prior to intense periods of exercise or before a game, is important. Where this does not help, migraine prophylactic medication may be required.

## SECONDARY HEADACHE

### Cervicogenic headache

A large survey of the general population revealed that people who suffer from headache seek physical treatment from physiotherapists and other complementary medical practitioners.<sup>35</sup> These people believe that their headache may be a referred phenomenon from a disorder affecting structures in their cervical spine. While not all patients with headache respond to these varied treatments, many do and there is now substantial evidence of a distinct subgroup of headache, termed cervicogenic headache, where treatment to the cervical spine has a substantial lasting effect.<sup>36</sup>

### Mechanism

The underlying pathophysiology of cervicogenic headache is one of convergence, whereby afferents from the upper three cervical nerve roots converge in the same brain region as trigeminal afferents.<sup>37</sup> Hence, in the presence of sensitisation of this complex, cervical afferent input is misinterpreted, and as well as perceiving neck pain, headache is also felt. Evidence of such sensitisation in cervicogenic headache was shown in a study comparing trigeminocervical sensory processing in patients with cervical facet joint pain with and without headache.<sup>38</sup>

Sensitisation of the trigeminocervical nucleus is an important factor in many different forms of headache.<sup>38-40</sup> To explain this, it has been postulated that primary headaches form a spectrum, with shared common

pathophysiological mechanisms,<sup>41</sup> and with cervicogenic headache one part of this spectrum,<sup>42</sup> despite being a secondary headache. Notwithstanding this shared pathophysiology among different headache forms, it is apparent from systematic reviews that different headache forms respond to different forms of intervention; for example, in the long-term, migraine does not respond to physical intervention.<sup>43</sup> Knowledge of the underlying mechanisms of headache may provide insight into potential management and will be discussed later.

### Clinical features

A thorough history and comprehensive examination is required.

#### History

The subjective features of cervicogenic headache contrast to those reported by people with migraine and other headache forms. Table 21.3 identifies the characteristics

of cervicogenic headache and Table 21.1 illustrates the difference in presentation between migraine and cervicogenic headache based on a survey of all people with chronic headache evaluated in a small town in Norway.<sup>9, 10</sup> Despite this, it can still be difficult to distinguish migraine from cervicogenic headache and an incorrect diagnosis is made in up to 50% of cases.<sup>44, 45</sup>

A good example might be a cyclist who develops headache during training after a specific time period on his or her bike. This could be exercise-induced migraine or cervicogenic headache from neck stress as a consequence of an incorrectly adjusted bike or poor posture and associated altered muscle function. In this case, the physical examination becomes increasingly important in differential diagnosis. A further difficulty is that patients more often than not present with multiple rather than single headache forms, making definitive diagnosis more challenging. Amiri et al. reported that 55% of subjects in a sample of 196 people had multiple forms of headache, with up to four different types.<sup>46</sup>

**Table 21.3 Classification of cervicogenic headache**

	International Headache Study Group <sup>47</sup>	International Headache Society <sup>3</sup>
Symptoms	<ul style="list-style-type: none"> <li>• Unilateral headache without side shift</li> <li>• Ipsilateral neck, shoulder and arm pain of a rather vague, non-radicular nature</li> <li>• Pain episodes of varying duration or fluctuating, continuous pain</li> <li>• Moderate, non-excruciating pain, usually of a non-throbbing nature</li> <li>• Pain starting in the neck, eventually spreading to head, where the maximum pain is often located</li> <li>• Pain triggered by neck movement and/or sustained awkward position</li> <li>• Sustained neck trauma prior to the onset</li> <li>• Autonomic symptoms and signs (e.g. nausea, vomiting, dizziness, photo- and phonophobia, blurred vision)</li> </ul>	A. Any headache fulfilling criterion C
Physical examination	<ul style="list-style-type: none"> <li>• Reduced cervical spine range of motion</li> <li>• Symptoms on palpation of the cranium or neck</li> <li>• Anaesthetic blockades abolish the pain transiently</li> </ul>	B. Clinical, laboratory and/or imaging evidence of a neck disorder, known to be able to cause headache C. Evidence of causation demonstrated by at least two of the following: <ol style="list-style-type: none"> <li>1. Headache has developed in temporal relation to the onset of the neck disorder</li> <li>2. Headache has significantly improved in parallel with improvement in the neck disorder</li> <li>3. Cervical range of motion is reduced and headache made worse by provocative manoeuvres</li> <li>4. Headache is abolished following cervical diagnostic anaesthetic blockade</li> </ol>
Other		D. Not better accounted for by another headache diagnosis

### Examination

Any structure innervated by the upper three cervical nerve roots is a potential contributing factor to sensitisation of the trigeminocervical nucleus and a factor in cervicogenic headache, hence a thorough clinical examination is required of these structures including the cervical articulations C0–1, C1–2 and C2–3, as well as cervical myofascial and neural structures. Caution is required as abnormalities found do not necessarily indicate the involvement of the cervical spine in headache and need to be considered in a diagnostic framework. For example, cervical movement impairments<sup>48</sup> and abnormal neurodynamic tests<sup>49</sup> have been reported in people with migraine.

There are a number of classification systems described to aid in identifying cervicogenic headache. These include those published by the IHS<sup>3</sup> and the International Headache Study Group<sup>13</sup> and are shown in Tables 21.1 and 21.3. Using the criteria in Table 21.1, it is possible to gain a level of confidence regarding the diagnosis of cervicogenic headache, with five criteria required for diagnosis.<sup>47</sup> Successful management from treatment directed to the cervical spine would be confirmatory evidence based on the IHS criteria.<sup>3</sup> In the absence of these criteria, further clinical evaluation should be undertaken.

#### PRACTICE PEARL

Examination of the patient with suspected cervicogenic headache involves a systematic examination of the articular, myofascial and neural structures of the cervical and orofacial region, including temporomandibular joints.

As with any musculoskeletal examination, one of the aims of the examination is to reproduce the patient's symptoms, but this by itself does not indicate a musculoskeletal cause for pain. In a recent study, headache was reproduced on palpation of the cervical spine in all but one patient with migraine and tension-type headache.<sup>42</sup> If headache can be provoked and, importantly, then relieved by manual techniques to the cervical spine then there is greater confidence of a cervical musculoskeletal cause and the potential for such treatment to be effective in the management.

Articular function can be determined by examining range of motion of the cervical spine, either in single cardinal planes or combined. Combining movements

**Figure 21.4** The cervical flexion–rotation test

increases the potential to identify movement impairment at the segmental levels between the occiput and C3. One example is the flexion-rotation test (Fig. 21.4), which can be used to isolate impairment of movement in the upper cervical spine. The neck is placed in end-range flexion and range of rotation to each side recorded. Normal range is 44° to each side.<sup>50</sup> The minimum cut-off value for a positive test is approximately 33° and there is a close relationship between headache severity and restricted range of movement (ROM) on a positive test.<sup>51–54</sup> This test has also been shown to be helpful, with good diagnostic accuracy, in distinguishing people with migraine from those with cervicogenic headache.<sup>52</sup>

A positive test is not universal in cervicogenic headache, but is found in as many as 72%.<sup>53</sup> While the test has been shown to be a valid marker of C1–2 segmental movement in normal people,<sup>55</sup> potentially unilateral altered suboccipital muscle tone (obliquus capitis inferior) associated with any painful articulation above C3, may give a positive flexion-rotation test. With further careful examination of the articular structures by palpation and segmental motion tests, it is possible to determine the spinal level of involvement.<sup>56</sup>

Temporomandibular disorder (TMD) is a common accompaniment to different headache forms, not specifically cervicogenic headache.<sup>57</sup> Evidence for the relationship between impairment of the cervical spine and TMD is shown in the significant correlation ( $r = 0.82$ ) between jaw disability and neck disability.<sup>58</sup> Upper cervical movement impairment identified by the flexion-rotation test is found in people with TMD,<sup>59</sup> and in people with TMD and cervicogenic headache.<sup>60</sup> Careful examination of the temporomandibular joints and

orofacial muscles should be performed according to recommended guidelines.<sup>61</sup>

Identification of impairment of cervical motor control and myofascial system is important in cervicogenic headache evaluation,<sup>62-65</sup> as illustrated by evidence of long-term improvement in cervicogenic headache symptoms following retraining cervical and scapular motor control.<sup>66</sup> Impairment includes loss of postural alignment (forward head posture) and neuromuscular control as well as muscle weakness, endurance and extensibility.<sup>67</sup>

Impairments of craniocervical flexion control are some of the defining features of neck-related headache.<sup>62, 63, 68</sup> This test evaluates the deep neck flexor muscles, which typically become substituted by the superficial flexors sternocleidomastoid, hyoids and platysma. Similar impairments in craniocervical flexion control have not been found in migraine or tension-type headache according to one study,<sup>62</sup> but were in tension-type headache in another.<sup>69</sup> Other changes to the muscle system in cervicogenic headache include evidence of muscle tightness<sup>65</sup> and trigger points.<sup>70</sup> See Chapter 23 for more details of evaluation of cervical muscle control.

Sensitisation of the upper cervical neural tissue is found in approximately 10% of cases with cervicogenic headache, less commonly when compared to the cervicobrachial region.<sup>65, 71</sup> Identification is important, as the presence of such sensitisation is likely to lead to treatment failure unless addressed. Typically, the patient will adopt an antalgic forward head posture with retraction and upper cervical flexion will be provocative and limited in range. Suboccipital muscle tone may be raised as a protective measure. Neurodynamic tests (Chapter 15), such as in Figure 21.5 involving upper cervical spine flexion with the arms in a neural provocative position, should reproduce head pain. The upper cervical neural tissue (e.g. greater occipital nerve) is likely to be sensitive to palpation in positive cases (Fig. 21.6).

In this section, various aspects of examination have been described to aid in the identification of cervicogenic headache. While the individual items of assessment may be of importance, consideration of multiple physical examination criteria is likely to increase the accuracy of diagnosis. This is supported by one study which revealed that collectively, impairment in motor control identified by the craniocervical flexion test and restricted neck movement, in association with evidence on manual examination of upper cervical joint dysfunction had 100% sensitivity and 94% specificity to identify cervicogenic headache.<sup>62</sup>

**Figure 21.5** Upper cervical neurodynamic test involving upper cervical spine flexion with the arms in various neural provocative positions, with an aim to reproduce head pain

**Figure 21.6** Palpation of the greater occipital nerve

**Figure 21.7** Management of cervicogenic headache

### Treatment

The clinician's confidence in diagnosis of cervicogenic headache, and thus potential for response to physical interventions, are improved by combining information from all aspects of the examination, as currently there is no consensus as to which examination criteria predict success for cervicogenic headache.<sup>72, 73</sup> Hence treatment, as illustrated in Figure 21.7, should ideally target all factors identified during the examination as contributing to the athlete's problem. An important factor associated with recovery from neck pain is sleep quality,<sup>74</sup> hence physical factors (articular, neural and muscle function) are not the only ones to consider in management. Since cervicogenic headache is associated with sensitisation of the trigeminocervical nucleus, factors that might reduce this, such as neuroscience education and lifestyle management, as well as reducing stress and anxiety, should also be considered.

Evidence for a multisystem approach to management was shown in a multicentre randomised controlled trial.<sup>66</sup> While manipulation/mobilisation and, separately, motor control re-education were found to be effective in the long-term, combining both these approaches was found to be more effective.

There is evidence for a range of different manual therapy techniques in management of cervicogenic headache. Manipulation of the cervical spine may be effective,<sup>75</sup> but is potentially more hazardous and has been found to be no more effective than more gentle, potentially less dangerous forms of treatment including joint mobilisation or Mulligan mobilisation with movement.<sup>76</sup> Joint

**Figure 21.8** Passive upper cervical rotation mobilisation technique

COURTESY OF TOBY HALL

mobilisation might include Maitland passive accessory mobilisation or physiological mobilisation techniques in appropriate cervical positions (based on assessment) to stretch the impaired joints to restore normal movement (Fig. 21.8). Such techniques should include exercise to maintain improved mobility.

Mobilisation with movement is a combination of pain-free passive accessory joint glide applied together with active movement (Fig. 21.9) and can be used to improve segmental joint mobility at any level in the cervical spine.<sup>77</sup> The aim of this approach is to restore normal segmental movement in a painless way by encouraging normal biomechanics. For example, a cyclist may develop cervicogenic headache due to abnormal movement at the C2-3 segment, which might provoke headache during prolonged cycling activity. Improving C2-3 segmental motion with a mobilisation with movement technique together with a self-mobilisation home exercise, postural control exercise and muscle re-education typically eliminates the problem.

Another common clinical situation in athletes with chronic cervicogenic headache is a positive flexion-rotation test (Fig 21.4). This usually responds in a rapid and sustained way to a simple Mulligan self-mobilisation technique (Fig. 21.10) directed to the upper cervical spine.<sup>78</sup> In this case, treatment is aimed at the impaired cervical articulations in an attempt to increase mobility specifically in the upper

**Figure 21.9** Mobilisation with movement into flexion at C2–3  
COURTESY OF TOBY HALL

**Figure 21.10** Mulligan self-mobilisation for upper cervical rotation impairment identified by the flexion–rotation test

cervical spine. The positive sustained long-term improvement following this intervention goes some way to validate the use of mobilisation in cervicogenic headache.<sup>78</sup>

Dosage of mobilisation and manipulation is important. For example, a single session of manipulation is not effective in the long term,<sup>79</sup> but eight sessions are effective, as are 16.<sup>75</sup> Specific trigger point and other soft tissue techniques may be used if these have been found to be involved in the disorder. There is some evidence to show that simple soft tissue therapy techniques can improve the flexion-rotation test, thus helping headache symptoms.<sup>80</sup>

**Figure 21.11** Tape to improve scapula control

#### PRACTICE PEARL

A comprehensive exercise program should include motor control exercises including postural control, particularly in the functional complaint activity/position.

For example, cervical and scapular postural control needs to be addressed while riding a bike in the patient with cycling-induced cervicogenic headache, but to achieve this may also require attention to lumbopelvic posture and bike set-up. Postural faults may develop through repetitive sporting activity. For example, an increased thoracic kyphosis, cervical protrusion and scapula anterior tilt and protraction may develop in a swimmer, cyclist or body builder through uncorrected muscle activity. This position may abnormally stress the upper cervical spine, inducing headache. Correcting these faults may require joint mobilisation as well as postural and motor control re-education. Sports tape may be used to facilitate postural correction of the scapula (Fig. 21.11) until the athlete learns to correct his or her posture independently.

Exercise may also include stretching of any muscles found to be short, together with strengthening of the shoulder girdle and neck muscles. Important muscles for stretching include pectoralis minor, upper trapezius, levator scapula and suboccipitals, among others.<sup>65</sup> Neck strengthening combined with stretching exercises were found to be more effective compared to endurance training

**Table 21.4 The IHS criteria for the diagnosis of headache attributed to trauma or injury to the head and/or neck (IHS 5.1 and 5.2)<sup>3</sup>**

- A. Any headache fulfilling C and D
- B. Traumatic injury to the head
- C. Headache is reported <7 days after
  - 1. injury to the head
  - 2. regaining consciousness following head injury
  - 3. discontinuing medication that impairs ability to sense headache following injury to the head
- D. Headache disappears within 3 months after trauma (acute) or headache persists for greater than 3 months (persistent)

or stretching alone in the management of cervicogenic headache.<sup>81</sup>

Recent evidence suggests a close interaction between the upper cervical spine, temporomandibular dysfunction and cervicogenic headache.<sup>59, 82</sup> This might explain why combining manual therapy techniques to the temporomandibular joint and orofascial muscles with cervical manual therapy was found to be more effective in the management of cervicogenic headache than cervical manual therapy alone.<sup>83</sup> The clinician should consider incorporating management of temporomandibular dysfunction when this is evident in examination.

### Post-traumatic headache

Trauma to the head and neck in sport may lead to the development of headache. The initiating traumatic event may not necessarily be severe and could involve repetitive minor blows as in boxing. The IHS diagnostic criteria for post-traumatic headache are shown in Table 21.4.<sup>3</sup>

Most often these forms of headache resemble cervicogenic headache, tension-type or migraine. Not surprisingly, trauma to the head affects the neck and could lead to cervicogenic headache. Indeed, the presence of neck pain appears important in post-traumatic headache sufferers without premorbid headache.<sup>84</sup> Hence the diagnosis is made on the close temporal relationship between the traumatic event and the onset of headache, but should also require careful examination of the cervical spine and the potential for cervicogenic headache.

The presence of migraine-like headache after concussion correlates with more severe injuries and identifies athletes at risk of prolonged recovery to baseline.<sup>85</sup> Headache may occur in isolation or may be part of a range of symptoms including dizziness, sleep disturbance, balance disturbance and loss of cognition. This is dealt with in more detail in Chapter 20 on concussion.

Evidence for the management of post-traumatic headache is not well established. Generally, treatment should be provided according to the category the particular headache most resembles.<sup>4</sup> The clinician should be aware

of the potential for medication overuse headache, a known factor in the development of persistent symptoms, unless analgesic medication is carefully monitored.<sup>86</sup>

### Post-traumatic migraine

Headache may follow repetitive relatively minor traumatic events to the head and neck. This may be seen in sports such as soccer, where repetitive heading of the ball gives rise to the term 'footballer's migraine'.<sup>87, 88</sup> Boxing and similar sports also lead to problems like these. Even mild head trauma can induce migraine. One particular syndrome that is recognised in the setting of minor head blows is migrainous cortical blindness. This disturbing condition often raises fear of serious cerebral injury but tends to resolve over 1-2 hours.

### External compression headache

External compression headache (IHS 4.2), formerly known as 'swim goggle headache,' presents with pain in the facial and temporal areas produced from wearing excessively tight face masks or swimming goggles. It is commonly seen in swimmers and divers. In divers, this may be referred to as 'mask squeeze', and is seen on descent to depth as the effects of pressure reduce the air space inside the mask. The aetiology is believed to be due to continuous stimulation of cutaneous nerves by the application of pressure.

### High-altitude headache

High-altitude headache (IHS 10.1.1) is a well-recognised accompaniment of acute mountain sickness (although it can occur on its own), which occurs within 24 hours of ascent to altitudes above 3000 m.<sup>89</sup> The headaches are vascular in nature and are seen in unacclimatised individuals. Typically, these are associated with other physiological effects of altitude or may be an early manifestation of acute mountain sickness. The treatment is to descend to lower altitude, although pharmacological interventions such as ibuprofen, acetaminophen/paracetamol and acetazolamide may be used.

### Hypercapnia headache

Headache in divers, while uncommon and generally benign, can occasionally signify serious consequences of hyperbaric exposure such as arterial gas embolism, decompression sickness, and otic or paranasal sinus barotrauma. Inadequate ventilation of compressed gases can lead to carbon dioxide accumulation, cerebral vasodilatation and headache.<sup>90</sup>

Since carbon dioxide (CO<sub>2</sub>) relaxes cerebrovascular smooth muscle, hypercapnia leads to cerebral vasodilatation and increased intracranial pressure. Carbon dioxide can accumulate insidiously in the diver who intentionally holds the breath intermittently (skip breathing) in a mistaken attempt to conserve air, or takes shallow breaths to minimise buoyancy variations in the narrow passages of a wreck or cave. The diver may hypoventilate unintentionally if a tight wetsuit or buoyancy compensator jacket restricts chest wall expansion, or if ventilation is inadequate in response

to physical exertion when swimming against a strong current.

The headache associated with CO<sub>2</sub> retention develops gradually and affects the bifrontal, bitemporal or bioccipital head regions. Throbbing pain ranging from mild to severe in intensity typically lasts from 10 to 30 minutes, yet in some may persist for several hours along with nausea and malaise. Onset accompanies a slow buildup or may follow a reduction in sharply rising CO<sub>2</sub> tension. Pain typically worsens during the decompression phase of the dive or upon surfacing, possibly because of the disparity between increased intracranial pressure and more rapidly decreasing ambient pressure. Non-steroidal anti-inflammatory and ergotamine preparations have been reported to be ineffective.<sup>90</sup>

Other types of headache encountered in divers include exertional headache, cold stimulus headache, migraine, tension-type headache, acute traumatic headache, cervicogenic headache, carbon monoxide poisoning headache and headache associated with envenomation.

### REFERENCES

References for this chapter can be found at [www.mhhe.com/au/CSM5e](http://www.mhhe.com/au/CSM5e)

1. The first part of the document discusses the importance of maintaining accurate records of all transactions and activities. It emphasizes that proper record-keeping is essential for transparency and accountability, particularly in financial matters. The text outlines various methods for organizing and storing data, including digital databases and physical filing systems. It also mentions the need for regular audits and reviews to ensure the integrity of the information.

2. The second section focuses on the role of communication in achieving organizational goals. It highlights the importance of clear and concise communication channels, both internally and externally. The text discusses the benefits of regular meetings, reports, and updates, as well as the potential pitfalls of poor communication. It encourages the use of technology to facilitate communication and collaboration among team members.

3. The third part of the document addresses the issue of resource management. It discusses the importance of identifying and allocating resources effectively to support the organization's mission. The text provides guidance on how to prioritize tasks and manage budgets, as well as strategies for recruiting and retaining talent. It also touches on the importance of maintaining a healthy work-life balance for employees.

4. The final section discusses the importance of continuous improvement and innovation. It encourages the organization to regularly evaluate its processes and procedures, and to seek out new and better ways of doing things. The text mentions the importance of staying up-to-date with industry trends and best practices, and of fostering a culture of learning and growth. It concludes by emphasizing the importance of leadership in driving change and innovation within the organization.

# Face, eyes and teeth

with RODNEY FRENCH, GEOFFREY ST GEORGE, IAN NEEDLEMAN and STEFFAN GRIFFIN

*Having looked at it on YouTube, I don't like to look at it too much because it freaks me out a bit. The ball hit me in the eye and went two centimetres back.*

South African cricket player Mark Boucher on his career-ending eye injury

Injuries to the face in sport usually result from direct trauma. After reviewing clinical assessment and soft tissue injury management, we outline management of injuries to the nose, ear, eye, teeth and facial bones.

### FUNCTIONAL ANATOMY

The bones of the face are shown in Figure 22.1. As most of these bones are subcutaneous, they are easily examined. Examination should include palpation of the forehead and supraorbital rims for irregularities and contour deformities.

The orbit is a cone-shaped cavity, with a margin that consists of the supraorbital ridge above, the infraorbital margin below, the zygomatic arch laterally and the nasal bone medially. The recess formed protects the eye from a blow from a large object. A smaller, deformable object such as a squash ball may, nevertheless, compress the globe and orbital contents, leading to a 'blow-out' fracture in the orbital floor that orbital content can herniate through.

The zygomatic arch of the malar bone creates the prominence of the cheek. Fractures in this region may cause flattening of the cheek and a palpable irregularity in the inferior orbital margin.

The maxilla forms the upper jaw. Its superior surface helps create the floor of the orbit and the inferior surface forms the major part of the hard palate. Mobility of the hard palate, determined by grasping the central incisors, may indicate a maxillary fracture.

The lower jaw consists of the horseshoe-shaped mandible. The mandible is made up of body, angle and ramus, which are easily palpated. The coronoid process can be palpated by a direct intraoral approach. The gingiva overlying the alveolar ridge may be lacerated in mandibular body fractures.

**Figure 22.1** Facial bones

### CLINICAL ASSESSMENT

Facial injuries<sup>1</sup> are frequently associated with profuse bleeding. While it is important to control the bleeding, it is also vital to fully assess the underlying structures. All head and neck injuries should be considered closed head injuries. Cervical spine precautions should be taken if the patient is unconscious, has neurological deficits or cervical spine tenderness, or if cervical spine injury is feasible considering the mechanism of injury. The airway is particularly vulnerable to obstruction because

of bleeding, structural compromise of bony structures (e.g. mandible), or dislodged teeth, tooth fragments or dental appliances. The practical steps to assess facial injuries are:

- ascertain the mechanism of injury and locate the source of the patient's pain
- check for blurred vision, diplopia (double vision), concussion or cerebrospinal fluid leakage
- inspect the nasal septum and external ear for haematomas and nasal obstruction
- observe facial asymmetry or structural depressions
- look for a sunken eye globe suggestive of a blow-out fracture
- observe lacerations or deep abrasions overlying suspected fractures.

Palpate facial bones (orbital rims, nasal bones, temporomandibular joints) for significant tenderness, crepitus, numbness or contour irregularities. Midface instability or crepitus may be demonstrated by stabilising the forehead with one hand while gently pulling on the maxillary incisors with the other gloved hand. Bimanual palpation along the mandible and maxilla (one gloved hand palpating intraorally) will uncover instability, irregularity or tenderness.

Assess extraocular eye movements and cranial nerves III, IV and VI by having the patient keep his or her chin in a fixed position while tracking the examiner's finger movements in all four quadrants. If the patient is able to track the movements without reporting diplopia, acute extraocular nerve entrapment caused by an orbital blow-out fracture can be ruled out. An inability to raise the eyebrow or wrinkle the forehead following laceration to the eyebrow suggests injury to the temporal branch of the facial nerve on that side. Reduced sensation over the skin below the eye in the distribution of the infraorbital nerve may be associated with a blow-out fracture of the orbit. The nerve distribution includes the upper gum and lip.

#### PRACTICE PEARL

If the patient is unable to open his or her mouth or exhibits severe pain along the lateral aspect of the cheek or jaw when attempting to open, a fracture of the mandible or zygoma must be considered.

With the mouth open, the oral cavity should be assessed to rule out damage to the teeth and lacerations in the intraoral mucosa or tongue. Locate fractured or missing teeth, when possible, to avoid accidental aspiration. When asked to close the mouth, the patient's sense of malocclusion suggests a significant fracture of the mandible, maxilla or palate.

Leakage of cerebrospinal fluid (CSF) following a blow to the nose (CSF rhinorrhea) may indicate a fracture of the base of the anterior cranial fossa. CSF is a clear discharge and

the patient may report a salty taste in the mouth. If there is doubt about the origin of a nasal discharge associated with trauma, the discharge should be tested with a urinary dipstick for glucose. CSF is positive for glucose.

A list of common conditions and conditions not to be missed is shown in Table 22.1.

## LACERATIONS AND CONTUSIONS

Lacerations and contusions to the face and scalp are prevalent in sports such as football, ice hockey, martial arts and racquet sports.<sup>1</sup> Examination should include palpation of the underlying bone to detect bony tenderness. Neurological examination is required if there is a history of loss of consciousness or suspected skull fracture.

### Immediate management of lacerations

Begin immediate management with ice and pressure to reduce local swelling. Control bleeding with direct pressure over the wound using sterile gauze. A player with a bleeding wound must be removed from the field of play immediately as there is concern that the presence of blood may increase the risk of hepatitis B or human immunodeficiency virus (HIV) infection for other players.

After removing the athlete from the field of play, examine the laceration closely under good light. Further cleaning and removal of foreign bodies may be required. If necessary, infiltrate a local anaesthetic agent to adequately clean the wound. The local anaesthetic used should be 1% or 2% lignocaine (lidocaine) containing adrenalin (epinephrine) 1:100 000 to provide some vasoconstriction as well as analgesia.

### Management of larger lacerations

Lacerations greater than 0.25–0.5 cm long should be closed if they appear clean. Closure may be obtained by suturing or by taping with adhesive strips (Steristrips®). Steristrips are ideal for small wounds; however, persistent bleeding or excessive sweating may prevent adhesion. To overcome this, tincture of benzoin (friar's balsam) may be applied to increase adhesiveness. Adequate dressings will be required to keep the adhesive strips in place, especially if the player is returning to the field. Scalp wounds often bleed profusely. Small wounds can be controlled with local pressure, but larger ones require suturing.

If facial lacerations require suturing, use 5/0 or 6/0 nylon. It is important that the skin edges are healthy. Pieces of devitalised skin should be debrided. Take care to approximate the skin edges carefully while suturing. Remove sutures after 5 days and place adhesive strips over the wound for a further week. The wound should be kept dry for at least 48 hours.

An alternative to suturing is skin staples. These must be covered if the player is returning to the field to prevent them from being accidentally torn out or from injuring

**Table 22.1 Facial injuries in sport**

Category	Common	Less common	Not to be missed
Facial soft tissue	Contusion Laceration		Associated underlying fracture/nerve injury
Nose	Fracture of nasal bones Epistaxis	Fracture of nasal septum	Septal haematoma
Ear	Contusion ('cauliflower ear') Otitis media Otitis externa	Laceration Ruptured tympanic membrane	Fractured petrous temporal bone Torn auditory nerve
Eye	Corneal abrasion Corneal foreign body Conjunctival foreign body Subconjunctival haemorrhage Eyelid laceration	Chemical burns Vitreous haemorrhage Retinal haemorrhage Retinal oedema Hyphaema	Corneal laceration Retinal detachment Lens dislocation Blow-out fracture of the orbit Optic nerve injury Injury to lacrimal system
Teeth	Enamel chip fracture Luxated tooth Avulsed tooth	Crown fracture	Impacted tooth
Facial bones	Temporomandibular joint sprain or malalignment Zygoma fracture Orbital blow-out fracture	Fractured maxilla Fractured mandible	

**Table 22.2 Management of specific lacerations**

Laceration type	Management considerations
Deep lacerations (e.g. to galea aponeurotica in forehead)	Interrupted 5/0 absorbable sutures (prior to skin closure)
Eyebrow laceration	Do not shave eyebrow hair. Strict anatomical approximation required
Partial-thickness lip laceration at vermilion border	Place first suture at mucocutaneous junction to ensure accurate alignment
Full-thickness lip laceration	Three layer closure required (preferably by plastic surgeon) consisting of: oral mucosa first; orbicularis oris second; skin last
Deep intraoral laceration	Use 3/0 silk sutures and keep in place for 1 week

another player in a collision. Another alternative is the use of histoacryl glue.

### Additional considerations

All patients with potentially contaminated wounds should receive tetanus prophylaxis and a short course of oral antibiotic therapy, for example, cephalexin (250–500 mg, 6 hourly) or flucloxacillin (250–500 mg, 6 hourly). Wounds that may be contaminated by another player's saliva, such as bite wounds, should not be closed but should be cleaned meticulously. The player should be treated with oral metronidazole (400 mg, 8 hourly) in addition to penicillin and observed very closely for the development of cellulitis. If signs of infection appear, treat with intravenous antibiotics.

### NOSE

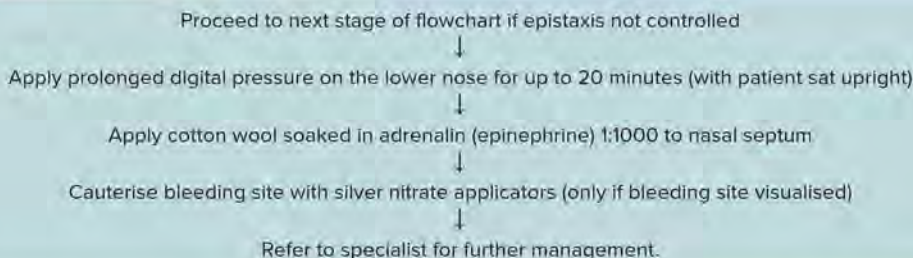

The three main conditions that affect the nose in sports medicine are epistaxis (bleeds), fractures and septal haematomas.

### Epistaxis (nosebleed)

Nasal haemorrhage occurs frequently in association with nasal injuries. It usually arises from the nasal septum, which receives its blood supply from branches of the internal and external carotid arteries. In most non-traumatic cases, the bleeding arises from a rich plexus of vessels in the anterior part of the septum, known as Little's or Kiesselbach's area (Fig. 22.2), whilst bleeding will originate from the vessels local to the affected area in traumatic cases.

## Epistaxis 'game-day' management flowchart

Initial management consists of prolonged direct digital pressure on the lower nose for up to 20 minutes, compressing the vessels on the nasal septum with the patient sitting upright. Cold compresses over the bridge of the nose promote vasoconstriction. If bleeding continues, apply cotton wool soaked in adrenalin (epinephrine) 1:1000 to the nasal septum. If the bleeding site can be located, it may be cauterised with silver nitrate applicators (cotton swabs soaked in 4% trichloroacetic acid).

If bleeding persists, specialist referral is indicated. The nose will usually be packed with 1 cm ribbon gauze impregnated with bismuth iodoform petroleum paste (BIPP) and left for 48 hours. Post-nasal packing may be required if the bleeding originates from the back of the nose. In the rare cases that bleeding persists despite these local measures, maxillary artery or anterior ethmoidal artery ligation may be indicated.

### Nasal fractures

Fractures of the nose are usually caused by a direct blow. Symptoms and signs of nasal fracture include pain,

epistaxis, swelling, crepitus, deformity and mobility of the nose. Nasal distortion may not be obvious once soft tissue swelling develops. Initial management is directed towards controlling the nasal haemorrhage. An associated laceration should be sutured with 6/0 nylon and requires prophylactic antibiotic therapy. The nasal passages should be examined to exclude a septal haematoma and patients should be advised to return if they notice increased pain or develop a fever (see below).

Radiographs are probably not required as undisplaced fractures require no treatment and displaced fractures are clinically obvious. Displaced nasal fractures may require reduction. There are two indications for reduction of fractures. The first is obstruction of the nasal passages and the second is cosmetic deformity.

In young athletes, displaced fractures are almost always reduced because of a tendency towards increased sinus infections and a decrease in the size of the nasal passage. Attempts at immediate reduction of nasal fractures are associated with a risk of arterial damage and severe acute haemorrhage. It is preferable to delay fracture reduction and refer the patient to a surgeon within 7 days of the injury. When the soft tissue swelling has settled sufficiently, reduction, if necessary, can be carried out under general anaesthesia.

### Septal haematoma

This important condition can complicate what seems to be a trivial nosebleed. A septal haematoma is caused by haemorrhage between the two layers of mucosa covering the septum (Fig. 22.3). The presenting complaint is either nasal obstruction or nasal pain. The patient may be febrile and nasal examination reveals a cherry-like structure (the dull, red swollen septum) that occludes the nasal passages. Treatment of a large septal haematoma involves evacuation of the clot using a wide-bore needle or through a small incision followed by nasal packing to prevent recurrence of the haematoma. Antibiotic prophylaxis should be given to prevent development of a septal abscess and subsequent cartilage necrosis.

Figure 22.2 Little's (Kiesselbach's) area

**Figure 22.3** Septal haematoma

## EAR

Ear injuries in most sports are not common. Nonetheless, they can pose a clinical challenge to sports physicians working in sports such as rugby and wrestling. The most frequent injury is a contusion to the ear known as an auricular haematoma.

### Auricular haematoma

This injury occurs mainly in rugby scrums, boxing or wrestling as a result of a shearing blow. Recurrent contusions result in haemorrhage between the perichondrium and the cartilage. This may eventually develop into a chronic swelling, commonly known as 'cauliflower ear'. An acute haematoma (Fig. 22.4) should be treated initially with ice and firm compression, but may need to be drained by aspiration under strict aseptic conditions. A pressure dressing (cotton wool soaked in collodion) is then applied and is carefully packed against the ear to follow the contours of the outer ear. This is bandaged firmly. The ear must be examined daily to assess progress. Return to

**Figure 22.4** Acute auricular haematoma

non-contact sports can be immediate, but headgear or a helmet is required for return to contact sport. Rugby forwards frequently wear headgear which protects their ears as a preventive measure.

Lacerations to the ear require careful cleansing and suture. As lacerations located between the scalp and the ear are easily missed, this area should always be examined, especially if there is a history of the ear being pulled forwards. If the auricular cartilage is torn, the overlying skin should be carefully aligned and sutured with absorbable 5/0 sutures; however, the cartilage itself has natural physical 'memory' properties, leading to natural alignment without the need for sutures. The perichondrium should be closed as a separate layer. Prophylactic oral antibiotic therapy is recommended.

### Perforated eardrum

A blow across the side of the head may occasionally injure the eardrum. Pain, bleeding from the ear or impaired hearing suggest tympanic membrane rupture.

These ruptures usually heal spontaneously. Prophylactic antibiotic therapy (amoxycillin 250–500 mg, 8 hourly if not allergic to penicillin) should be administered. It is important to keep the ear dry while a perforation is present. In sports where significant pressure changes occur, such as platform diving, scuba diving and high-altitude mountain climbing, athletes should not return to play until the tympanic membrane has healed. Athletes participating in water sports, such as swimming and water polo, should use custom-fabricated ear plugs to maintain a dry ear canal. Dry land athletes may return to play as soon as any vertigo has resolved.<sup>1</sup>

Athletes will often ask whether it is safe to fly with a perforated eardrum. It is generally considered safe to do so, unless they have had surgery to repair the perforation (myringoplasty), in which case guidance should be sought from the surgeon.

A severe blow across the head may fracture the skull and cause inner ear bleeding. Discharge from the ear (otorrhoea) may signal a neurosurgical emergency and, thus, patients should be referred immediately for specialist treatment.

### Otitis externa

Otitis externa is the most common ear condition affecting competitive swimmers. It is generally caused by bacteria, although fungal infection can also contribute. Symptoms include earache, pruritus, discharge and impaired hearing. On examination, there may be discharge in the ear and local redness along the external auditory meatus. There may be tragal tenderness and pain on tragal pull.

Management involves careful aural toilet combined with topical antibiotic and corticosteroid ear drops. The patient should, preferably, abstain from swimming until fully recovered and avoid rubbing or drying the ear until after the infection has cleared. The use of earplugs in this condition is controversial. They may traumatise the ear canal and predispose the swimmer to infection.

### PRACTICE PEARL

Recurrent attacks of otitis externa may be prevented by instillation of alcohol ear drops, for example, 5% acetic acid in isopropyl alcohol (aqua ear®), after each swimming session.

### EYES

Eye injuries occur most commonly in stick sports, racquet sports, especially squash, and contact sports.<sup>2</sup> All eye injuries, even those that appear to be minor, require thorough examination. All serious eye injuries should be referred immediately to an ophthalmologist. The indications for immediate referral to an ophthalmologist are shown in the box below.

Athletes with a previous history of impaired vision in one or both eyes or previous eye trauma or surgery should be evaluated by an ophthalmologist prior to participating in a high-risk sport.

### Assessment of the injured eye

To assess the injured eye, it is important to understand the anatomy. The anatomy of the eye is shown in Figure 22.5.

For a thorough assessment of the injured eye, an 'eye injuries kit' (Fig. 22.6) is very useful and can be carried as part of the 'physician's bag' (Chapter 47).

### History

The history of the eye injury provides useful diagnostic information. Seek to discover the history of the mechanism of injury. Were glasses, contact lenses or a protective device being worn at the time of injury? Note any previous eye injury or problems. Ask about symptoms such as pain, blurred vision, loss of vision, flashing lights and diplopia.

### Examination

Test the visual acuity of each eye using a Snellen chart, with and without glasses or contact lenses. If a Snellen chart is not available, use pages of a newspaper with

### Clinical indications for immediate referral to a specialist ophthalmologist

#### Symptoms

Severe eye pain  
Persistent blurred or double vision  
Persistent photophobia

#### Signs

Suspected penetrating injury (corneal laceration, pear-shaped pupil)  
Hyphaema  
Embedded foreign body  
No view of fundus (suspected vitreous haemorrhage or retinal detachment)  
Markedly impaired visual acuity: 6/12 or less  
Loss of part of visual field

**Figure 22.5** Anatomy of the eye

**Figure 22.6** Eye injuries kit

variable print sizes as an approximate assessment of visual acuity. On the sporting arena, a scoreboard can be used to test distant vision.

### Eye injuries kit

Small mirror  
Pencil torch  
Ophthalmoscope  
Snellen chart  
Sterile solution for irrigation  
Local anaesthetic eye drops  
Fluorescein  
Antibiotic drops and ointments  
Cotton buds  
Contact lens lubricant and case(s)  
Eye patches  
Tape

Inspect the eyelids for bruising, swelling or laceration. Note any obvious foreign body, haemorrhage or change in pupil size.

If there is pain or photophobia due to the injury prevent examination of the eye, instil a drop of a sterile topical anaesthetic agent, such as amethocaine, to assist examination.

### PRACTICE PEARL

Inspect the cornea for foreign material and abrasions. Fluorescein staining under cobalt blue light will help reveal areas of corneal ulceration or foreign bodies. Evert the upper lid to exclude the presence of a sub tarsal foreign body.

Test eye movements in all directions. A restriction in any direction or the presence of diplopia may indicate orbital fracture. Compare the size, shape and light reaction of the pupil with the uninjured eye. An enlarged, poorly reacting pupil may be present after injury to the iris. A pear-shaped pupil suggests the presence of a full thickness corneal or scleral laceration (penetrating injury).

Inspect the anterior chamber for the presence of blood. Blood in the anterior chamber is known as hyphaema (Fig. 22.7).

### PRACTICE PEARL

Ophthalmoscopic examination should routinely be performed to inspect the lens, vitreous humour and retina.

The absence of a red reflex on ophthalmoscopic examination may be due to a corneal opacity, a lens opacity (cataract), intraocular bleeding or a retinal detachment. Failure to visualise the fundus may be a sign of vitreous

**Figure 22.7** Hyphaema—note the fluid level in the anterior chamber

haemorrhage, which can result from a retinal tear. Contusion of the retina may produce retinal oedema, seen as areas of pallor (and thickening) as well as retinal haemorrhage.

#### PRACTICE PEARL

**Radiological examination of the orbit is indicated in all cases of traumatic eye injury with diplopia and in cases where an intraocular or intraorbital foreign body is suspected.**

### Corneal injuries: abrasions and foreign body

Corneal injuries in sport include abrasion, foreign body and, less commonly, alkali burn. Corneal abrasion, one of the most frequent injuries to the eye during sport, occurs as a result of a scratch from either a fingernail or foreign body. The patient complains of pain, a sensation of a foreign body being present in the eye and blurred vision if the central cornea is involved.

A topical anaesthetic drop should be instilled to assist corneal examination. Fluorescein staining under cobalt blue light will help locate corneal abrasions or foreign bodies. Evert the upper lid to exclude a subtarsal foreign body.

Treatment of corneal abrasions includes the instillation of antibiotic eye drops, for example, chloramphenicol and padding of the eye (Fig. 22.8). If pain and photophobia are severe, add a topical mydriatic (e.g. 2% homatropine). A local anaesthetic agent should never be used for pain relief as it can delay healing and result in further damage.

### Eye-injury 'game-day' assessment

1. Test the visual acuity of each eye using a Snellen chart, with and without glasses or contact lenses (use newspaper pages or a scoreboard if unavailable)
2. Inspect the eyelids for bruising, swelling or laceration. Note any obvious foreign body, haemorrhage or change in pupil size (instil a drop of sterile topical anaesthetic agent to assist examination if pain or photophobia prevent examination)
3. Evert the upper lid to exclude the presence of a subtarsal foreign body
4. Inspect the cornea for foreign material and abrasions (fluorescein staining under cobalt blue light will assist greatly)
5. Test eye movements in all directions
6. Compare the size, shape and light reaction of the pupil with the uninjured eye
7. Inspect the anterior chamber for the presence of blood
8. Ophthalmoscopic examination should be performed to inspect the lens, vitreous humour and retina.

Corneal foreign bodies can be removed with a cotton tip applicator by a trained clinician. If foreign bodies are more deeply embedded, patients should be referred to an ophthalmologist. Rust rings, which occasionally remain after metallic foreign bodies have been embedded in the cornea, require removal by an ophthalmologist. Antibiotic eye ointment should be administered following foreign body removal and the eye padded for 24 hours until the corneal epithelium has healed.

If an athlete has sustained an alkali burn (from line markings), irrigate the eye copiously for 20 minutes with sterile saline or tap water and instil a local anaesthetic agent to assist this. The athlete should be seen as soon as possible by an ophthalmologist.

### Subconjunctival haemorrhage

Trauma to the conjunctiva may cause subconjunctival haemorrhage—a bright red area in the white conjunctiva. Unless the haemorrhage is extensive or visual symptoms or photophobia are present, it is not clinically important.

#### PRACTICE PEARL

**Subconjunctival haemorrhage is a classic finding with periorbital fractures, which need to be ruled out if the athlete participates in a sport where facial trauma is possible.**

**Figure 22.8** Eye padding

Blood pressure should be measured to rule out hypertension. Subconjunctival haemorrhage may obscure a perforation of the globe. If this is suspected, the patient should be referred to an ophthalmologist. In most cases, however, the athlete merely requires reassurance.

### Eyelid injuries

Direct trauma to the eyelids may cause a large amount of bruising, which should be treated with cold compresses in the first 24 hours. Haemorrhage may spread subcutaneously across the midline to the other eye. A coexisting orbital fracture needs to be excluded in these patients.

Lacerations of the eyelid require meticulous primary repair. Each anatomical layer (conjunctiva, tarsal plate and skin) should be repaired separately by an ophthalmic or plastic surgeon.

Trauma near the medial canthus may lacerate the upper or lower lacrimal canaliculus (tear duct). If this is not repaired, the patient may have permanent watering of the eye. Such injuries require ophthalmological referral for microscopic suturing of the cut ends of the canaliculus.

### PRACTICE PEARL

**In all injuries to the eyelids, the eye also needs to be examined to exclude ocular injury.**

### Hyphaema

Bleeding into the anterior chamber of the eye results from ruptured iris vessels and may only be visible with slit lamp examination. More significant bleeds will present with a bloody layer in the anterior chamber (Fig. 22.7). In hyphaemas of small volume, visual acuity may be unaffected. Associated injuries may occur and all patients with a hyphaema should be referred to an ophthalmologist.

The aim of treatment of this condition is to prevent further bleeding, which may, in turn, result in uncontrollable glaucoma or blood staining of the cornea. The patient needs to rest in bed while the haemorrhage clears, usually over 3–5 days. Aspirin and other anti-inflammatory medications should be avoided as these may provoke further bleeding.

### Lens dislocation

Blunt trauma may result in varying degrees of lens displacement. Partial dislocation causes few symptoms. Complete lens dislocation results in blurred vision. A common sign of lens dislocation is a quivering of the iris when the patient moves the eye. Iritis and glaucoma are possible sequelae of lens dislocation. Immediate ophthalmological referral is required. Surgical removal of the displaced lens may be indicated.

### Vitreous haemorrhage

Bleeding into the vitreous humour signifies damage to the retina, choroid or ciliary body. Ophthalmoscopic examination reveals loss of the red reflex and a hazy appearance. Treatment generally consists of bed rest, but more severe cases may require specialist referral for removal of the blood and vitreous humour.

### Retinal haemorrhage

Injury to the retina can result from a direct blow to the eye or a blow to the back of the head. Valsalva manoeuvres (e.g. in weightlifting) may also produce retinal oedema and haemorrhage. The patient may remain asymptomatic if peripheral areas of the retina are affected. Central retinal damage, however, blurs vision. On ophthalmoscopic examination, central retinal oedema appears as a white opacity that partially obscures the retinal vessels. Boxers may develop atrophic macular holes and loss of central vision as a result of recurrent contusive injuries. This condition requires specialist management.

## Retinal detachment

Retinal detachment is more common in those with extreme myopia and may result from any blunt or perforating trauma. The patient complains of flashes of light or the appearance of a 'curtain' spreading across the field of vision, which can present months or even years after the initial injury. Ophthalmoscopic examination reveals elevation and folding of the detached retina, which trembles with each eye movement. Immediate referral for surgical treatment is indicated. An unusual case of retinal detachment in sport occurred in a swimmer who received an accidental blow to the goggles.<sup>3</sup>

## Prevention of eye injuries

Athletes with certain eye problems should avoid contact sports altogether. These problems include:

- functionally only one eye
- severe myopia
- Marfan syndrome
- previous retinal detachment.

For squash, protective eyewear must be worn by people who have either only one good eye, amblyopia (lazy eye), recent eye surgery, history of pre-retinal detachment conditions or diabetic retinopathy. Protective eyewear should meet the Australian Standard AS4066 1992 or the US Standard ASTM F803.

Contact lenses offer no protection against eye trauma. Hard contact lenses are not suitable for sporting activity and should never be used in contact sport. Soft lenses appear to be reasonably safe in contact sport. One of the most common 'crises' in injury management is a lost contact lens. The athlete will complain that the contact lens is no longer in its correct position and cannot be located. Usually the lens has been displaced and with careful examination can be located elsewhere on the eye, often at the lower lid. Occasionally, the lens is displaced completely from the eye and lost on the playing surface. Those who wear contact lenses during sport should always carry a spare pair of contact lenses or a pair of protective spectacles as a back-up.

Those athletes who cannot or do not like to wear contact lenses can use protective goggles made of polycarbonate, which are available for most prescriptions. These polycarbonate goggles are also used as eye protection in sports with a high risk for eye injuries. The most obvious examples of these are squash and racquetball, where the size of the ball enables it to enter the orbit and compress the globe. The routine use of closed goggles is strongly recommended.

Certain sports require protection not only of the eye, but of the other facial structures. In sports such as American football, ice hockey, cricket and lacrosse, protective helmets and faceguards should also provide adequate eye protection. Because of the profound effect of major eye injury, we encourage athletes and sport governing

bodies to be proactive in promoting and enforcing the use of eye protection where indicated.<sup>4</sup>

## TEETH

Trauma to the teeth and dental tissues is a relatively common occurrence in certain sports. A large study, from over 70 000 episodes of basketball, showed mouth guard wearers had a reduced number of dental injuries and referrals to the dentist when compared to those who did not wear mouth guards.<sup>5</sup> This illustrates the importance of the team doctor or coach in preventing injuries through education of athletes and also the requirement to know how to manage dental trauma, when it occurs.

## Nature of injuries

Within the mouth are a number of tissues which can be traumatised as seen in the image below (Fig. 22.9).

Trauma results in tissues being crushed, stretched or torn, as seen in the image of a dento-alveolar fracture (Fig. 22.10). The damage caused to teeth and their supporting tissues following trauma is dependent on a number of factors, such as the energy of the impact, the direction of the blow, the tissues traumatised, the resilience or elasticity of the striking object, and the local anatomy. Therefore, dental trauma may present in a number of different ways despite apparently similar causes.

## Emergency management

Options for treatment of dental injuries at a sporting event may be limited, due to lack of equipment and facilities. Some injuries may not be visible and may require further special investigations to diagnose. However, many injuries do not need immediate treatment and the most common injuries seen are detailed in Table 22.3 below.

**Figure 22.9** Sagittal view showing the jaw and a tooth in the maxillary incisor region identifying the tissues that may be damaged following dental trauma

**Figure 22.10** Dento-alveolar fracture showing fracture (1) and displacement of a tooth (2) from its socket (3)

Certain situations require special consideration in dental trauma:

- Mouth guard in situ—in general, leave a mouth guard in place as removal might further damage traumatised teeth. If mouth guard must be removed, ensure the patient is seated upright and check the mouth and mouth guard following its removal for teeth and teeth fragments. The mouth guard should not be used to splint teeth due to the problems of oral hygiene.
- Dentures, crowns and bridges—if loose, then remove if possible as they present a choking hazard.
- Unconscious patients—store avulsed teeth in a suitable storage medium and pass to the Emergency Department.

### Dental management and follow-up

Injured athletes must be examined by a dentist as soon as possible, with a referral letter if time permits. Treatment

can be complex and complications of healing are common. Therefore, athletes who experience trauma should be informed they need close follow-up at regular intervals over a number of years.

### Prevention

Although prevention of injuries is often thought to just include the wearing of protective mouth or headguards, an important aspect is education. Athletes should be individually assessed to determine if guards should be worn, for example when engaging in high-risk contact sports, and if prominent upper incisor teeth are present. All efforts should be made to encourage their use.

The two most common types of protection are listed below.

#### Faceguards:

- are pre-formed cages that attach to a helmet
- provide protection from blows to the front of the head
- often fail to prevent similar blows to the chin, therefore mouth guards also may need to be worn
- significantly reduce injuries in certain sports such as hockey<sup>6</sup> and baseball.<sup>7</sup>

#### Mouth guards:

- use has also reduced the frequency of dental trauma-related injuries<sup>8</sup>
- prevent damage to teeth, soft tissues and mandible, by cushioning against the opposing teeth following a direct blow
- can also prevent teeth from being lost from the mouth, swallowed or inhaled
- do not appear to prevent concussion injuries.<sup>9</sup>

Three types of mouth guard exist (Fig. 22.11):

1. Stock mouth guard (Fig 22.11a)—loose fitting, made of plastic or rubber and should be avoided as they provide none of the protective functions already discussed.

(a)

(b)

**Figure 22.11** (a) Stock mouth guard (b) Mouth-formed mouth guards

(c)

**Figure 22.11 (cont.)** (c) Custom-made mouth guard**Figure 22.12** Maxillary incisors and canines showing how tooth/root axes are inclined towards the back of the mouth to guide tooth replantation if avulsed**Table 22.3** Emergency dental treatment

Injury	Treatment required
Fractured teeth	<ul style="list-style-type: none"> <li>• Collect tooth fragments and store in milk or saline</li> <li>• Fragments can be re-attached to teeth in the dental surgery</li> <li>• Assume lost fragments have been swallowed or inhaled. These must be located with chest or abdominal radiographs as the consequences of inhaling infected tooth fragments are serious</li> <li>• Attached fragments should be left unless they can be easily detached</li> </ul>
Avulsed tooth	<ul style="list-style-type: none"> <li>• Reposition in socket as soon as possible (within 5 minutes<sup>10</sup>)</li> <li>• Hold avulsed tooth up by its crown, not root</li> <li>• Wash with saline or water for 10 seconds only, until the root looks clean</li> <li>• Re-implant the tooth in its socket</li> <li>• Check it is correctly aligned and the athlete can bite together</li> <li>• Bite on clean gauze</li> <li>• Visit general doctor for a tetanus booster if needed</li> </ul>
Multiple avulsed teeth	<ul style="list-style-type: none"> <li>• Teeth are unique in shape and their sockets closely replicate their contour</li> <li>• Gently insert into their sockets, one at a time</li> <li>• If teeth do not fit in their sockets, try another socket</li> <li>• Do not force teeth into their sockets</li> <li>• Upper central incisors are larger than lateral incisors</li> <li>• Lower incisors are difficult to tell apart</li> <li>• As a guide, the root tips of teeth are tilted towards the back of the mouth (Fig 22.12)</li> </ul>
Displaced teeth	<ul style="list-style-type: none"> <li>• Gently reposition</li> <li>• If any resistance to repositioning or pain are felt, the athlete should attend their dentist for this to be performed under local anaesthetic</li> </ul>
Avulsed teeth that cannot be reimplanted	<ul style="list-style-type: none"> <li>• Teeth must be kept in a suitable storage medium for transport to the dentist. Never store in water</li> <li>• Type of storage medium depends on storage time:               <ul style="list-style-type: none"> <li>– &lt;10 minutes—physiological saline</li> <li>– Up to several hours<sup>11</sup>—fresh milk (cold, low fat is best)<sup>12</sup></li> <li>– Up to 24 hours<sup>13</sup>—special culture medium, available commercially as Dentosafe® or EMT™ Tooth Saver</li> </ul> </li> <li>• If no medium is available, store in athlete's saliva</li> </ul>

2. Mouth-formed mouth guards (Fig. 22.11b)—two types:
  - a. a shell filled with a plastic or rubber to improve fit
  - b. pre-formed plastic mouth guard softened in hot water and moulded to the shape of the teeth and soft tissues
 Both types can be tight fitting, but can be bulky, less comfortable and therefore less likely to be used.
3. Custom made (Fig. 22.11c)—constructed on accurate models of the athlete's teeth. They are well retained and less bulky than other designs, but are more expensive to purchase. Due to their size and fit, they are more comfortable to wear than other types of mouth guards, and as a result more likely to be used in sport.

Mouth guards should be kept clean using standard mouthwashes to rinse. They should be kept away from extreme heat, such as hot water, which will cause distortion of fit.

Therefore a custom-made mouth guard from a dentist is advised, as this will be the most comfortable, least bulky and best fitting. If not available, consider using one that can be moulded in the mouth.

### FRACTURES OF FACIAL BONES

In sport, facial fractures may result from blows by implements such as bats or sticks, equipment such as skis<sup>14</sup> and from collision injuries. Mountain biking is a sport that causes a significant proportion of facial injuries. Eye wear<sup>15</sup> and face shields<sup>16</sup> can protect against facial injuries.

Symptoms and signs range from pain, swelling, ipsilateral epistaxis, laceration and bruising to gross deformity. Examination may reveal facial asymmetry, crepitus, discoloration or obvious deformity. Most facial fractures are not overly painful and so there should be little objection to firm palpation, which aids in the diagnostic process. Objectively, the bite should be examined for malocclusion while the patient should also be subjectively asked whether their bite 'feels' out of alignment. Bimanual examination of the facial bones may show areas of discontinuity and mobility. If maxillary fracture is suspected, the upper teeth can be grasped to determine evidence of excessive movement of the upper jaw and midface. Opening and closing the jaw may reveal pain, limitation or deviation with mandibular injuries.

Initial management of facial fractures is directed towards maintenance of the patient's airway. In mandibular body fractures or maxillary fractures, this may require emergency manual reduction. Associated head and cervical spine injuries should be excluded. The oral cavity requires inspection for bleeding or dental damage. CT scans have supplanted plain radiographs as the imaging modality of choice.

**Figure 22.13** A squash ball fits precisely into the eye socket

### Orbital fracture with and without globe trauma

'Blow-out' fracture of the orbit results from direct trauma such as a fist, cricket ball, baseball<sup>17</sup> or squash ball (Fig. 22.13). Compression of the globe and orbital contents produces a fracture in the weakest part of the orbit, the orbital floor. Contents of the orbit may herniate through the defect. The patient typically presents with a periorbital haematoma, protruding or sunken eye, double vision on upward gaze and numbness of the cheek. Double vision on upward gaze is due to the entrapment of the inferior rectus muscle in the fracture.

A detailed examination of the eye must be performed to exclude intraocular injuries such as hyphaema, lens dislocation or ruptured globe. If an orbital fracture is suspected, a birds-eye plain radiograph should be performed. The radiograph may not show the fracture, but may demonstrate some clouding of the maxillary sinus. CT examination is used to confirm the fracture. Children require early surgery and as such should be investigated with high clinical suspicion.

Antibiotic therapy should be commenced immediately and the patient referred to an ophthalmologist. Surgery may be required to release the trapped muscle and repair

**Figure 22.14** CT scan confirming a fractured zygomatic arch; plain radiography did not detect the fracture

the bony defect. Athletes who undergo surgery should be warned not to blow their nose, due to the risk of displacing the fracture and further haemorrhage.

### Fractures of the zygomaticomaxillary complex

Zygomaticomaxillary complex fractures (Fig. 22.14) occur from a direct blow to the cheek such as from a fist, hockey stick or baseball. Signs include swelling and bruising, flatness of the cheek and mandibular function disturbance. If associated with an orbital fracture, there may be concomitant diplopia, limitation of ocular movement and asymmetry of the eyes, as well as numbness of the affected cheek, nose, upper lips and upper teeth.

Surgical treatment consists of closed or open reduction under general anaesthesia. Unstable fractures require

fixation. Associated orbital fractures are treated by open reduction and reconstruction of the orbital floor.

### Maxillary fractures

Maxillary fractures usually result from a direct high-velocity crushing blow to the middle portion of the face, and are extremely rare in sports other than motor sports. They are classified as Le Fort I, II and III fractures (Fig. 22.15) depending on whether the nasal or cheek bones are involved. Le Fort I fractures result in the separation of the maxilla from the nasal-septal structures and the pterygoid plates. Clinically, Le Fort I fractures are identified when the entire maxilla moves as a separate unit. Le Fort II fractures separate the maxilla and the nasal complex from the orbital-zygomatic structures. On clinical examination the maxilla and nose move together as one unit. Le Fort III fractures separate the maxillary, zygomatic, nasal and orbital structures from the cranial base (Fig. 22.16).<sup>18</sup>

Maxillary fractures are often accompanied by cranial damage, obstruction of the nasal airway, oedema of the soft palate, haemorrhage into the sinuses and disturbance of the contents of the orbit. CSF rhinorrhoea may occur, indicating fracture of the cribriform plate. Reduced sensation in the infraorbital region is common.

Examination findings include lengthening of the face, midface mobility, malocclusion of the bite and periorbital bruising. Initial treatment is aimed at protecting the airway—the conscious patient should sit leaning forward. This should be followed by rapid transfer for definitive diagnosis and treatment. Surgical treatment involves reduction and fixation with plates and screws.

### Mandibular fractures

Fracture of the mandible is one of the most common facial fractures in sport and usually results from a direct blow. The most common fracture sites are the mandibular angle and the condyle. The mandible usually breaks in more than one place as a result of the trauma and these

**Figure 22.15** Le Fort I, II and III fractures

**Figure 22.16** CT scan of Le Fort III fracture (arrow)

fractures usually occur on opposite sides of the midline. Fractures may be undisplaced or displaced.

### Undisplaced fractures

Minor mandibular fractures are painful, tender and swollen. These are managed conservatively with analgesia and rest. The patient should eat soft food only for up to 4 weeks as symptoms resolve.

### Displaced mandibular fractures

Displaced mandibular fractures are severe injuries that result from considerable force. Alveolar (tooth-bearing) fractures are the most common type. These fractures range from single tooth fractures or avulsions to complete segment mobility. The clinical diagnosis is obvious when two or more teeth move as a unit.

Inspection may reveal malalignment of teeth and bruising to the floor of the mouth. Palpation reveals malocclusion, tenderness and defects along the lower border of the mandible. Paraesthesia or anaesthesia of the lower lip and chin suggest damage to the inferior alveolar nerve.

Initial treatment includes maintenance of the airway in a forward sitting position with the patient's hands supporting the lower jaw. A jaw bandage can be used in comminuted or badly displaced fractures, although this is generally not used due to the increased associated risk of compromising the airway by causing backward displacement of the mandible. A cervical collar can be used as an alternative. A concussed or unconscious patient should be placed in a lateral position with head tilt and jaw

support after the mouth has been cleared of any dislodged teeth or tooth fragments. Occasionally, the tongue may need to be held forward to maintain an open airway.

Most displaced mandibular fractures require closed reduction and intermaxillary fixation for 4–6 weeks. If adequate closed reduction cannot be achieved, then open reduction and internal fixation is required. A fracture of one condyle usually does not require immobilisation except to control pain. Active jaw exercises should be commenced as soon as pain permits.

During the period of intermaxillary fixation, the athlete may perform mild exercises such as stationary bike riding and light weightlifting. Resumption of contact sport should be delayed until at least 1–2 months after the jaws are unwired. Earlier resumption is possible when internal fixation has been used. The use of a protective polycarbonate facial shield may offer some protection if early return to play is contemplated.

Patients with mandibular fractures who are eating soft food or have their jaws wired can be referred to a dietitian for advice on suitable liquid meals and foods suitable for vitamising.

### Temporomandibular injuries

Blows to the mandible can produce a variety of temporomandibular joint (TMJ) injuries. Trauma to the jaw while the mouth is open occasionally produces TMJ dislocation. Other injuries include haemarthrosis, meniscal displacement and intracapsular fracture of the head of the condyle.

Examination of the injured TMJ may reveal limitation of opening, pain and malocclusion. Dislocation of the TMJ causes inability to close the mouth. A dislocated TMJ may be reduced by placing both thumbs along the line of the lower teeth as far posteriorly as possible and applying downward and backward pressure. Longstanding dislocations may require general anaesthesia for reduction. Management of TMJ dislocation includes rest with limitation of mouth opening for up to 7–10 days, a soft diet and analgesics such as aspirin. Contact sport should be avoided for up to 2 weeks depending on the symptoms. Boxers should not attempt sparring for at least 6 weeks.

### Chronic temporomandibular pain

Chronic TMJ problems are sometimes referred to as 'temporomandibular joint dysfunction' or 'myofascial pain dysfunction syndrome'. This syndrome appears to affect males more than females with a peak incidence in the early twenties. Patients complain of pain, limitation of movement, clicking and locking of the TMJ. Treatment should include assessment by a dentist to exclude any

malocclusion problem. Physiotherapy evaluation with a view to manual therapy and exercise therapy can be invaluable.

### PREVENTION OF FACIAL INJURIES

Protective equipment has been designed for sports where facial injury is a risk (Chapter 9). Properly designed helmets have reduced the incidence of faciomaxillary injuries. Helmets are designed for a single impact or multiple impacts, and should be individually fitted for

each athlete. Single-impact helmets such as most pushbike and motorbike helmets must be discarded after the user has had a fall.

Facial protective equipment is constantly developing, with items such as face shields, cages and eyeglasses often used in high-risk sports such as ice-hockey and baseball. Such equipment may also be a useful adjunct to minimise any re-injury risk in the return-to-play process. The legality of the equipment should always be checked with the sport's governing body.

# Neck pain

by GWENDOLEN JULL and DEBORAH FALLA

*It makes your arm very hot, heavy and difficult to move. Stingers don't tend to last too long; you get pins and needles down your arm as the heaviness goes away. Sometimes it's 10 seconds, sometimes maybe a minute.*

England Rugby star Jonny Wilkinson, who required neck surgery after recurrent injuries

This chapter focuses on the assessment and management of non-catastrophic painful neck conditions in the athlete. While there is much attention on prevention and acute management of catastrophic neck injuries, these injuries occur predominantly, but not exclusively, in contact sports.<sup>1,2</sup> Yet, many athletes suffer from debilitating non-traumatic neck pain that can affect both their participation in sport and their quality of life. Such conditions range across a spectrum from acute muscle injury to chronic repetitive strains to cervical degenerative joint disease.<sup>3-5</sup>

### ANATOMICAL CONSIDERATIONS

It is usually not possible to make a definitive patho-anatomical diagnosis in most neck pain conditions. Lesions can be identified on imaging with injuries such as cervical fractures or dislocations, or disc disruption (linked with symptoms of a radiculopathy), as can anatomical abnormalities which may predispose the athlete to neck pain or injury.<sup>6</sup> However, for the majority of neck pain presentations in both the athletic and the general population, radiological imaging is unable to identify the pathoanatomical pain source with any certainty. As a result, the majority of disorders are generically classified as non-specific or mechanical neck pain. Despite having one label, the presentation of neck pain conditions is highly variable. Thus, the clinical examination assumes primary importance in identifying the symptom sources and any sensory, neuromuscular and sensorimotor abnormalities associated with the individual athlete's neck pain. The clinical examination relies on a foundation of anatomical knowledge.

The cervical spine is designed for movement, in contrast to the lumbar spine that is designed to carry load. As the most mobile region of the spine, its movements ensure a wide visual field. The functional cervical spine extends from the atlanto-occipital (C0-1) segment to the upper thoracic region (approximately T3-4 segment).

There are many key features to note when performing a clinical evaluation. Movement occurs independently and interdependently between the cranio-cervical, cervical and cervicothoracic regions. The atlanto-axial (C1-2) segment contributes about half the total rotation of the cervical region and this head movement can be performed relatively independently. Most of the remaining rotation occurs at the cervical segments (C2-7), but the head will not rotate to its full excursion unless the upper thoracic region provides the necessary 10° of this movement.<sup>7</sup> From a postural perspective, there is interdependence of the lumbar, thoracic and cervical spinal curves.<sup>8</sup> Evaluation must be both local and regional.

The neck muscles have many diverse roles given the broad functional requirements of the cervical region. For example, an ice hockey player needs fast movements to locate an opponent or puck, a target shooter requires fine movement adjustments for clear vision and head alignment, and a soccer player requires good stability of the neck to head a ball. To perform these tasks there must be fine muscle coordination for movement and adequate kinaesthetic awareness, as well as muscle strength.

There are 44 muscles in the neck, topographically arranged to provide these functional requirements (Fig. 23.1). Some act exclusively over the cranio-cervical

(a)

(b)

(c)

**Figure 23.1** Anatomy of the neck (a) Anatomy of the anterior neck—superficial musculature (b) Anatomy of the anterior neck—deep musculature (c) Anatomy of the posterior neck—deep and superficial musculature

(d)

**Figure 23.1 (cont.)** (d) Anatomy of the posterior neck and scapulothoracic region

region (e.g. suboccipital muscles), others act mainly on the cervical region (e.g. semispinalis cervicis), and still others span the cranio-cervical and cervical regions with attachments from the upper thoracic region (e.g. splenius capitis). The mobile structural design of the cervical spine also relies on the vital role of the muscle system to provide stability.<sup>9</sup> For stability, there is some functional specificity between the layers of both the neck flexor and the extensor muscles.

Broadly, the superficial muscles have larger lever arms and cross-sectional areas with a greater capacity to exert torque than the deep muscles.<sup>10</sup> In contrast, the deeper muscles are more segmentally arranged with segment-to-segment attachments, larger spindle densities and muscle fibre compositions that enable them to guide and support the cervical motion segments.<sup>11</sup>

Coordination between the deep and superficial muscles is required for normal neck function as the deep muscles cannot support the load of the head and the superficial muscles are not placed to support the cervical segments.<sup>12</sup> The cervical region also provides a point of attachment for muscles of the shoulder girdle (Fig. 23.1d) and must bear the load and absorb the forces induced on the cervical segments during upper limb function.<sup>13, 14</sup>

All structures of the cervical region are innervated and thus any could be a source of nociception. These

may include the zygapophysial joints, discs, ligaments, muscles and nerves. Pain may be perceived in the neck, upper thoracic region, upper limb or head (cervicogenic headache). Various studies have mapped pain areas when discs or zygapophysial joints have been stimulated.<sup>15, 16</sup>

The overlap between pain patterns of both the zygapophysial joints and discs challenges the ability to make a structural diagnosis from pain distribution alone. Furthermore, the pain distribution from symptomatic joints is more extensive than that of experimentally stimulated asymptomatic joints.<sup>17</sup> Importantly, the suboccipital and deep cervical muscles in the neck region (multifidus and longus colli) have the highest density of muscle spindles of all muscles in the body.<sup>11, 18, 19</sup> There are reflex connections between the neck and the vestibular and ocular systems (for review, see R  jezon and Treleaven).<sup>20</sup> Thus, when cervical afferentation is altered, these interconnections can underlie symptoms of unsteadiness, light-headedness or visual disturbances when associated with neck pain.

## CLINICAL PERSPECTIVE

Neck pain is considered within a biopsychosocial framework that embraces biological, psychological (e.g. anxiety, fear) and social (e.g. sports or training requirements) features and their interactions that may contribute to the athlete's disorder and recovery (Fig. 23.2). Neck pain can be a recurrent condition with repeated episodes over a lifetime, with variable degrees of recovery between bouts.<sup>21, 22</sup>

The Global Burden of Disease 2010 study ranked the burden of neck pain as the 4th highest in terms of years lived with disability and ranked it 21st of 291 conditions in terms of overall burden.<sup>23</sup> The lifetime impact of neck conditions should not be underestimated in planning rehabilitation programs for athletes. The challenge is not only to resolve an acute episode of pain to meet an immediate goal of return to sport, but to also prevent or limit recurrence for future quality of life.

Effective management of individuals with neck pain is based on good communication, a thorough history and physical examination, and sound clinical reasoning in a patient-centred approach (Fig. 23.3). The clinician carefully elicits information from the athlete and interprets it on several levels for the purposes of: ensuring patient safety (red flag conditions); making a provisional pathoanatomical diagnosis; making a definitive physical diagnosis in terms of pain mechanisms, movement, neuromuscular and sensorimotor impairments to inform a treatment plan; identifying social (sport) factors which might be driving or causing the disorder; identifying psychological features (e.g. fear of movement, anxiety)

**Figure 23.2** The biopsychosocial model for neck pain in sport. The biological, psychological and social components are artificially equally weighted in this diagram. The relationship is fluid. Weighting of biological, psychological and social features differ within and among domains, and within and between individuals. They also change at various time points within the course of an athlete's recovery

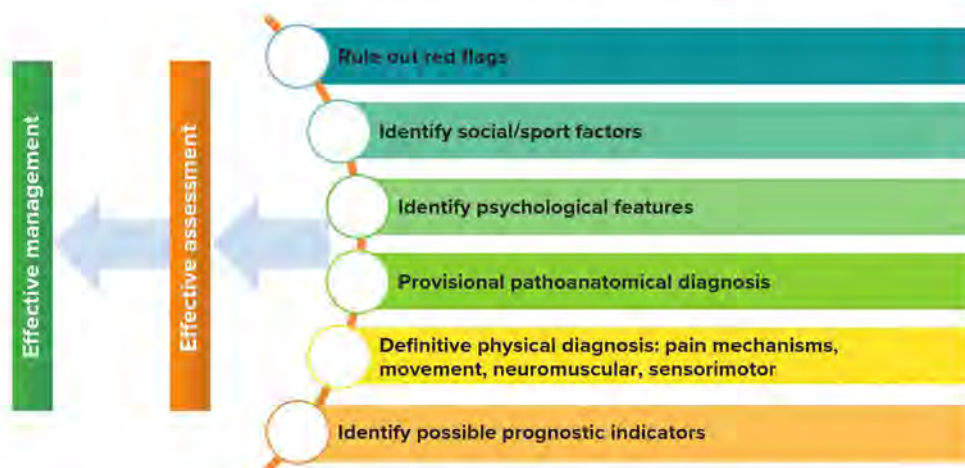

that might moderate recovery; and identifying possible prognostic indicators.<sup>24, 25</sup> There is more certainty in decision making when the assessment reveals a clinical pattern that aligns with current knowledge of painful cervical conditions. This pattern should reflect the relationships within and between biological, psychological and social features.

## History

There are four key areas of information to elucidate when taking an athlete's history. First, establish the athlete's sport and understand its requirements and implications for loads and strains on the neck region. Second, ascertain whether this is an initial onset or a recurrent neck pain condition. Third, determine the duration of neck symptoms in this current presentation (i.e. whether acute, subacute or longstanding in nature). Fourth, clarify how the neck condition began: whether symptoms arose from trauma, either direct or indirect forces (and their direction), or was insidious; and whether the onset was rapid or gradual in nature.

Identifying red flags is a vital aspect in managing athletes with cervical conditions, and the history often raises first suspicions. Except for catastrophic trauma, there are fortunately relatively few serious or life-threatening conditions that present as acute neck pain. Nevertheless, there are two conditions in particular that require clinicians' vigilance in younger to middle-aged athletes: cervical arterial dissection (CAD) and cranio-cervical ligament injury (Table 23.1). CAD can initially be misdiagnosed as a cervical musculoskeletal disorder, and the history and presentation are central to recognition of the condition. Immediate referral for medical investigation and management is essential if suspicions are raised.<sup>26, 27</sup> It is unknown how frequently the alar or transverse ligaments are non-catastrophically injured. Magnetic resonance imaging (MRI) studies have found no convincing evidence of alar or transverse ligament involvement in the common motor vehicle collision and resultant 'whiplash' injury.<sup>28, 29</sup> Immediate referral for medical investigation and management is essential if suspicions are raised.

In more benign cervical conditions, a detailed history can provide valuable information on adverse repetitive

**Figure 23.3** Decisions made from effective assessments will inform safe, individualised and effective management plans

**Table 23.1 Red flags in acute neck pain presentations**

Condition	Presentation
Cervical arterial dissection	<ul style="list-style-type: none"> <li>• Acute onset 'unusual' neck pain or headache, increasing in severity over hours or days</li> <li>• Neurological or ischaemic signs</li> <li>• Recent infection or minor trauma</li> </ul>
Cranio-cervical ligament injury	<ul style="list-style-type: none"> <li>• Head or neck trauma</li> <li>• Acute neck pain with perioral paraesthesia, tinnitus, 'lump in the throat' or nausea</li> </ul>

movements or prolonged abnormal postures relating to the athlete's sport or training which may be underlying the condition. If the neck pain is recurrent, determine the original time and nature of the onset and the pattern of recurrence, and track the progression of the condition.

### Symptoms and their behaviour

Clinicians should obtain information about the area, nature and intensity of pain. The area of pain will give some idea of the likely segmental level that is the source of the pain. Nociception from the C0-4 segments is usually perceived in the upper cervical and possibly the head region, C4-5 in the mid to lower neck, and C5-7 in the lower neck, upper thoracic region and shoulder/arm. Identification of a particular zygapophysial or disc disorder by area of pain is not possible due to overlap of their referral patterns.<sup>15-17</sup> If the athlete pinpoints the pain more posterolaterally, there is an increased possibility that a zygapophysial joint is the source of pain, as these joints are relatively superficial. Pain from irritation of nerve structures can refer into the back of the head (upper cervical nerves) or down into the shoulder and arm (C4-T2), often in a fairly typical dermatomal pattern.

The nature and intensity of the pain can give some indication of pain mechanisms. As a very basic statement, neck pain may reflect a peripheral nociceptive source (e.g. from the joints, ligaments, muscles). When there is an injury or irritation of nerves, it is termed a neuropathic pain. The former is the more common in neck pain conditions and often manifests as an ache or catching pain of mild to moderate intensity. A neuropathic pain is usually a more severe, well-delineated pain that may have lancinating and burning qualities (e.g. a 'stinger' or 'burner' caused by traction to the brachial plexus during a tackle in rugby). Pain from either source may be associated with peripheral or central nervous system sensitisation. In instances of neuropathic pain, the clinician should question the patient regarding more widespread sensitivity to touch or sensitivity to cold.<sup>30, 31</sup> Pain neuroscience has advanced remarkably over the past decades. Chapters 5 and 6 provide a more comprehensive overview of pain physiology.

The presence of other symptoms should be investigated. If the athlete has a 'stinger' or a cervical radiculopathy, there may be paraesthesia or anaesthesia in the upper limb and feelings of weakness. Other symptoms such as unsteadiness, light-headedness or visual disturbances may accompany neck pain as manifestations of cervical sensorimotor disturbances. These symptoms may also be associated with concussion, a vestibular disorder or, more often in the older patient, a vascular disorder. Thus their temporal relationship with neck pain and movement should be explored. If the athlete reports headache in association with neck pain, additional information is necessary to determine whether it is cervicogenic in nature or if it is a primary headache, such as migraine or tension-type headache. Cervicogenic headaches are typically unilateral, side-consistent headaches, associated with neck pain, and pain usually begins in the neck, later developing into a headache.<sup>32</sup> Refer to Chapter 21 for a fuller discussion on headache.

Understanding the behaviour of symptoms as well as which activities, postures or movements provoke and ease symptoms, and how they respond to rest/sleep, can confirm the mechanical nature of the condition and inform the clinician on the possible pain source. If local neck movements are the main aggravator of symptoms, the pain source may be a segmental joint dysfunction. If lifting is the primary aggravating activity, then how the axioscapular muscles are transferring the loads to the cervical segments should be examined. If the cocking phase of throwing is the main aggravator, then any link with mechanosensitivity in the upper quadrant nervous system should be investigated. The reported aggravating activities and positions should be confirmed in the physical examination, as they can direct treatment and guide re-education of appropriate postures and movements/skills pertaining to the athlete's sport or work.

Irritability of the pain and condition is also evaluated (i.e. how easily the pain is aggravated and how long it takes an acute exacerbation to settle). Sleep disturbance is also an important indicator of pain severity. High pain intensity, irritability and acuteness of the condition will limit the extent of the physical examination and the intensity of early treatment.

### Psychological features

Psychological reactions to pain such as anxiety and fear of re-injury are normal responses.<sup>33</sup> It is important for the clinician to listen to how the athlete describes his or her pain, how he or she is dealing with it and how it has affected his or her training or sports participation to gain an impression of whether the athlete seems to be unduly anxious or is expressing any fear of movement or activity because of the neck condition. This informs the nature and extent of the assurance and education required in their management. Mild depression could be expected if the neck injury has prevented the athlete from competing in his or her sport; however, moderate or marked depression is a psychopathology requiring expert assessment and care. The clinician can also gain an impression of the athlete's pain-coping strategies (e.g. high reliance on medication or passive treatment modalities versus continuing with activities and actively coping with the pain).

### Social/sport factors

It is vital for the clinician to explore and understand the requirements of the athlete's sport, training regimens and occupational activities, and their relationship to the neck pain. A formal analysis of provocative activities is mandatory (e.g. analysis of a tennis serve which aggravates/causes neck pain, analysis of the heading skill in football, analysis of cycling and bike fit, or analysis of weight-training regimens). It is also important to assess the effects

of correcting the skill on the athlete's immediate neck pain, to provide some proof of the relationship between the action and pain. This is convincing evidence for the athlete on the need to modify the skill. If the 'driver' of the pain can be removed, this increases the chances of preventing neck pain recurrences. However, the nature of certain sports makes it difficult to remove the 'driver'. For example, modifications of spinal postures and head positions may be limited in road cycling. It will be important to determine tissue tolerance to these postures and develop a program that relieves the strain on these structures before this threshold for pain is reached. This analysis of the symptom-provoking aspects of the sport is crucial for any long-term solutions for the athlete's neck pain.

### Patient-reported outcome measures

There are numerous patient-reported outcome measures (PROMs) recommended for the assessment of neck pain. Three common measures are the Numeric Pain Rating Scale (NPRS),<sup>34</sup> the Neck Disability Index (NDI)<sup>35</sup> and the Patient Specific Functional Scale (PSFS).<sup>36</sup> They are described in detail in Table 23.2. PROMs allow the clinician to understand the pain and disability level of the athlete in relation to all individuals with neck pain (NPRS and NDI), as well as to understand the specific functional concerns of the individual (PSFS). PROMs are essential to evaluate the course of recovery throughout treatment.

**Table 23.2 Patient-reported outcome measures (PROMs) in neck pain**

Measure	Description	Minimum clinically important difference (MCID) <sup>37</sup>	Minimal detectable change (MDC) <sup>38</sup>
Numeric Pain Rating Scale	Quantifies self-reported pain levels and measures pain changes over time. Athletes rate their pain on a scale from 0 and 10; 0='no pain'; 10='the worst pain imaginable'	1.3 points <sup>39</sup>	3 points <sup>40</sup>
Neck Disability Index	Ten items on functional abilities and symptoms. Each item has a 5-point scale and the score is summed and converted to a percentage	9.5 points (19%) <sup>39</sup>	10.2 points (20%) <sup>41</sup>
Patient Specific Functional Scale	Athletes nominate at least 3 activities where they are experiencing difficulty as a result of their condition. For each activity, they rate their ability to perform it, with 0='completely unable' and 10='able to complete the task at full, pre-injury level'	2.0 points <sup>41</sup>	2.1 points <sup>41</sup>

MCID: The smallest difference that patients perceive as beneficial

MDC: The amount of change that must be observed before the change can be considered to exceed the measurement error

## Imaging

When the neck pain has resulted from trauma (e.g. collisions, crashes, falls), imaging (plain radiography, computed tomography [CT] scans) is indicated to identify or rule out such lesions as fractures or subluxations/dislocations. There are clear protocols (Canadian C-Spine Rule; NEXUS Criteria) to guide the need for imaging after trauma which have proven sensitive, although their specificity has been challenged.<sup>42, 43</sup> This can affect adherence to these guidelines, as clinicians and athletes want to ensure that serious pathology is not missed. Imaging is also indicated when, on clinical grounds, there is any suspicion of a lesion or fracture.

There is long-standing debate about the need for routine imaging of people presenting with neck pain because the majority of routine imaging provides no additional or certain information to assist structural diagnosis. Even recent studies using MRI have failed to detect and define differences between the non-pathological age-related changes of the cervical spine in people without neck pain and the cervical spines of people with neck pain conditions.<sup>28, 44, 45</sup> Thus routine diagnostic imaging is not indicated for most people with neck pain. The decision to order imaging for the athlete with a neck pain condition should be based on clinical grounds to confirm a clinical diagnosis or clinical suspicion.

## Physical examination

The clinical reasoning process commenced in the history continues throughout the physical examination. The physical examination further defines the condition and has three principal aims:

1. to gain a clear picture of the immediate source(s) of pain and the nature of the dysfunction (e.g. a painful cervical segment, protected by local muscle spasm that is restricting segmental and regional motion)
2. to detect and document the effect of pain and injury on the sensory, neuromuscular and sensorimotor systems, and gain an understanding of the interactions between these systems
3. to develop a management program directed by the findings of the physical examination; this management program may be moderated by knowledge of history of onset and pain intensity/mechanisms.

No single test will provide the answer; rather, the clinician seeks a pattern of test responses from the various systems. Two clinical examples illustrate this important point.

The first is the athlete who reports that neck and right arm pain is provoked in the early cocking phase of throwing. Nothing abnormal was detected in the glenohumeral complex. It was reasoned that a cause of

this pain could be mechanosensitivity of nerve tissue of the upper quadrant. The pattern of signs that would fit this hypothesis<sup>46</sup> is shown in the box below. If such a pattern of physical impairment and pain responses was not elicited, the clinician would need to reflect on his or her provisional diagnosis and propose an alternative hypothesis to test.

The second is an athlete who presents reporting headaches that are increasing in frequency and who believes they are caused by his or her neck (the athlete has neck pain and tenderness with the headache). The clinical confounder is that most primary frequent intermittent headaches (migraine and tension-type headache) have some neck pain and tenderness in association with headache.<sup>47</sup> This reflects the bi-directional pathway of the trigeminocervical nucleus.<sup>48</sup> A cervicogenic headache is classified as a secondary headache (i.e. secondary to a primary cervical musculoskeletal dysfunction). If the athlete's headache is cervicogenic, then it would be expected to be associated with a pattern of cervical musculoskeletal dysfunction: cervical movement impairment, segmental joint dysfunction (C0-4 which refers pain into the head) and muscle function impairment.<sup>49</sup> Neck tenderness as a single sign has no diagnostic significance. Failure to find this pattern of cervical musculoskeletal dysfunction would rule out a cervical cause of headache. This chapter does not cover the temporomandibular joint complex. Nevertheless, the clinician is reminded of the role that craniomandibular dysfunction may play in head, face and neck pain.

There are many tests that may be employed in the physical examination to evaluate the function and integrity of articular, neural, neuromuscular and sensorimotor systems of the cervical region. The tests used will depend on the individual athlete. For example, there is no indication to use the upper limb neurodynamic tests or Spurling's test in an athlete presenting with right upper cervical pain aggravated by looking upwards. Likewise, in acute injury or pain, examination will be curtailed to those tests absolutely necessary to gauge severity and to inform initial management. The order in which tests are conducted in the physical examination usually considers the athlete's position and comfort. However, for ease of description here, tests will be described in groups rather than the ideal order of application.

The physical examination involves the following.

1. Postural analysis
  - a. dynamic postures (symptom provoking positions or relevant sports/activity-related positions)
  - b. static posture of the spine and axioscapular region in sitting and standing in all three planes
  - c. axioscapular posture.

### An example of clinical reasoning in the physical examination to confirm the hypothesis that an athlete's neck and arm pain while throwing was related to mechanosensitivity of nerve tissue of the upper quadrant

**Functional complaint:** Neck and (R) arm pain provoked in the early cocking phase of throwing

**Shoulder joint:** No abnormality detected in any test

**Reasoning:** Pain from mechanosensitivity of nerve tissue of the upper quadrant

**Physical examination confirmation**

**Posture:** Slightly elevated (R) shoulder

Scapular depression reproduced slight arm pain (stress on brachial plexus)

**Active/passive movement dysfunction:** Cervical lateral flexion (LF) to the left most provocative of arm pain (strain on right nerves)

Range of lateral flexion is restricted (compared to normal) and right arm pain is present when the nerves are pre-tensioned

Arm pain ↓ when arm passively supported in 90° abduction and external rotation with elbow flexed (nerves off tension)

**Adverse responses to neurodynamic tests:**

Upper limb neurodynamic test

– lacks 30° elbow extension and neck and arm pain reproduced

– cervical LF (L) increases pain; LF (R) decreases arm pain

**Evidence of a local area of pathology:** Manual examination: painful segmental joint dysfunction C5–6

2. Active movement tests—each assessed for cranio-cervical (C0–2), cervical (C2–7) and cervicothoracic (C7–T4) regions
  - a. flexion
  - b. extension (Fig. 23.4)
  - c. lateral flexion
  - d. rotation
  - e. flexion/rotation (Fig. 23.5).
3. Quantitative sensory testing (e.g. pressure pain threshold, thermal pain threshold)
4. Manual examination of segmental dysfunction (e.g. posterior-anterior glides [Fig. 23.6], PPIVMs)
5. Tests of the nervous system
  - a. clinical neurological examination (if indicated)
  - b. upper limb neurodynamic tests (movement and mechanosensitivity of nerves)—Chapter 15.
6. Tests of muscle function
  - a. cervical flexors
    - i. cranio-cervical flexion test (Fig. 23.7)
    - ii. cervical flexor strength and endurance.
  - b. cervical extensors
    - i. cranio-cervical extension test (Fig. 23.8a)
    - ii. cranio-cervical rotation test (Fig. 23.8b)
    - iii. cervical extensors (biased towards the deep cervical extensors) (Fig. 23.8c)
    - iv. modified Biering-Sorensen test.
  - c. axioscapular
    - i. dynamic scapular control (Fig. 23.9)
    - ii. lower trapezius, serratus anterior in prone and quadruped
    - iii. muscle length tests (e.g. levator scapulae, pectoralis major/minor).
7. Tests of cervical sensorimotor function
  - a. test of joint position sense (Fig. 23.10)
  - b. test of movement sense (Fig. 23.11)
  - c. static and dynamic balance
  - d. ocular motor tests (gaze stability, smooth pursuit neck torsion test [SPNTT] and evaluation of rapid eye movements).
8. Additional tests (if indicated)
  - a. cervical arterial dysfunction
  - b. additional passive movement tests when indicated (e.g. Spurling's)
  - c. cranio-cervical ligament tests (e.g. Sharp-Purser test; alar ligament tests).

### Postural analysis

One of the most important assessments is the analysis of the relevant sports/work or activity-related postures and movements that aggravate the athlete's pain. The athlete demonstrates the activity or position that is pain provoking. The clinician analyses the movement and its control from local and regional perspectives. The clinician should facilitate correction of the posture, movement or technique to gauge the effect on pain or performance. This will accurately and relevantly inform the management approach.

Posture is then formally examined in standing and sitting. The regions of the spine are interdependent, and assessment of head and neck orientation can only be made in relation to orientation of the lumbopelvic region and thoracic spine. The most common poor sitting posture is the slumped 'flexed' posture which facilitates a forward head posture. Some persons have an extended spinal

posture in sitting (e.g. some ballet dances and gymnasts) while others have a good 'neutral' posture. It is necessary to determine whether the person's 'non-ideal' posture is contributing to their neck pain.

An answer can be gained by a simple test-retest approach. Test cervical rotation in the person's natural posture and note any movement restriction or reproduction of their neck pain. Correct posture to the ideal upright neutral position and retest cervical rotation. If the range and pain response improve significantly, this suggests that poor posture is one driver of the neck pain or loss of function and indicates that postural re-education will be an important strategy in management.

At the other extreme, if there is no change in rotation range or pain with postural correction, then the clinician can reason that posture is not a major contributor. In this case, postural correction will not be taught with a rationale that it is a driver of pain. As will be discussed in the management section, postural correction will be taught, but with the intent of facilitating the postural supporting muscles.

A similar process is undertaken in the evaluation of scapular orientation and this is described more fully in the later section on axioscapular muscles.

### Active movement tests

The observation of reduced cervical range of movement is valuable in the diagnosis of cervicogenic headache, cervical radiculopathy and cervical spine injuries.<sup>50</sup> Movement is an impairment in most neck pain conditions. Movements of flexion, extension, lateral flexion and rotation should be assessed in the three functional regions of the cervical spine: cervical (C2-7), cranio-cervical (C0-2) and cervicothoracic (C7-T4) regions. The information gained from this movement analysis includes range of motion, pain with motion and the ability to control motion. Movements can be affected by articular, muscular or neural tissue, and differentiation of the source of restriction or pain will inform treatment planning.

In the examination of cervical flexion, ensure that the chin stays in a neutral position since anatomically, full

(a)

(b)

**Figure 23.4** (a) Cervical extension. Note the displacement of the head behind the line of the shoulders (b) Cervical extension. If movement is only occurring in the upper cervical region, there is no posterior displacement of the mid to lower cervical segments

cervical flexion cannot be performed with simultaneous full upper cervical flexion. Extension is informative in detecting both articular and motor control problems. Normally, the head should displace behind the line of the shoulders in full extension. While the person's face may be directed to the ceiling (upper cervical extension), it is often observed that the mass of the head is not displaced posteriorly to a sufficient extent (Fig. 23.4). This may be a protective strategy for a painful cervical joint, or masking poor muscle control of the region (or both). Encouragement is given to perform the movement correctly and the response noted. If pain limits the movement, the movement usually stops at the segmental source of the pain. If the problem is poor control (i.e. poor eccentric control of the deep cervical flexors), a 'give' in the mid-cervical region may be observed as the neck extends, or the patient may protrude their chin as the initiating action on return from extension to the upright position (due to poor concentric control of the deep cervical flexors).

Assessment of axial rotation gives a clear indication of the contribution of the cranio-cervical, cervical and cervicothoracic regions to total head rotation. Cranio-cervical rotation can be tested in relative isolation from the remainder of the cervical region with the flexion-rotation test (Fig. 23.5a).<sup>51, 52</sup> The contribution of the cervicothoracic region<sup>7</sup> to total rotation can be assessed through observation, and the segmental contribution to the movement can be determined by palpation of the movement at each spinous process as the patient repeatedly rotates his or her head (Fig. 23.5b). The clinician can detect segments that are hypomobile and not contributing to the movement.

Lateral flexion is probably the most useful movement to differentiate between an articular, neural or muscular restriction to movement (see box above).

Despite difficulties in imaging relevant pathoanatomy, selected movement tests can identify facet joint dysfunction. The flexion-rotation test has been proven to be a reliable test with content and discriminant validity.<sup>51-55</sup> It can be used with confidence to locate C1-2 joint dysfunction, especially in the diagnosis of cervicogenic headache. The extension-rotation test,<sup>56</sup> when used in combination with a palpation and manual

(a)

(b)

**Figure 23.5** (a) The cervical flexion rotation test (C1-2 rotation). The athlete is positioned in supine and the head is supported by the clinician. The athlete is asked to look down at his/her toes (cervical flexion) and simultaneously the clinician moves the athlete's neck into full flexion. The head is then rotated to the left and right and the clinician is assured of performance of a correct test when there is a definite end to the movement. There should be at least 30° of rotation, and a side-to-side difference of 10° is considered a positive test result<sup>53</sup> (b) Assessment of cervicothoracic rotation. The athlete actively and repeatedly rotates his/her head. Using a gentle lateral glide on the spinous process in time with the active movement, the clinician perceives the presence (or not) of rotation of each thoracic vertebra to approximately the T4 level

examination, is able to detect the painful zygapophysial joint—as tested against facet anaesthetic blocks.

### Quantitative sensory testing

Many neck pain conditions involve peripheral nociception with or without peripheral sensitisation. Of particular concern are athletes who present with central nervous system sensitisation. Care must be taken in both the examination and management approach for these individuals as overzealous examination and management may easily aggravate their condition. Examination and management techniques should cause no further pain. Conditions in which central sensitisation may occur include cervical radiculopathy,<sup>30</sup> cervicogenic headache<sup>57</sup> and whiplash-associated disorders (WAD).<sup>58</sup> Such individuals may present with many sensory disturbances including widespread mechanical hyperalgesia and cold hyperalgesia. Pressure pain thresholds may be tested with an algometer or the clinician could determine if the athlete seems oversensitive to touch, not only over the neck but also more distally in the arms and legs. A simple clinical test can test cold hyperalgesia.<sup>59</sup> If patients report pain >5/10 on a NPRS after a 10-second application of an ice pack to the neck region, the clinician could be suspicious of the presence of cold hyperalgesia.

### Passive tests

#### Manual examination of segmental dysfunction

Manual examination is used to detect the painful segment(s), and to qualitatively assess segmental motion and tissue resistance to the manually induced movement ('end feel'). The segments from C0-1 to the upper thoracic region are examined. Posterior-anterior glides (Fig. 23.6) can be regarded as a gentle provocative test to locate the symptomatic facet joint or cervical segment. Passive physiological intervertebral movements (PPIVMs) are used to both confirm the segment(s) with altered mobility and to understand the nature of the movement impairment. Although not without historical controversy, manual examination is proving to be an accurate method to locate the symptomatic segment(s). Manual examination with and without other physical tests accurately identifies segmental levels of dysfunction and assists in differential diagnosis of disorders such as cervicogenic headache.<sup>49, 56, 60</sup>

#### Other passive movement tests (when indicated)

There are several additional testing procedures that can be employed when necessary in the examination of an athlete with a neck pain condition. Some clinicians extend the examination to direct a particular treatment approach; for example, examining movements in combination or gauging the effect of repeated movements.<sup>61, 62</sup> Other

**Figure 23.6** Posteroanterior glides on the C2–3

zygapophysial joint. Gentle manual forces are applied over the lamina of the zygapophysial joints of all segments as well as over the spinous processes to determine which is the painful segment associated with the athlete's neck pain disorder. Good technique is required and the posteroanterior glides must be applied painlessly to avoid false positive results

tests seek a particular pathoanatomical compromise, such as Spurling's test. This test, a combination of cervical extension and lateral flexion, narrows the intervertebral foramen and is used to determine if arm symptoms are related to a sensitive and/or compromised cervical nerve root.<sup>63</sup> There are clinical tests for the cranio-cervical ligaments, specifically the transverse ligament, tectorial membrane and alar ligament, as well as the integrity of the cervical segments. Such tests would be indicated after trauma. A variety of symptoms are proposed that might arouse suspicion, such as feeling unable to hold the head up or a desire for support either by a collar or hands.<sup>64</sup> The test for the transverse ligament (Sharp-Purser test) has been validated in a population with rheumatoid arthritis.<sup>65</sup> MRI has established the construct validity of both the side-bending and rotation clinical stress tests for alar ligament integrity.<sup>66</sup> However, clinicians should consider that the true clinical utility of these tests has yet to be proven and the true incidence of non-catastrophic cranio-cervical ligament injury is yet to be established.<sup>28, 29</sup>

### Tests of the nervous system

#### Clinical neurological examination

A clinical neurological examination (sensation, muscle strength and reflexes) is indicated when there is suspicion of a cervical radiculopathy and compromised nerve conduction (i.e. athlete presents with referred arm pain or has suffered a 'stinger' due to traction of the brachial plexus or compression of the cervical nerve roots).

### Tests of movement and mechanosensitivity of nerve structures

Nerves and their surrounding structures are pain sensitive and can contribute to neck pain conditions. The classic upper limb neurodynamic test (see Chapter 15) is a valid and reliable test of brachial plexus mechanosensitivity.<sup>46, 67-69</sup> The test is considered positive when there is at least partial reproduction of symptoms and these symptoms can be altered via structural differentiation.<sup>67</sup> Further, there is usually a side-to-side difference in the range of movement in the final test component (usually elbow extension) with increased muscle resistance to limit the provocative movement. As illustrated earlier (see Box earlier in the chapter), there is usually a pattern of clinical symptoms and signs that nerve tissue mechanosensitivity is a pain source.

### Tests of muscle function

There are potential changes in control and structure of neck and axioscapular muscles in the presence of neck pain and injury. Changes in motor control include altered coordination between deep and superficial neck muscles, which may compromise the deep muscles' capacity to support the cervical segments in posture and movement.<sup>12</sup> Evidence of this impairment is strong for the flexor muscles<sup>70-72</sup> and is emerging for the extensor muscles.<sup>73, 74</sup>

Altered muscle coordination has been found in persons with neck pain of both insidious and traumatic onset,<sup>70-72, 75</sup> indicating that it is common motor dysfunction (analogous to the inevitable quadriceps muscle dysfunction that occurs with knee conditions regardless of cause). Muscles lose directional specificity,<sup>76</sup> and increased co-activation of the neck flexor and extensor muscles during isometric and functional tasks has been found.<sup>75-77</sup> Onsets of muscle activity are delayed, as demonstrated by an increased latency between the onset of the deltoid muscle and onset of the neck muscles with rapid arm movement,<sup>78, 79</sup> and by delayed activation of the neck muscles in response to full-body perturbations.<sup>80</sup> This has implications for unprotected loading on cervical segments during sport and functional activities. People with neck pain also display reduced strength and endurance at various contraction intensities, and their neck muscles may demonstrate increased muscle fatigability.<sup>81-83</sup>

Muscle biopsies reveal changes in fibre type within the neck flexors and extensors in people with longstanding neck pain.<sup>84</sup> Specifically, there is an increased proportion of type IIC transitional fibres, consistent with a transformation of slow-twitch oxidative type I fibres to fast-twitch glycolytic type IIB fibres, which aligns with the cervical muscles' decreased endurance capacity. Muscle atrophy has been documented in individuals with chronic neck pain conditions<sup>85-87</sup> and widespread fatty infiltrate

has been identified in the flexor and extensor muscles, particularly in the deep muscles of those with moderate to severe chronic WAD.<sup>88</sup> It appears that fatty infiltrate may be a feature of chronic whiplash, but not of chronic, insidious-onset neck pain,<sup>89, 90</sup> which suggests there might be differences in pathophysiological mechanisms between these two neck pain groups.

The axioscapular muscles are commonly tender to palpation but more importantly, poor muscle function of the shoulder girdle may overload cervical structures and contribute significantly to pain. The upper trapezius attaches to the cranium and ligamentum nuchae, and the levator scapulae attaches directly to the upper four cervical segments. Normal upper limb function induces both compressive loads and movement in the cervical segments.<sup>13, 14</sup> Poor scapular muscle control may adversely increase these loads and strains.

Electromyographic studies have revealed greater fatigability of the upper trapezius<sup>91</sup> and altered patterns of trapezius muscle function in functional tasks in individuals with neck pain disorders.<sup>75, 92</sup> Moreover, the spatial distribution of upper trapezius muscle activity changes in the presence of pain.<sup>93, 94</sup> Evidence for serratus anterior dysfunction in neck pain patients is also emerging.<sup>95</sup> A link between neck pain and altered axioscapular muscle function has recently been established in an experimental pain study, where the neck pain resulted in some reorganisation in axioscapular muscle activity.<sup>96</sup>

### Assessment of cervical flexors

The cranio-cervical flexion test (CCFT) assesses the activation and holding capacity of the deep longus capitis and colli muscles (for review see Jull et al.).<sup>97</sup> It is a low load test performed in supine. The test is conducted in two stages (Fig. 23.7).

The first stage evaluates motor control. The athlete performs five progressive stages of increasing cranio-cervical flexion range and is guided to each stage by feedback from a pressure sensor (such as the Stabilizer Pressure Biofeedback unit) placed behind the upper neck. The pressure sensor indirectly monitors the slight flattening of the cervical curve that occurs with longus colli contraction. The displacement, registered by the pressure sensor, permits some quantification of deep cervical flexor muscle performance.<sup>98</sup> The assessment determines the pressure level that the athlete can achieve in the test when asked to target each of the five stages of 2 mmHg pressure increments from a baseline of 20 mmHg to a maximum 30 mmHg. A 'correct' performance is when the athlete performs a slow and controlled cranio-cervical flexion action (rather than retraction) and no excessive activity of the sternocleidomastoid (SCM) or anterior

(a)

**Figure 23.7** (a) The cranio-cervical flexion test (CCFT). The pressure sensor is placed suboccipitally and inflated until a stable baseline of 20 mmHg is gained. In stage 1 of the test, the athlete is instructed to feel the back of his or her head slide up the bed to nod his or her chin. The athlete repeats the action five times, progressively targeting increasing increments of 2 mmHg from 22–30 mmHg, holding each pressure target for 1–2 seconds and relaxing between each. The clinician analyses the quality of cranio-cervical flexion movement at each point. Each pressure target should be achieved with increasing ranges of flexion, which will not be observed if the patient substitutes with a retraction action. Any excessive use of the superficial flexors should be observed and palpated. In stage 2 of the test, the athlete nods to the target pressure and holds the contraction. In an acceptable performance, the athlete uses the correct cranio-cervical flexion action and can hold the pressure steady. Inadequate performance is judged when the patient cannot hold the pressure steady (the pressure drops off target), it is held with a jerky action, or dominant activity of the superficial flexors is observed

COURTESY OF GWENDOLEN JULL

(b)

**Figure 23.7** (b) The face of the pressure sensor showing the marked 2 mmHg increments that the patient targets in the CCFT

scalene (AS) muscles is observed. Note the SCM and AS muscles flex the neck but not the head, so they should not be excessively active during cranio-cervical flexion.

Stage 2 tests the endurance of the deep cervical flexors at functionally relevant low contractile intensities. Stage 2 is performed when the patient can correctly perform the cranio-cervical flexion action; thus, this stage may be tested at the second treatment session, once the athlete has mastered the action.<sup>97</sup> In a formal assessment of the endurance capacity, the athlete performs 10 repetitions of 10-second holds at each progressive pressure level from 22 mmHg until failure. Most asymptomatic individuals perform well to at least 26 or 28 mmHg whereas individuals with neck pain can usually only achieve stages 22 or 24 mmHg.<sup>97</sup> As a clinical note, the formal assessment of endurance can take up to 5 minutes or more to perform, which is a long time in a busy practice. The clinician can take a shortcut and use the test to determine at which pressure level the athlete can commence training. In this case, the clinician judges the athlete's performance on approximately three repetitions of 5-second contractions at 22 mmHg. If performance is satisfactory, the test is quickly progressed to 24 mmHg and so forth, until the patient shows difficulty in maintaining a steady contraction. Training commences at the level below the stage of failure.

Strength and endurance of the neck flexors (both superficial and deep flexors) are tested at a time only when the patient's pain and muscle performance level permits. These are tested with a head lift task while maintaining a cranio-cervical flexion position. This is a test predominantly of the SCM and AS muscles, which provide more than 80% of the cervical flexion torque.<sup>10, 99</sup>

If the patient's chin protrudes when attempting to lift or hold the head position, this means the deep cervical flexors are too weak to cope with the level of load.<sup>100</sup>

#### Assessment of cervical extensors

Impairment in the suboccipital muscles is common and recent research is suggesting that the deeper cervical extensors may have greater impairments than the superficial extensors.<sup>73, 74</sup> Hence, these muscles are of particular interest in clinical tests. The topographical arrangement of the extensor muscles allows some targeting of these muscle groups.

The athlete is positioned in four-point kneeling or lies prone, propped on elbows, with the cranio-cervical region in a neutral position.<sup>101</sup> All extensors work in this position to support head mass, but the suboccipital muscles are targeted with a test of cranio-cervical extension (chin lift and lower, rectus capitis posterior major and minor) and cranio-cervical (C1-2) rotation (rotate 30-40°, obliquus capitis superior and inferior) (Fig. 23.8a & b). Often no obvious impairment is observed due to the low load nature of the test. However, in athletes with an upper cervical disorder, it is not uncommon to observe that the athlete has difficulty in actually performing rotation at C1-2, and rotates through the mid and lower cervical region. This deficit should be remediated in the exercise program.

The deeper cervical extensors, semispinalis cervicis and multifidus, are targeted by testing cervical extension with the cranio-cervical region maintained in a neutral position.<sup>102, 103</sup> The superficial extensors attach to the cranium and the neutral head position takes away some of their mechanical advantage. The axis of motion for cervical extension passes through the lower cervical region.

To test cervical extension of the deeper muscles, the athlete flexes his or her head and neck to look at the knees and then curls the head and neck back into extension (Fig. 23.8c). The neutral cranio-cervical region is maintained with eye facilitation. The athlete pretends that there is a book between his or her hands, keeping his or her eyes on the book while curling the head into extension. Neck extension should be around 30°. An inadequate performance occurs when the athlete can only extend to the neutral position, reports fatigue after a few repetitions, or cannot extend without use of cranio-cervical extension (i.e. the superficial extensors).

The second phase of strength and endurance testing for the neck extensors is performed once the athlete can perform multiple repetitions of cervical extension in the four-point kneeling position, and only as their pain permits. The modified Biering-Sorensen test can be used.<sup>104</sup> The athlete lies prone with his or her head supported over the end of the couch such that the cranio-cervical and cervical regions are in a neutral position.

(a-i)

(a-ii)

**Figure 23.8** (a) The suboccipital extensors are tested with the movement of head extension (a 'yes' nodding action). The cervical spine should remain in neutral and the athlete should be able to perform discrete cranio-cervical extension. The neutral starting position is shown in (i), the cranio-cervical extension position in (ii).

Support is released and the time for which the athlete can hold the head/neck position without deviation is recorded. The test can be made more time-efficient if a light weight (e.g. 1 kg) is placed on the head and baseline values recorded. The test can be extended to evaluate the thoracic extensors by having the athlete raising their shoulders from the supporting surface.

### Axioscapular muscles

It is the interaction of several muscles that control the movement of the scapulae. Clinical assessment of scapular muscle function involves analysis of scapular posture at

(b)

**Figure 23.8 (cont.)** (b) The suboccipital rotators are tested with the movement of head rotation (a 'no' action). The cervical spine should remain in neutral. Movement should occur as a head rotation only, without rotation in the mid lower cervical spine. The clinician may gently fix C2 to help the patient localise the C1–2 rotation (c) The cervical extensors are tested by performing cervical extension while maintaining the cranio-cervical region in a neutral position. This neutral position is attained and maintained through eye facilitation. The athlete first curls his/her head down to look towards the knees (i). As the athlete curls the head and neck in extension, the eyes are kept fixed on an imaginary book located between the hands, which will encourage the cranio-cervical neutral position (ii). Good cervical extension is demonstrated here, but many athletes cannot extend past the neutral position

(c-i)

(c-ii)

rest, under light load with arm movement, as well as by using formal tests of the muscles' contractile abilities and extensibility.

Variation in scapular orientation is common and examination is necessary to disentangle normal variations from scapular dysfunction contributing to the athlete's neck pain. There are several common scapular positional faults.<sup>105</sup>

A downwardly rotated scapula ('ski slope' appearance of line of the nape of the neck) may be due to poor function of the three portions of the trapezius and overactivity or tightness of the levator scapulae muscle. Medial border winging of the scapula may be caused by weakness of serratus anterior muscle, and prominence of the inferior scapular border because of excessive anterior scapular tilt may be due to weakness of the lower trapezius muscle. There may be increased resting tone and tenderness to palpation of the levator scapulae and rhomboid muscles if they are compensating for poor upper trapezius function.

An indication of a direct relationship between scapular posture, poor axioscapular muscle function and the neck pain can be assessed with a simple test (Fig 23.9).<sup>101, 106</sup> First, the athlete's baseline cervical range of motion and pain is assessed. Next, the clinician manually corrects scapular position and the athlete repeats the cervical rotation movement. An improvement in range and/or pain signals that poor scapular posture and muscle dysfunction is likely contributing to the cervical pain or restricted movement and warrants attention in treatment.

There is minimal scapular motion within the first 30–40° of arm elevation.<sup>107</sup> An initial impression of dynamic scapular control in this neutral posture can be

**Figure 23.9** Testing the effect of manually correcting the scapula to a neutral position on range and pain in cervical rotation. Improved range and reduced pain indicates a role for aberrant scapular posture in the neck pain condition

gained by applying very light isometric resistance to shoulder flexion, abduction and external rotation while observing any subtle movement of the scapula. With resisted flexion, an inability to maintain posterior tilt of the scapula would suggest weakness in the lower trapezius and serratus anterior muscles. With resisted abduction, an inability to maintain an upward rotation of the scapula (i.e. there is a slight depression of the acromion) suggests weakness of the upper trapezius muscle. With resisted external rotation, an inability to maintain external rotation of the scapula suggests weakness in the serratus anterior and lower trapezius muscle. In summary, with assessment of arm elevation, impaired trapezius and serratus anterior muscle function is revealed by a reduced ability to posteriorly tilt, upwardly rotate and externally rotate the scapula during full arm elevation as well as by poor eccentric control with arm lowering.

Control and endurance of the axioscapular muscles relevant to their postural function is tested in prone lying under low load, using a modified grade 3 muscle test for the lower trapezius<sup>108</sup> (i.e. the arms rest on the bed by the side with the elbow in 90° flexion). One side is tested at a time. The athlete's scapula is passively placed in a neutral position on the thorax and the athlete holds the position. Muscle activity to hold the scapula is analysed by observation and palpation. Signs of compensation for poor axioscapular muscle activation are noted such as adduction and extension of the arm via compensation by the latissimus dorsi. Signs of fatigue (tremor or loss of position) are also noted. The capacity of the axioscapular muscles to fix the scapula to the thorax in a neutral position is also tested under load in the quadruped position. Substantial winging of the medial border of the scapula is an indication of poor axioscapular muscle control, particularly of the serratus anterior muscle.

A protracted scapula may indicate that length tests of levator scapulae or pectoralis major and minor muscles are warranted. Muscle length tests should not be performed when the neck pain is acute or in the presence of mechanosensitive neural tissue. Testing may aggravate the neck condition in these circumstances, as the upper trapezius and the scalene muscles provide protection to sensitive nerve structures. The upper trapezius muscle is a common sight of pain and tender points; however, the muscle is often in a lengthened position (in association with a downwardly rotated scapula). Stretching is not indicated in these circumstances; rather, rehabilitation should target its contractile capacity, along with the other portions of trapezius and serratus anterior muscle.

### Tests of cervical sensorimotor function

The cervical sensorimotor system is one of three systems contributing to postural control (i.e. the control of both

static and dynamic postural equilibrium). The others are the vestibular and visual systems. The cervical muscles, and especially the suboccipital muscles, contain a high percentage of muscle spindles per gram of muscle and these relay sensorimotor information to the central nervous system.<sup>11, 18, 19</sup> These afferent signals are important for the control of head and neck position and coordination.

Cervicogenic dizziness is caused by altered afferent input from cervical structures in the presence of pain, inflammation, morphological changes or altered muscle activity. Typical symptoms include a vague unsteadiness, light-headedness, nausea and an array of visual symptoms such as blurred vision, the need to concentrate to read, visual fatigue, difficulty judging distances and sensitivity to light.<sup>109</sup> Symptoms are thought to result from conflicting input from the altered cervical afferentation and normal afferent input from the visual and vestibular systems (for reviews, see Clark et al.<sup>110</sup> and R  jezon et al.<sup>111</sup>).

It should be noted that these symptoms may also arise from concussion or vestibular dysfunction, or possibly a combination of both. In a blow to the head sufficient to concuss an athlete, the neck and particularly the upper cervical region will also absorb the force and could be injured. Some clinical tests have some differential diagnostic potential<sup>112, 113</sup> but often it is difficult to differentiate the source unequivocally.

Cervical sensorimotor function may be impaired in any neck pain condition, but is most frequent when the neck pain is a result of trauma or when the athlete complains of such symptoms as light-headedness, unsteadiness or visual symptoms.<sup>114-117</sup> Three functions are tested: joint position and movement sense, standing balance and oculomotor control.

Joint position sense is measured clinically by assessing the accuracy with which an athlete returns to their natural head posture following movement. Tests of relocation accuracy using rotation in each direction and extension are most common. The athlete sits in a chair positioned 90 cm from a wall to which a pre-calibrated target is attached.<sup>118</sup> A laser fastened to a headband is mounted on the athlete's head. The target is positioned on the wall, the centre of which corresponds to the athlete's natural starting position. Following a familiarisation session, the athlete closes his or her eyes, rotates the head as far as possible to the left (at least 45° for a valid test), then returns as closely as possible to the starting position (Fig. 23.10). The test is repeated at least 3-5 times and the mean measurement recorded. Relocation with more than 4.5° of error (the outer red circle and beyond) is outside normal limits.

Movement sense may also be tested by having the athlete follow a moving object with the laser pointer.<sup>119</sup> Patterns of movement with increasing difficulty are tested, and normative values have been established for each

(a)

(b)

(c)

**Figure 23.10** Testing joint reposition sense from rotation (a) The athlete should sit in a supported position with eyes closed throughout the test (b) Each movement direction is tested three times (c) The clinician repositions the head on target between each repetition

**Figure 23.11** A test of movement sense. The athlete must trace the shape with the laser as accurately and as fast as possible. Emphasis is placed on accuracy and the patient must keep the laser on the marked lines

scenario.<sup>120</sup> Alternatively, the athlete can be requested to trace a static target with a laser, with irregular trajectories being assessed (Fig. 23.11).<sup>121</sup>

Balance can be measured both statically and dynamically. The cervical sensorimotor system is best challenged with higher-level balance tests than those that may be initially used for a sprained ankle. This is especially so for the athletic population, where balance problems may be overlooked if tests are not challenging enough to detect high-level balance deficits.

Static balance is first assessed by testing the athlete's ability to stand in tandem stance with eyes open for 30 seconds. The test is progressed from eyes open to eyes closed, or from standing on a firm surface to a soft surface (e.g. 10 cm thick dense foam). Further testing progression includes single leg stance or placing the head in a rotated position while in the different stance positions.<sup>122</sup>

Dynamic balance tests include the conventional Dynamic Gait Index, a 10-metre walk with head turns, or a step test.<sup>123, 124</sup> These tests could also be progressed to include sport-specific positions and performing multiple tasks. For example, a fencing athlete could be asked to perform an 'advance lunge' while accurately targeting the sword tip. A more dynamic task could be practice of 'balestra', which demands holding a steady end position.

Oculomotor control is tested qualitatively using three tests: gaze stability, the smooth pursuit neck torsion test (SPNTT) and evaluation of rapid eye movements.

Gaze stability is tested by requesting that the athlete fix his or her gaze on an object (e.g. a pen) while comfortably rotating the head to the left and right. The clinician holds a pen about 1 metre away in line with the athlete's nose and observes whether he or she can easily dissociate eye movement from head movement.

The SPNTT evaluates eye follow ability. Impairments in eye follow can be a normal phenomenon or due to neck pain, concussion or a vestibular disorder. The SPNTT was designed to differentiate a probable cervical cause.<sup>125</sup> In the test, the clinician moves a finger or pen back and forth, crossing the athlete's midline, and assesses eye movement control by watching the athlete's eyes follow the target, noting any saccadic movements (rapid 'catch-up' movements). The test is then repeated with the trunk rotated 45° (the head remaining in neutral position). This targets the neck, but has no effect if the underlying cause is vestibular or due to a concussion. The cervical spine is implicated if eye saccades increase in the turned position compared to the neutral position.<sup>116</sup> It is not uncommon for one side only to be compromised. Finally, quickly alternating gaze between two targets (saccadic movements) can also be tested.

### Additional tests

#### Cervical arterial dysfunction

Clinicians who use cervical manual therapy as a treatment modality are very mindful of cervical arterial dysfunction, inclusive of vertebral artery insufficiency and cervical arterial dissections (see Table 23.1). This is reflected in a recently developed international framework that provides safety guidelines for vascular screening prior to hands-on orthopaedic intervention.<sup>126</sup> Any suspicion of a cervical arterial dissection in progress requires immediate referral to an emergency department.

While any age group could present with symptoms of vertebral artery insufficiency, the risk increases with age due to increased atherosclerosis. Tests are indicated when the athlete complains of symptoms such as dizziness (vertigo), visual disturbances, unsteadiness or other neurological signs. Testing arterial integrity is also recommended as routine before any high-velocity manipulation is performed.

However, clinical provocative tests for the vertebral artery have been shown to have poor validity with low sensitivity.<sup>127, 128</sup> The sustained rotation and extension tests probably more generally assess the adequacy of collateral flow to the brain rather than the competency of one artery. Yet, they still may have a place to identify the few persons with abnormal vessels in whom collateral compensation is insufficient.<sup>129</sup> As mentioned previously, of greater concern in the sport context is recognition of CAD (vertebral or carotid) which can be triggered by even minor trauma in the susceptible young to middle-aged athlete.<sup>129</sup> This history of trauma is a warning signal.

### Performance-based outcome measures

Measurements of pain, function and participation levels are important patient-reported outcomes, but equally

important are performance-based outcome measures. These physical measures serve several purposes including testing the immediate effectiveness of a treatment technique, guiding treatment progression, and ensuring that physical impairment associated with the pain and injury has been rectified and the sporting performance skill restored. In addition, showing athletes the results of their individual performance-based outcome measures, in conjunction with objective evidence of improvement over time, can provide powerful incentives for treatment compliance.

A combination of performance-based outcome measures is used for an athlete who has a painful neck condition. An outcome measure should be documented for each impaired system in the athlete's presentation. This could include, for example, a measure of cervical range of motion; a measurement of the upper limb neurodynamic test (range of elbow extension); a measure of motor control (e.g. the cranio-cervical flexion test: stage 1–pressure level achieved with correct movement, and stage 2–pressure level which was achieved and on which training commences); and relocation error in the test of joint position sense. Equally important are performance-based outcome measures of functional skills specific to the athlete's sport. All outcome measures will need to be revisited and upgraded as the athlete progresses in treatment.

## MANAGEMENT OF MECHANICAL NECK PAIN

It is usually not possible to make a definitive patho-anatomical diagnosis in most people presenting with a neck pain condition, but this should not compromise conservative management. After red-flag pathologies have been eliminated, the athlete's presenting complaint, the physical examination and any other athlete- or sport-specific issues will direct the treatment approach. In some cases, definitive pathology can be identified, such as a cervical radiculopathy. Alternatively, various syndromes such as a 'stinger', an acute wry neck or a whiplash-associated disorder can provide a label for the neck pain condition. These labels may suggest a certain lesion or underlying structural cause, but the treatment approach should be directed by the examination findings and the athlete's needs. Reference will be made to these syndromes later in this section.

Most athletes fall under the broad diagnosis of mechanical neck pain. The inadequacy of this single classification is that it belies the heterogeneity of neck pain conditions. There are no recipe approaches for mechanical neck pain and each athlete should be regarded as an individual, with management programs designed and tailored to meet their own needs. This section will mention many different treatment approaches. Not all are needed for every athlete. Specific treatment strategies

should be selected based on the current research, the sound clinical reasoning and experience of the clinician, and the unique presentations and goals of the athlete.

Systematic reviews have synthesised and scrutinised the effectiveness of treatment strategies that can be used to reduce pain and disability in the conservative management of neck pain.<sup>130-136</sup> Of these various treatments, exercise and manual therapy as single modalities show greatest effect, albeit with modest effect sizes. Used together as a multi-model approach, there is a larger effect.<sup>132, 133, 136</sup> Other methods of management (e.g. education),<sup>130</sup> when used as a single-treatment approach, have not been found to be effective. This is hardly surprising considering the nature and extent of all of the impairments or features that may present within biological, psychological and social domains in neck pain conditions, as well as the potential interactions between these domains.

No single modality or method can address such a spectrum. A multimodal approach is essential when neck pain is considered within the biopsychosocial framework. A multimodal approach is summarised in Figure 23.12.

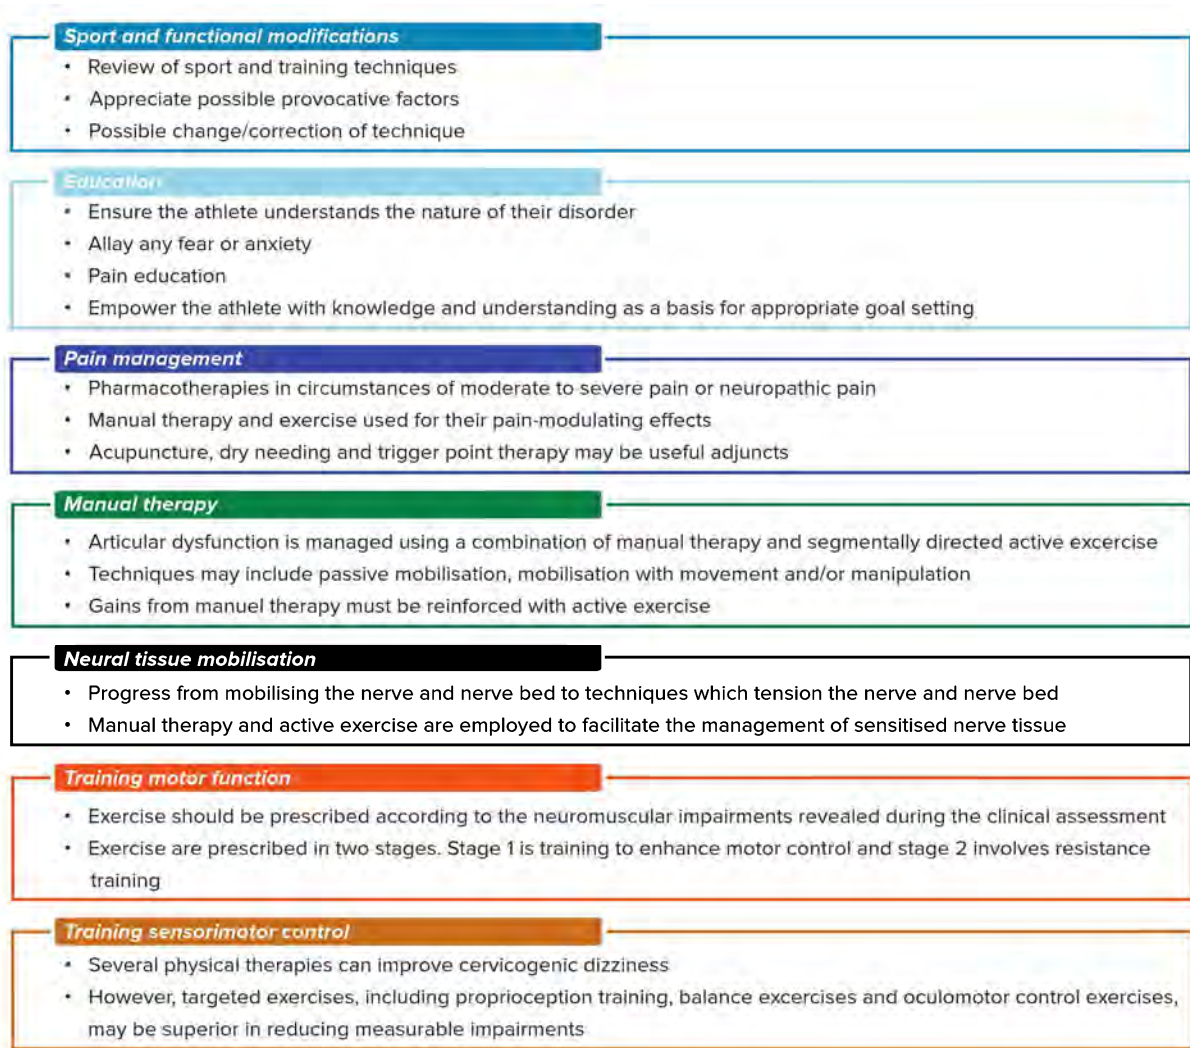

## Sport and functional modifications

A comprehensive understanding of the physical requirements of the athlete's sport and training demands, as well as his or her occupational or other recreational activities, is essential to understanding possible provocative factors in order to meet the goals of rehabilitation. If an athlete is performing a task (during sport or work) that is producing or aggravating neck pain, long-term pain relief and prevention of recurrence will not be achieved until this potential 'driver' of the condition is addressed.

For example, an athlete's weight-training regimen is causing neck pain and analysis reveals that when the athlete does a certain lift, his/her head subtly drifts forward. This posture unnecessarily places the upper cervical joints into extension and increases the activity in the neck extensors,<sup>137</sup> with a net result of added, unnecessary compressive load on the cervical joints. Management must include correction of neck posture to maintain the cervical and cranio-cervical regions in a neutral position during weight training. This may require a temporary reduction in resistance/weight for the lift to allow the neck joints to settle, and rehabilitation of the deep and superficial neck muscles to be effective so that there is adequate muscular support of the cervical region.

As a second example, throwing is aggravating an athlete's neck pain. It is important to consider that there is normal movement of the cervical segments during arm movements.<sup>14</sup> In the presence of neck pain, irregular movements may occur at the cervical segments with throwing and catching actions.<sup>138</sup> The posture and muscle control of the neck, as well as any deficiency in throwing

**Figure 23.12** Components of a multimodal approach for the management of neck pain disorders. The findings of the assessment will direct precisely the components of management for the individual athlete

technique, should be assessed and addressed in this athlete to eliminate this potential 'motor performance' driver.

A third example involves cycling, which can be provocative for neck pain.<sup>3</sup> Despite an ideal bike fit, the neck will inevitably be subjected to non-ideal postures and susceptible to strains in road racing. The athlete is encouraged to reverse the pain-provoking forward-head, upper cervical extension posture as regularly as possible during the ride. Adjusting his postures slightly out of an end-range position may help. In addition, there should be follow-up to ensure that in all other daily activities, the athlete avoids the pain-provoking posture as much as possible.

A final example involves a rugby player with neck pain. Contact sports can be challenging for prevention of neck injury. While rules, equipment and technique may protect

the neck to some extent, it will still be placed under unpredictable forces.<sup>4, 139-141</sup> A review of the player's rugby tackling techniques or scrum techniques should be a part of the management to lessen the risk, to treat the painful neck condition and to prevent recurrences.

## Education

While education alone might not be sufficient for the management of neck pain,<sup>130</sup> effective multi-modal rehabilitation cannot be delivered without education to ensure the athlete understands the nature of his or her condition. The clinician must demonstrate appropriate interest and empathy, provide assurance and understand the athlete's beliefs about his or her condition as well as his or her coping style, to develop an effective

partnership. Good communication skills are essential and all explanations about the condition should be provided in non-mystical, non-alarmist language.

Pain education is proving to be an important aspect of management. It is also important that the athlete understand what is causing and moderating the condition and how it will be addressed by the management approach. Discuss the evidence for the effectiveness of the proposed management program with the athlete. Education aims to empower the athlete with knowledge and understanding as a basis for appropriate goal setting and stimulates the athlete's participation and compliance with the management program.

## Pain management

Pain relief is usually a first priority in people with neck pain and thus most clinical trials have pain as a primary outcome measure, regardless of what treatment is investigated. Pain is an individual, multidimensional sensory and emotional experience, and clinical trials reveal that there are many ways in which the pain experience can be modulated, albeit some more effective than others.

Pharmacotherapies are indicated in circumstances of moderate to severe pain or neuropathic pain. In these circumstances, conservative management or rehabilitation strategies must be limited and not provoke pain, and management can be very challenging for all health professionals. Conservative therapies alone are often not successful for these severe pain states,<sup>142, 143</sup> and multi-disciplinary management is necessary. Fortunately, most people with neck pain do not have these severe or neuropathic pain states, and conservative management is the typical first-line approach.

Physical modalities including manipulative therapy, exercise and electrophysical agents can modulate pain. Research indicates that a major effect of manual therapy is pain relief through neurophysiological mechanisms.<sup>144</sup> In addition, both low-load and high-load exercises can relieve pain.<sup>132</sup> Manual therapy and exercise will be discussed in some detail in subsequent sections for, in addition to their effects on pain, they are used for improving motion and enhancing neuromuscular function. Electrophysical agents have little evidence of added benefit,<sup>145</sup> but clinical experience would suggest that they can be quite soothing when part of a multi-modal treatment regimen. There is some evidence for acupuncture, dry needling and trigger-point therapy for immediate and short-term effects on pain.<sup>135, 146-148</sup> Thus these modalities may also be useful adjuncts to a rehabilitation program.

It is quite normal for some level of anxiety and depression to accompany pain of any origin<sup>33</sup> and this could be especially so if the athlete has had to withdraw from competition. Psychological features can moderate the pain state. Thus appropriate assurance and information

to address such features is an important part of pain management. A decrease in pain parallels a decrease in anxiety and general distress.<sup>142</sup>

## Manual therapy

Restriction of neck movement is pathognomonic of painful cervical conditions.<sup>50</sup> The cervical facet joints and discs are common sources of nociception and movement dysfunction. Articular dysfunction can be managed using a combination of manual therapy (also termed 'manipulative therapy') and segmentally directed active exercise.

Manual therapy techniques generally fall under three categories. The first is passive mobilisation, or rhythmically applied, segmentally directed passive movements. The second is mobilisation with movement, and the third is manipulation, a single high-velocity thrust technique.

There is always concern about cervical manipulation because of the rare possibility of a vertebral or carotid arterial dissection and the associated catastrophic outcomes of stroke or even death.<sup>126, 129</sup> In response, there has been a recent shift away from the use of purportedly riskier end-of-range cervical rotation techniques.<sup>149</sup>

If a clinician has any reservation about the use of cervical manipulation, the evidence suggests that outcomes achieved with cervical mobilisation and manipulation are similar.<sup>133</sup> One randomised controlled trial compared outcomes of mobilisation versus manipulation for subacute neck pain. Patients were randomised to manipulation or mobilisation only after the clinician had decided that the patient would benefit from a manipulation.<sup>150</sup> The results showed that even when manipulation was considered to be clinically indicated, but the patient received mobilisation, the outcomes for these patients were the same as those patients who received cervical manipulation. There is no doubt that cervical manipulation can be very effective, but if there is a perceived risk, or the clinician lacks skills to manipulate safely, then the evidence suggests the patient will respond equally well to passive mobilisation.

There are many different theoretical models and clinical approaches to guide specific treatment techniques for the cervical spine, both within and between the different healthcare professionals who use manipulative therapy.<sup>151-153</sup> Evidence continues to emerge that outcomes are similar regardless of the approach used.<sup>154, 155</sup>

Selection of technique should be based on the examination findings including: the direction(s) of movement restriction; segmental level of pain and dysfunction; pain severity; the nature of resistance to segmental motion (e.g. muscle spasm); and the provisional diagnosis. The athlete must be informed about the approach to be used and consent to the treatment, especially in relation to high-velocity procedures. For the latter, pre-manipulative protocols should be utilised as required by the relevant discipline.<sup>126</sup>

Once an initial technique has been selected, it should be trialled for its effectiveness by assessing its immediate effect on pain and range of motion. Positive within-session changes have been shown to be good predictors of between-session improvements.<sup>156</sup> As indicated previously, mobilisation techniques can be applied passively only, or they can be applied in conjunction with active movement (mobilisation with movement).<sup>151-153</sup>

The upper thoracic area should not be neglected as full head rotation is reliant on an approximately 10° contribution from the upper thoracic area.<sup>7</sup> There is early evidence of improvement in neck pain and range of motion when upper thoracic manipulation is included in the management of neck conditions.<sup>157, 158</sup>

Manual therapy should be progressed as the patient improves. This can be done in a variety of ways such as increasing the duration of the technique, changing the neck position while the technique is performed using the principles of a combined movement approach,<sup>159, 160</sup> using a combination of techniques in a single session or, where indicated, adding a high-velocity thrust technique.

### Range of motion exercises to accompany manual therapy

Any gains in range of movement from manual therapy<sup>50</sup> must be reinforced and maintained with a program of active exercise. Active exercises can be performed in any plane of movement and it is logical to prescribe exercises to target the segment(s) that are hypomobile and that have just been treated. As an example, Figure 23.13 illustrates two self-guided ways that active (a) or assisted active (b) exercise can target (albeit not strictly localise)

(a)

(b-I)

(b-II)

**Figure 23.13** Range of motion exercises (a) Active exercise for lateral flexion. The athlete is taught to localise the segment of interest with his or her fingertip (e.g. if the segment is C2–3, the fingertip is placed on the lamina of C3). The athlete then laterally flexes down to the fingertip to ensure that the segment is moved into lateral flexion (b) The patient uses an assistive strap to localise segmental rotation. For rotation at C1–2, the strap is placed on C1. These techniques are part of the mobilisation with movement regimen<sup>151</sup>

**Figure 23.14** An active exercise which will mobilise rotation throughout the functional cervical spine (C0–1 to T3–4). The athlete imagines shooting a bow and arrow (holding the bow in alternate hands). The athlete must focus on rotation through the upper thoracic region, keeping the mid and lower thoracic regions relatively still

movement to a segmental level. In the acute stage, exercise should be gentle and can be performed three or four times throughout the day as tolerated. It can be progressed in repetitions and intensity as the athlete improves.

Figure 23.14 illustrates an exercise that focuses on mobilising the cervicothoracic region into rotation. It would be an appropriate exercise to prescribe once any acute pain has settled. It is an easy exercise that an athlete can practise throughout the day, which encourages compliance. Alternatively, the combined movements of arm elevation and ipsilateral cervical rotation can also be used to help mobilise the cervicothoracic region.

### Neural tissue mobilisation

Treatment of neural tissue mechanosensitivity is a priority when the physical examination confirms that it is contributing to the athlete's neck and arm pain. Some exercises, such as cranio-cervical flexor training, scapular postural correction and certain neck and arm movement exercises, can stress sensitive nerve structures and thereby aggravate pain. Such exercises should not be commenced until the nerve tissue has been addressed.

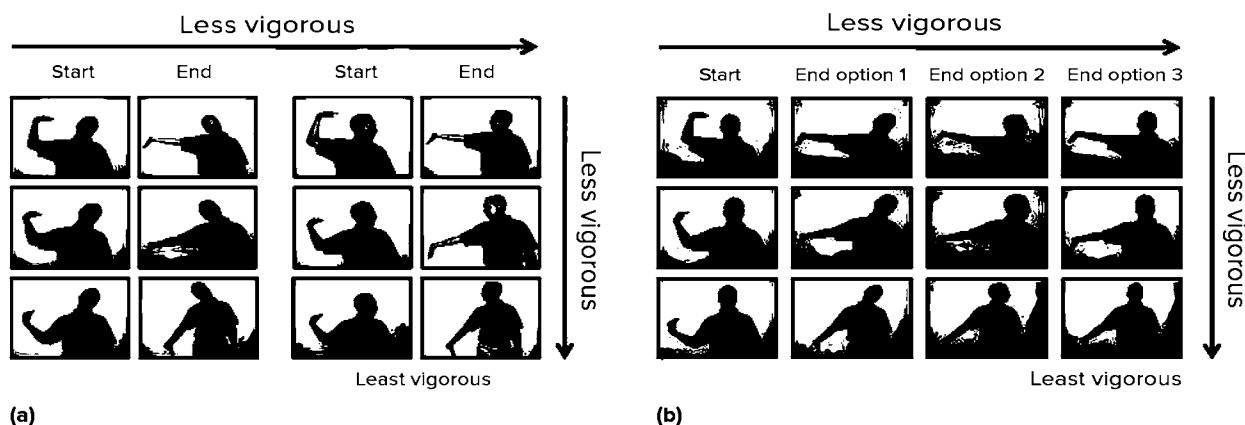

**Figure 23.15** Cervical lateral glide technique. If the (L) C6 nerve and brachial plexus are mechanosensitive, the clinician gently maintains the scapular position, grips C6 and glides the head and neck down to C6 to the right. The movement should be gentle and rhythmical. The athlete can contribute to the techniques by gently moving their arm in sequence with the passive technique to enhance the sliding of the nerve and nerve bed

Nerve tissue pain (neuropathic pain) should always be respected, regardless of the presenting pain intensity and the acuteness or chronicity of the condition. Restriction in motion during the upper limb neurodynamic tests is principally due to protective muscle guarding.<sup>161, 162</sup> The emphasis in contemporary management of neural tissue mechanosensitivity is on mobilising the nerve and nerve bed, with final progression—as the athlete improves—to techniques that tension the nerve and nerve bed.<sup>163</sup> Both manual therapy and active exercise can be employed in the management of nerve tissue mechanosensitivity.

The cervical lateral glide technique is one efficacious technique (Fig. 23.15).<sup>164–167</sup> The sliding of the nerve and nerve bed can be enhanced by using combinations of movements to lengthen a nerve bed across one joint while shortening the nerve bed of an adjacent joint. This results in greater nerve excursion with minimal nerve strain and is achieved by the athlete performing the active arm movement while the clinician performs the cervical lateral glide.<sup>163, 168</sup> For example, in an acute state, the athlete's arm could be positioned by his or her side. As the clinician glides the neck away from this side (lengthens the nerve bed), the patient flexes his or her wrist (shortens the nerve bed). When the clinician returns the neck to neutral (shortens), the patient extends the wrist (lengthens). Progression is achieved by increasing the angle of arm abduction, as well as by flexing or extending the elbow, wrist and hand. A further progression could be to slowly convert the sliding technique to a tensioning technique (i.e. when the neck is glided away, the athlete extends the wrist and hand).

**Figure 23.16** (a) Active exercise is used in addition to clinician-delivered technique. The progression for the 'sliding' nerve gliding exercise is illustrated and the level chosen is one that does not provoke the patient's symptoms. The most gentle sliding technique combines neck rotation with elbow and wrist movements while the arm is in 30° abduction. The most vigorous (and the ultimate goal) is to perform the sliding technique in 90° abduction with cervical lateral (top left). The figure illustrates the various transitions from least to most vigorous.<sup>169</sup> (b) The progression for the 'tensioning' nerve gliding exercise. The level chosen is one that does not provoke the patient's symptoms. The most gentle tensioning technique uses elbow and wrist movements with the neck in neutral and the arm in 30° abduction. The most vigorous (and the ultimate goal) is the tensioning exercise in 90° abduction and contralateral lateral flexion (top left). The figure illustrates the various transitions from least to most vigorous.<sup>169</sup>

REPRINTED FROM NEE RJ, VICENZINO B, JULL GA, CLELAND JA, COPPIETERS MW. A NOVEL PROTOCOL TO DEVELOP A PREDICTION MODEL THAT IDENTIFIES PATIENTS WITH NERVE-RELATED NECK AND ARM PAIN WHO BENEFIT FROM THE EARLY INTRODUCTION OF NEURAL TISSUE MANAGEMENT. *CONTEMP CLIN TRIALS*. 2011;32(5):760–70 WITH PERMISSION FROM ELSEVIER

This treatment should be supplemented with a home program of active exercise (Fig. 23.16).<sup>169</sup> These exercises are designed to replicate the precise stage of the cervical lateral glide. In relation to dosage, it is prudent to start with low repetitions (e.g. 5 repetitions) two or three times a day to evaluate the athlete's response. Treatment can be progressed by increasing the number of repetitions or altering the arm and neck position, or changing the intention (slide or tension).

### Training motor function

A research-informed exercise protocol is used to address the changes identified in the neuromuscular system of the athlete with neck pain (see section on muscle tests above). The neuromuscular and functional changes induced by training are specific to the mode of exercise performed.<sup>79, 170–173</sup> People with neck pain present with an array of deficits ranging from subtle changes in muscle coordination through to reduced neck strength. Different forms of exercise must be considered and prescribed to address the specific neuromuscular impairments revealed during the clinical assessment. Exercises are prescribed in two stages. Stage 1 is training to enhance motor control. This stage includes exercises to: increase the activation and endurance of the deep cervical postural muscles; improve

coordination between the deep and superficial layers of the neck flexor and extensor muscles and the axioscapular muscles; and train muscle coordination within functional and work activities. Stage 2 involves resistance training and commences once adequate motor control of the region is achieved. As the goal of therapeutic exercise is to restore normal motor control, function and quality of movement, the exercises should be challenging, yet be performed with correct technique and without aggravation of symptoms. Pain can inhibit the motor learning process.<sup>174</sup> For convenience, the rehabilitation of each muscle group is outlined separately, but rehabilitation is concurrent and prescribed based on assessment findings.

### Stage 1. Motor control

#### Neck flexors

Based on assessment findings, any altered coordination between the deep and superficial cervical muscles or decreased endurance capacity of the deep neck flexors must be addressed. Often, athletes must first learn the correct movement of cranio-cervical flexion. They practise a large extension-to-flexion excursion head movement in the supine position, gaining feedback of correct movement by feeling the back of their head sliding up and down the bed. The movement is facilitated with eye movement

**Figure 23.17** Training the deep cervical flexors in stage 1. The patient concentrates on performing the correct cranio-cervical flexion movement and palpates to ensure that there is no dominant activity of the superficial flexors. Inner-range contractions are held to improve endurance capacity of these muscles at contraction intensities in line with those required in sitting and standing postures. The pressure biofeedback is used only to teach the patient the holding contraction and to monitor progression of the exercise

and the athlete can palpate his or her sternocleidomastoid and anterior scalene muscles to ensure they are relaxed throughout the entire range of movement (Fig. 23.17). Once the correct movement is attained, endurance of the deep cervical flexors can be trained.

Feedback on performance is necessary so that the athlete knows he or she is performing the task correctly. A pressure sensor can be placed behind the athlete's neck to indicate his or her ability to perform and hold a contraction of the deep cervical flexors (Fig. 23.7). The athlete can practise with the feedback under the clinician's supervision, while learning the sensation of the movement and holding contraction in order to be able to practise at home without the external feedback.<sup>101</sup> Training commences at the pressure level that the athlete can control. The athlete practices to achieve 10 repetitions of 10-second holds at that level, twice per day.

### Posture

Postural re-education training for spinal and scapular posture commences immediately. The physical examination may have directly linked the athlete's spinal posture to his or her pain state and, importantly for a training effect, the correction of posture facilitates the activity of the deep cervical flexors.<sup>175, 176</sup> The motor learning process requires multiple repetitions within a day, and postural correction allows the patient to perform multiple repetitions of the muscle contraction during the day with convenience. Furthermore, training the deep cervical flexors in this exercise will help remediate the altered behaviour between

**Figure 23.18** Spinal posture correction is facilitated by first correcting the lumbopelvic region into a neutral upright posture. Correct the thoracic posture if necessary, and correct head position by asking the patient to gently lengthen the back of the neck. Once spinal posture has been addressed, the patient will be taught to correct scapular posture as is necessary

the deep and superficial flexors demonstrated in the CCFT.<sup>177</sup> An upright posture is facilitated by first moving the lumbopelvic region into a neutral position (Fig. 23.18). This will usually correct thoracic posture, although a slight correction of excessive thoracic flexion or extension may be necessary. As a final correction, the athlete should gently lengthen the back of the neck, which will not only facilitate the longus colli further,<sup>176</sup> but will correct the cervical and cranio-cervical position.

The athlete is advised to perform this posture correction exercise ideally 2-3 times per hour. They should hold the position for 10 seconds. The exercise can be incorporated into daily activities while sitting, standing and walking. Repetition is the key and the athlete must identify or develop 'cues' as reminders for the exercise.

Formal training of cranio-cervical flexion continues until the patient can perform 10 repetitions of 10-second holds at each of the five pressure increments on the CCFT from the baseline of 20 mmHg to the maximum of 30 mmHg. Once this goal for the deep cervical flexors is achieved, the program is progressed and the interaction between the deep and superficial flexor muscles is trained during movement. One of the movements to train is control of neck extension. This movement is initiated with cranio-cervical extension and return to the upright position from extension is initiated by cranio-cervical flexion. Concomitantly as required, control of neck position in any sport-specific position is trained.

### Neck extensors

Stage 1 training for the neck extensors commences in inclined sitting, prone on elbows or, most commonly, in a quadruped position, depending on the athlete's ability to control scapular and trunk posture. The athlete can train the movements of cranio-cervical extension and rotation and cervical extension (C2-7) (Fig. 23.8a and b). Instructing the athlete to read an imaginary book (eyes focused down between hands) while curling the head and neck backwards maintains the cranio-cervical region in a neutral position, facilitating the desired cervical extension (Fig. 23.8c). Manual resistance can be applied by the clinician in extension over the vertebral arch to emphasise the activation of the deep extensor muscles while familiarising the athlete with the exercise.<sup>178</sup> Athletes should train until they can perform three sets of 10 repetitions through a full excursion of movement without fatigue.

### Axioscapular muscles

Stage 1 training focuses initially on improving the activation and endurance capacity of the trapezius and serratus anterior muscles as well as re-educating the axioscapular muscles functionally to provide adequate scapular stability in posture and during arm movements.

In this motor relearning phase, the lower portion of trapezius can initially be targeted with the athlete in a side-lying (gravity-eliminated) position with the arm supported on pillows at approximately 140° of elevation. The athlete practises drawing the scapula diagonally across the thoracic wall and holding the position for 10 seconds (10 repetitions). Serratus anterior is formally trained with a scapular protraction exercise which can be progressed as indicated from a side-lying position, to standing against a wall, to a prone position on elbows, to a four-point kneeling position. The exercises in the latter two positions can be combined with neck extension exercises. The scapular muscles are also trained concurrently in the postural correction exercise and the athlete learns to hold

the scapulae in a neutral position on the chest wall in sitting and standing postures.

Once the athlete can control 'ideal' static scapular posture, scapular control is re-educated for functions requiring less than 30° of arm elevation (control of the scapula in a neutral position), during arm movement throughout range and, importantly, in sport- or occupation-specific arm postures and movements.

### Stage 2. Resistance training

Stage 2 addresses any deficits in muscle strength and demands greater levels of endurance. Neck flexor strength and endurance are trained at progressive contraction intensities by increasing the gravitational load using a head lift exercise.

Initially, the athlete sits on a chair close to a wall with his or her head resting on the wall in a neutral position. Cranio-cervical flexion is performed by sliding the back of the head up the wall, and then the head weight is lifted just off the wall (Fig. 23.19). Cranio-cervical control is essential in this exercise. If the patient loses cranio-cervical flexion when the head is lifted, this means that the exercise load is too high. The load is increased by progressively moving the chair further from the wall and ultimately moving to crook-lying and supine positions. The exercise can be further progressed in supine from having support of two pillows to no pillows to performing the exercise with weighted sandbags on the forehead.

**Figure 23.19** Head lifts from the wall. Note that the patient must control the cranio-cervical flexion position in this initial strengthening exercise in stage 2 training

For the cervical extensors, the athlete can perform repeated cervical extension or sustained neck extension holds in a prone or quadruped position. Progressive weights (commencing with 0.5 kg) can be attached to headgear (e.g. a bike helmet) if neck-specific resistance equipment is not available. For the axioscapular muscles, free-weight or machine-based exercises can be performed. Strengthening exercises should commence with light loads concentrating on spinal and scapular control with both concentric and eccentric arm loading. Strengthening exercises should be task-specific with a focus on upper limb movements that are relevant to the athlete's sport. Load is progressed, but the emphasis is always placed on control of scapular and spinal posture, and indeed all body segments. Resistance training for each muscle group is advanced as appropriate to the individual athlete's requirement (e.g. neck strength requirements for pistol shooting versus wrestling or rugby).

When the aim is to enhance strength, high loads should be prescribed for a low number of repetitions, whereas a large number of repetitions at low intensity will enhance endurance. A key principle in resistance training is that of overload.<sup>179</sup> This principle states that a greater-than-normal stress or load on the body is required to induce training adaptation. As performance improves with training, the intensity or volume of exercise must be increased to continue to put adequate demand on the athlete to stimulate muscle development.

### Training sensorimotor control

There are several treatment options that can improve symptoms of dizziness, lightheadedness and unsteadiness of cervical origin. These include specific and targeted exercises as described below which directly address the impairments,<sup>180-183</sup> as well as treatments such as manual therapy, exercise and acupuncture.<sup>154, 183</sup> There is some evidence that the targeted exercises may be best at making a measurable improvement in these impairments.<sup>180</sup>

Joint relocation sense can be trained with eyes open, progressing to eyes closed with use of a laser and target for feedback. Similarly, a target can be traced with a laser to train movement sense progressing from simple to complex patterns (Fig. 23.20). Following a moving target is another treatment strategy, and various computerised applications such as training with virtual reality are being developed to train cervical movement sense.<sup>120, 182, 184</sup> The task difficulty can be progressed in the training of both position and movement sense by changing the size or stability of the base of support (i.e. sitting to standing to tandem stance to one-foot stance).

When training balance in an athlete with neck pain, it is usually necessary to commence training at a fairly high level; for example, in tandem stance. This can be progressed

**Figure 23.20** Movement sense is trained with the athlete tracing simple to complex patterns with a laser light mounted on the head. The exercise can also be progressed by advancing the position in which the exercise is performed (e.g. from sitting to standing to one-foot standing)

to one-leg standing and performed on hard, then soft and then unstable surfaces. Ensure that training is progressed to the functional demands of the athlete's sport.

Training eye movement control could include any of the following strategies: gaze stability, eye follow and eye follow of rapid movements; it should be based on the impairments detected in the physical examination. The tests described above can be converted to training

exercises, with the clinician ensuring that the athlete can dissociate head and eye movement in all exercises. The exercises are usually commenced at a speed over which the athlete has control and they are progressed by increasing exercise speed or performing the exercises in more challenging postures (e.g. sitting to standing to tandem stance) as done when training joint relocation sense. Athletes with neck pain often need more advanced exercises, and combining training of two aspects of the cervical sensorimotor system (e.g. eye follow and balance) will produce a greater challenge to the cervical sensorimotor system.

### Maintenance program

Specific self-management and maintenance programs should be included within the athlete's training regimen. A self-management program developed during treatment should incorporate motor relearning, resistance and sensorimotor exercises as indicated. As previously mentioned, repetition and adequate dosage are vital components to the success of any training program. Neck pain is a recurrent condition. With the possibility of re-injury during sport or the potentially continuing influence of arthrogenous inhibition,<sup>185</sup> it is necessary for the athlete to continue to perform a simple maintenance program after formal management has ceased. For long-term compliance, this should consist of two or three key exercises aimed at reducing the probability of recurrent neck pain episodes.

## NECK PAIN CONDITIONS

The majority of neck pain conditions are grouped under the broad term 'mechanical neck pain' and then qualified by a description of duration as being acute, subacute, persistent or recurrent acute episodes. Management is based on examination findings, as discussed throughout this chapter. Certain neck pain conditions are further characterised in relation to a specific clinical presentation, injury mechanism, identifiable pain mechanism or pathology. Management will again be based on examination findings, but some additional notes are relevant from a diagnostic or treatment perspective.

### Cervicogenic headache

Cervicogenic headache is classified as a secondary headache (Chapter 21): it is secondary to a cervical musculoskeletal condition.<sup>186</sup> Pain sources are usually located in one or more of the upper three cervical segments and headache results from physiological convergence between cervical and trigeminal afferents in the trigeminocervical nucleus.<sup>187</sup> There is symptomatic overlap between migraine without aura headaches, tension-type headaches and cervicogenic headaches, and thus differential diagnosis is critical for proper management.

Research has sought to determine which physical tests characterise cervicogenic headache to differentiate it from migraine and tension-type headaches. In cervicogenic headaches, the athlete should present with a combination of cervical movement dysfunction, muscle function impairments and upper cervical joint dysfunction.<sup>49, 55, 188</sup> The clinical findings in the articular and neuromuscular systems are consistent with mechanical neck pain, and any reported unsteadiness or lightheadedness is consistent with sensorimotor disturbances. Management generally follows that described earlier in this chapter for mechanical neck pain, but care should be taken to ensure that treatments are non-pain provocative. This is because sensitisation of the trigeminocervical nucleus appears to be a factor in the development of cervicogenic headache.<sup>57</sup> If treatments are painful, the added peripheral nociception is likely to produce or worsen a headache.

### Acute wry neck

Acute wry neck is characterised by an acute onset of neck pain with protective deformity (contralateral lateral flexion position) and limitation of movement. It typically occurs after a sudden, quick movement or on waking. There may have been an unguarded movement or prolonged abnormal posture prior to the onset of pain. It is hypothesised that the zygapophysial joint or disc may be the source of symptoms. When of zygapophysial origin, there may be entrapment or extrapment of the meniscus.<sup>189</sup> If the disc is suspected to be the source of symptoms, treatment is more conservative (i.e. gentle mobilisation; manipulation is not recommended). The differentiation between a zygapophysial joint or disc origin of symptoms is principally made collectively from historical features, presenting symptoms and manual detection of a pain source either over the zygapophysial joint or centrally through the spinous process, which is interpreted as a discal origin.

Although relatively rare, the clinician should be alert for atlanto-axial rotary fixation, a fixed rotary subluxation of C1 on C2.<sup>190, 191</sup> It is principally observed in young children and may occur spontaneously or can be secondary to congenital anomalies of the upper cervical spine and arthritides (e.g. juvenile onset rheumatoid arthritis). It may be associated with trauma and there may be instability. Medical and radiological diagnosis is required.

### Cervical nerve injury Cervical radiculopathy

Cervical radiculopathy usually presents as neck and arm pain or, occasionally, arm pain only, and may be accompanied by sensory disturbances and weakness in the upper limb. This neuropathic pain can often be

intense and athletes require appropriate pharmacological pain management. The cervical nerve root can be compromised in the intervertebral canal by a disc lesion, or by zygapophysial or uncovertebral osteophytes. Inflammation also plays a significant role. Sensitisation of nerve tissue will be present. Surgery may be indicated in some instances, but conservative treatments should always be trialled in the first instance.<sup>192</sup>

### Brachial plexus injuries ('stingers/burners')

Brachial plexus injuries occur in contact sports such as rugby union and rugby league, and can vary from severe injuries with avulsion or rupture<sup>1923</sup> to less catastrophic traction injuries, often referred to as 'stingers' or 'burners' due to their characteristic symptoms.<sup>194</sup>

Assessment of an acute stinger involves first ruling out more serious injury such as spinal cord or brain involvement, fracture or vascular injury.<sup>195</sup> The athlete should be removed from the field if there are any such indications. In a stinger or burner, the athlete experiences transient neuropraxia characterised by upper extremity burning-type pain that may also be accompanied by paraesthesia and/or weakness. Tensile or compressive forces are the most likely underlying mechanism of this neuropraxia. Downward displacement of the shoulder with concomitant contralateral side flexion of the neck can cause a traction injury to either the cervical nerve root (most likely C5 or C6) or the brachial plexus. Alternatively, compression injuries can be caused by combined cervical extension and ipsilateral side flexion or a direct blow to the brachial plexus.<sup>194</sup>

Symptoms are usually transient, resolving over a varying period of time from minutes to days, but persistent neurological dysfunction and recurrent stingers may occur. A gentle exercise program that does not provoke typical

symptoms may be started early in treatment, with care to avoid aggravating positions. As in all cases of nerve damage, there will be an element of the recovery that is time- and rest-dependent, and treatment cannot speed this process.

### Acceleration/deceleration injury ('whiplash')

Acute acceleration/deceleration injury to the cervical spine is an injury commonly caused by a motor vehicle collision and it is commonly termed a whiplash-associated disorder (WAD). Theoretically, such an injury could also occur in sports when the cervical spine is subject to a sudden acceleration force. However, direct extrapolation from injuries sustained in motor vehicle collisions to a sporting injury may be unwise, and more comparative research is required. Management of most athletes with WAD will be similar to mechanical neck pain, but there is a small proportion of those with WAD who may not respond well to any treatments (medical, physical or psychological) and who generally have a poor prognosis.<sup>25, 196-198</sup>

### CONCLUSION

Mechanical neck pain conditions can be troublesome for any athlete, but most can be managed well with conservative therapies. Nevertheless, neck pain is characteristically recurrent and its lifetime impact should not be underestimated. Management must aim to first address the presenting condition and resolve the acute episode of neck pain. The challenge is the second stage of treatment that aims to prevent or limit the recurrence of neck pain to improve future quality of life and sports performance. This broader aspect of effective secondary prevention should be a focus of both clinical practice and research.

# Shoulder pain

by ANN MJ COOLS\*

*When I dislocated my shoulder back in 2005 and (went through) rehab throughout 2006, I was told by Dr Andrews 'you're always going to have to stay on top of that shoulder. You're always going to have to do a little bit extra to keep it at the level you want to keep it at'. In a lot of ways it was the best thing that ever happened to me because I started doing things that I'd never done before. So I learned so much about my shoulder and how to manage my shoulder.*

Drew Brees, NFL quarterback

Shoulder pain and dysfunction are a significant health issue, in the general population as well as in an athletic population. Whilst acute shoulder injuries occur mainly in collision sports or as a result of a sports accident like falling in skiing or biking, athletes performing overhead sports such as tennis, baseball, swimming and gymnastics are also prone to chronic shoulder pain, due to the high demands on their shoulders during their sports performance. In this chapter, the following topics regarding assessment and treatment of shoulder pain are discussed:

- functional anatomy and biomechanics
- overview of most common, less common, and not-to-miss causes of shoulder pain
- clinical examination: from history and basic clinical exam to special tests and outcome scores
- investigation
- general treatment and specific rehabilitation guidelines for the most common shoulder injuries in athletes
- less common causes of shoulder pain: overview of treatment guidelines
- special considerations for the overhead athlete: the thrower's program, sport-specific kinetic chain principles and return to play after injury.

## FUNCTIONAL ANATOMY AND BIOMECHANICS

The glenohumeral joint is an inherently unstable shallow ball and socket joint, often described as the equivalent of

a golf ball (head of humerus) on a tee (glenoid). In fact, the relationship between the humeral head and the glenoid cavity more accurately parallels a sea lion balancing a ball on its nose. Thus, effective shoulder function and stability requires both static constraints—the glenohumeral ligaments, glenoid labrum and capsule—and dynamic constraints, predominantly the rotator cuff and scapular stabilising muscles (Fig. 24.1).

## Static stabilisers

In the neutral position, the coracohumeral ligament and the superior glenohumeral ligament control inferior translation of the humeral head. In an abducted position, all parts of the inferior glenohumeral ligament prevent excessive inferior translation. During external rotation in slight elevation (0–45°), the medial glenohumeral ligament prevents anterior translation. The main static stabilisers of the shoulder in the functional position (abducted) are the anterior and posterior bands of the inferior glenohumeral ligament. Together with the axillary pouch, these three parts of the inferior glenohumeral ligament (IGHL) are the thickest of all glenohumeral ligaments (Fig. 24.1d). They are attached to the labrum, which, in turn, attaches directly to the margin of the glenoid fossa. The anterior band of the inferior glenohumeral ligament prevents anterior translation and the posterior band prevents posterior translation of the humeral head. The superior margin of the anterior band of this ligament attaches to the

**Figure 24.1** Anatomy of the shoulder region (a) Surface anatomy from the front (b) Surface anatomy from behind (c) Rotator cuff musculature from behind (d) Ligaments and muscles around the glenohumeral joint

glenoid fossa anteriorly at the two o'clock position. When the arm is placed into abduction and external rotation, this broad ligamentous band of the IGHL rotates anteriorly to prevent subluxation of the joint.<sup>1</sup> In addition, the

IGHL seems to have a dual role—it also forms a substantial posterior barrier when the arm is internally rotated in the abducted or forward flexed position. Shoulder stability is also enhanced by the glenoid labrum, a ring of fibrous

tissue attached to the rim of the glenoid, which expands the size and depth of the glenoid cavity. It increases the superior-inferior diameter of the glenoid by 75% and the anterior-posterior diameter by 50%. Moreover, the plasticity of the glenoid allows expanding the size of the glenoid fossa without losing range of motion, and is an attachment site for ligaments and the biceps tendon.

### Dynamic stabilisers

The dynamic stabilisers of the glenohumeral joint are the rotator cuff muscles, consisting of the supraspinatus, infraspinatus, subscapularis and teres minor, which act in co-contraction to seat the humeral head in the glenoid (Fig. 24.1c). Since the tendons splay out and interdigitate to form a common, continuous insertion to the humerus, their roles are highly interrelated. The specific roles of the different tendons are debated in literature. The most recent studies attribute similar stabilising roles to infraspinatus and supraspinatus performing external rotation, and avoiding anterior translation of the humeral head, whereas subscapularis is contracting to avoid posterior translation.<sup>2</sup> In addition, the rotator cuff muscles counteract the action of the deltoid (which elevates the humeral head) by preventing the head of the humerus from moving superiorly when the arm is raised. The key issue in this force couple concept of the rotator cuff, is muscular balance between the different components of the rotator cuff, in particular between the internal and external rotators (ER/IR ratio). Overhead athletes often exhibit stronger internal rotators, with subsequently relative weak external rotators,<sup>3</sup> resulting in a lower ER/IR ratio, and thus increasing the risk for chronic shoulder pain.

### The role of the scapula in normal shoulder function

The scapular stabilisers also play an important role in shoulder joint movement. Normal shoulder function requires smooth integration of movement not only at the glenohumeral joint but also at the scapulothoracic, acromioclavicular (AC) and sternoclavicular (SC) joints. This integrated movement is referred to as 'scapulohumeral rhythm'. Scapulohumeral rhythm should be smooth, coordinated and symmetrical. Full upper limb elevation requires three-dimensional rotation of the scapula and the clavicle as coupled movements into upward rotation, posterior tilting and adequate internal or external rotation, depending on the plane of the moving humerus, which ensures that the coracoacromial arch is removed from the path of the greater tuberosity of the elevating humerus, thus avoiding potential impingement.

Scapular control also enhances joint stability at greater than 90° of abduction by placing the glenoid fossa under

the humeral head, where stability is assisted by the action of the deltoid muscle. The muscles controlling the scapula are the trapezius (all three portions), serratus anterior (upper and lower portions), rhomboids, levator scapulae and pectoralis minor. These muscles work in coordinated patterns called force couples to control three-dimensional scapular motion.

The main upward rotation force couple involves the upper trapezius/lower part of the serratus anterior, with a stabilising role for the middle and lower trapezius. The rhomboids and levator scapulae are supposed to lengthen in order to allow sufficient scapular upward rotation. Anterior/posterior tilt involves the lower trapezius/lower part of the serratus anterior force couple, and requires relative relaxation of the pectoralis minor. Together with the levator scapulae and the rhomboid, pectoralis minor is considered to have a rather postural function, keeping the scapula steady on the thoracic wall in rest and during movement. Interestingly, these muscles (pectoralis minor, levator scapulae and rhomboid) are very often tight rather than weak in patients with shoulder pain, and need to be addressed aiming at relaxation rather than strengthening.

The third scapular movement, internal and external rotation, is controlled by a complex force couple consisting of both parts of the serratus anterior versus all three parts of the trapezius. All three movements, and their working force couples are summarised in Figure 24.2. A stable scapula provides a base for the muscles arising from the scapula and acting on the humerus, allowing them to maintain their optimal length-tension relationship.

There is a body of evidence suggesting altered scapular rhythm or scapular dyskinesis, consisting of abnormal scapular positioning and/or movement patterns in patients suffering from shoulder pain, although the cause-consequence relationship is still under debate. Scapular dyskinesis has been found to be related to shoulder instability, impingement and stiff shoulders in a variety of patient populations, and is identified as a primary risk

**Figure 24.2** Force couples controlling scapular motions (a) Internal/external rotation (b) Upward/downward rotation (c) Anterior/posterior tilting

SA = serratus anterior, UT = upper trapezius, MT = middle trapezius, LT = lower trapezius

factor for shoulder injury in handball<sup>3</sup> and rugby players.<sup>4</sup> Scapular malpositioning and abnormal muscle patterning have been associated with experimentally induced shoulder pain, thus suggesting scapular dyskinesis might be secondary to shoulder pain.<sup>5</sup> Abnormalities of scapulohumeral rhythm are most commonly due to shortening of the scapulohumeral or glenohumeral muscles, or weakness and/or poor motor control of the scapular stabilisers (with or without weakness of the rotator cuff muscles).

## CAUSES OF SHOULDER PAIN—OVERVIEW

Most athletic shoulder injuries are the result of one of two mechanisms: (1) an acute external force applied on the shoulder complex (macrotrauma) or (2) repetitive overhead activity and overuse (microtrauma).

### Acute versus overuse shoulder pain

The shoulder is susceptible to traumatic injuries such as dislocations, subluxations, acromioclavicular joint sprains, and soft tissue injuries, in particular in collision and contact sports. However, most injuries result from repetitive overuse mechanisms, due to overload, aberrant overhead throwing biomechanics and dysfunctional adaptations to the sport, leading to chronic symptoms like impingement and bursitis.<sup>6</sup> Moreover, the shoulder is predisposed to athletic injury because of the large amount of mobility of the glenohumeral joint, allowing powerful throwing and smashing, but putting the shoulder at risk for injury due to the inherently poor glenohumeral stability.

A list of possible causes of shoulder pain is presented in Table 24.1

## Impingement

Impingement is one of the most frequently described pathologic shoulder conditions in general practice and in sports medicine. Early literature described impingement as a pathology or a diagnosis but today impingement is considered to be a cluster of symptoms, rather than a pathology itself. Various investigations have confirmed the association between impingement symptoms and a variety of underlying pathologic mechanisms. Rotator cuff pathology, scapular dyskinesis, shoulder instability, biceps pathology and superior labrum anterior to posterior (SLAP) lesions, and glenohumeral internal rotation deficit (GIRD) or posterior shoulder stiffness have been suggested to cause shoulder impingement symptoms. In addition, thoracic posture and mobility are considered to be key factors in the development of shoulder pain.

The literature describes two types of impingement: subacromial and internal. Subacromial or external impingement is the mechanical encroachment of the soft tissue (bursa, rotator cuff tendons) in the subacromial space between the humeral head and the acromial arch (Fig. 24.3). This encroachment particularly takes place in the midrange of motion, often causing a 'painful arc' during active abduction.

Internal impingement comprises encroachment of the rotator cuff tendons between the humeral head and the glenoid rim. Based on the location of the impingement, anterosuperior and posterosuperior glenoid impingement have been described. Posterosuperior glenoid impingement involves mechanical encroachment of the rotator cuff tendons, particularly the supraspinatus and infraspinatus, between the greater tubercle of the humerus and the

**Table 24.1 Causes of shoulder pain**

Common	Less common	Not to be missed causes outside the shoulder girdle
Rotator cuff pathology (strain, tear, tendinopathy)	Other muscle tear (pectoralis major, long head of biceps (LHB))	Somatic referred pain (cervical and thoracic spine, myofascial structures)
Glenohumeral instability (traumatic, atraumatic, congenital)	Adhesive capsulitis	Tumour (bone tumours in proximal humerus)
Biceps related pathology (SLAP labral tears, biceps tendinopathy, tenosynovitis)	Neurovascular entrapment or traction injury (suprascapular nerve, long thoracic nerve, axillary nerve, axillary vein compression, thoracic outlet syndrome)	Visceral referred pain (e.g. diaphragm, gall bladder, heart, spleen, apex of lungs)
Posterior shoulder stiffness (GIRD)	Fractures (scapula, humerus, stress fracture of coracoid process)	
Scapular pathology and dysfunction, including AC and SC joint pathology (sprain, fracture, dislocation, clavicular fracture)	Snapping scapula	

SLAP = superior labrum anterior to posterior, GIRD = glenohumeral internal rotation deficit, AC = acromioclavicular, SC = sternoclavicular

**Figure 24.3** Subacromial impingement

posterosuperior rim of the glenoid (Fig. 24.4a). This occurs during the late cocking position of throwing, which is maximal external rotation, horizontal abduction, and depending on the specific sport discipline, a certain amount of elevation. Because of the specific position of this internal impingement, it is considered to be the primary cause of chronic shoulder pain in the overhead athlete. Internal impingement particularly occurs when the humeral shaft goes beyond the plane of the body of the scapula during the cocking position of throwing. Under normal circumstances, the scapula goes into retraction simultaneously with the horizontal abduction movement of the humerus. When the body of the scapula and the humeral shaft fail to remain in the same plane of movement during the cocking phase of throwing, encroachment of the rotator cuff tendons between the humeral head and the glenoid rim may cause internal impingement symptoms. This phenomenon is called 'hyperangulation' (Fig. 24.4b).<sup>7</sup>

Besides the classification of impingement based on the site of encroachment, impingement is also classified based on the cause of the problem, dividing it into primary versus secondary impingement. In primary impingement, a structural narrowing of the subacromial space causes pain and dysfunction, such as acromioclavicular arthropathy, type II or III acromion, subacromial bone spurs, or swelling of the soft tissue in the subacromial space, for instance the subacromial bursa. The bony subacromial abnormalities result from either a congenital abnormality (os acromiale) or osteophyte formation. In addition, the under surface of the acromion may be abnormally beaked, curved or hooked (Fig. 24.5). However, abnormalities are not necessarily associated with clinical symptoms.<sup>8</sup>

In secondary impingement, there are no structural obstructions causing the encroachment, but rather

(a)

(b)

**Figure 24.4** Internal impingement in overhead athletes (a) Posterosuperior impingement of the supraspinatus and infraspinatus tendons (b) Hyperangulation of the humerus in the late cocking phase of throwing is a common mechanism of internal impingement

functional problems occurring only in specific positions. Rotator cuff weakness, instability and scapular dyskinesis are possible underlying functional deficits, leading to secondary impingement symptoms. Secondary impingement may occur in the subacromial space as well as internal in the glenohumeral joint.

**Figure 24.5** Acromial shapes. Abnormalities are not necessarily associated with clinical symptoms (a) Normal acromion (b) Acromion with anterior osteophyte (c) Congenital sloped acromion

#### PRACTICE PEARL

Primary impingement might be considered as structural impingement, whereas secondary impingement is in most cases functional impingement.

In view of the assumption that impingement symptoms may be the result of various underlying pathologies, it is important to describe the biomechanical relationship between these symptoms and shoulder diagnoses. Rotator cuff pathology may be associated with impingement symptoms in primary as well as secondary impingement. In primary impingement, swelling of the injured rotator cuff tendons causes the narrowing of the subacromial space; in secondary impingement, dysfunction of the rotator cuff (whose function is amongst others performing a caudal glide of the humeral head during elevation in order to avoid impingement) results in more cranial migration of the humeral head, thus causing secondary impingement.

Scapular dyskinesia has also been described in relation to impingement symptoms. The rationale behind this association is that during arm elevation, impingement may occur if the scapula insufficiently follows the humeral head movements because of a lack of upward rotation, posterior tilting and external rotation, thus clearing the acromial arch or the glenoid rim from impinging the soft tissue.

The association between impingement symptoms and shoulder instability is well established. Excessive humeral head translation, based on capsular laxity and instability, cause temporal narrowing of the subacromial space, thus leading to impingement symptoms and pain.

Since the biceps plays an important role in shoulder stability and function, biceps pathology may cause secondary impingement symptoms. Indeed, biceps tendon problems (tendinopathy or tenosynovitis) as well as SLAP lesions (labral lesions at the site of origin of the long head of the biceps) compromise optimal shoulder function, and may result in impingement.

Glenohumeral internal rotation deficit, often referred to as GIRD, is a sport-specific adaptation of posterior shoulder structures to chronic excessive overload of these structures during frequent throwing. There are several theories concerning the occurrence and development of GIRD. A first hypothesis is that GIRD results from contracture or shortening of the posterior capsule. Other researchers believe that GIRD begins in the early years of overhead throwing with a bony adaptation of the humerus, resulting in altered humeral torsion. A third hypothesis regarding the cause of GIRD is muscle hypertonicity in the external rotators due to frequent eccentric loading. GIRD may cause aberrant glenohumeral kinematics and thus result in impingement symptoms.

#### CLINICAL APPROACH

A complete clinical assessment involves:

1. history
2. observation and pre-examination palpation
3. basic clinical exam (BCE) and tissue-specific palpation
4. special tests: diagnostic testing and symptom modification tests
5. screening of the kinetic chain
6. objective measurements and outcome scores.

## History

Endeavour to determine the exact site of the patient's pain; this can be difficult. Although acromioclavicular (AC) joint pain (C4 dermatome) and bicipital pain (along the bicipital groove and the line of the muscle belly) are well localised, the pain of most other shoulder pathologies is more diffuse. The onset of shoulder pain may be either acute, for example, a dislocation, subluxation or rotator cuff tear, or insidious, such as rotator cuff tendinopathy. Although most patients with chronic impingement-related shoulder pain report pain distribution in the deltoid area (and the C5 dermatome), overhead athletes with internal impingement and tissue involvement of the infraspinatus accentuate posterior shoulder pain in their history.

For acute injuries, identify the position of the shoulder at the time of injury. If the arm was wrenched backwards while in a vulnerable position, it suggests anterior dislocation or subluxation. A fall onto the point of the shoulder can cause AC joint injury. In chronic shoulder pain, the activity or position that precipitates the patient's pain should be noted, such as the cocking phase of throwing or the pull-through phase of swimming.

Note the severity of the pain, aggravating and easing factors, and the effect of the pain on activities of daily living and sporting activity. Night pain is very common in rotator cuff dysfunction and adhesive capsulitis. In order to identify the actual irritability of the injured tissue, ask (a) if the patient can sleep on the injured shoulder, (b) if the pain is only at the shoulder region, and not referring into the upper arm or elbow, and (c) if there is no pain at rest. If the answer is yes on all three questions, irritability is low, and controlled loading of the structures will be allowed. However, if the answer to one or two of the three questions is no, high irritability is present, meaning initial treatment will mainly have to focus on pain control and tissue protection.<sup>9</sup>

### PRACTICE PEARL

Shoulder pain should be considered irritable if the patient cannot sleep on the painful shoulder, if their pain extends into the upper arm or elbow, or if they have resting pain. Initial treatment should then focus on pain control and tissue protection.

Sensory symptoms such as numbness or pins and needles should be noted as well as any episodes of 'dead arm'. In a baseball pitcher this suggests a labral injury. He or she may report catching and locking, or inability to develop normal speed in the action.

Inquire as to past or present problems elsewhere in the kinetic chain such as knee or ankle sprains or lower back pain. Also, clarify the exact treatment for previous local or

distant problems. Look for predisposing factors. For example, a training diary may reveal excessive load on the region.

## Physical examination

Examination should begin with observation of the patient from the front, from behind, and from the side. Check for asymmetry in muscle bulk, scapular position, shoulder height, spinal curves, head position, general posture, and AC and sternoclavicular (SC) joint protuberances. Next, a pre-examination palpation should be performed, checking for muscle atrophy, swelling, temperature and general trophic condition of skin. Tissue-specific palpation should be avoided prior to the examination, as this might influence the results of the clinical examination.

A basic clinical examination should then be performed, consisting of active and passive movements and resistance tests.

### Active movements

These consist of forward flexion in the sagittal plane, abduction in the frontal plane, elevation in the scapular plane, functional external rotation (hand to neck) and functional internal rotation (hand behind back) (Fig. 24.6). Check for range of motion (ROM), pain and quality of

(a)

**Figure 24.6** Basic clinical examination—active movements  
(a) Forward flexion

(b)

(d)

(c)

(e)

**Figure 24.6 (cont.)** (b) Abduction (c) Elevation in the scapular plane (d) Functional external rotation—hand to neck (e) Functional internal rotation—hand behind back

movement. A specific pain pattern can be found in the painful arc, in which the patient experiences pain in the midrange of motion, and not in the extremes. Specifically observe scapular movements. Scapular dyskinesis may be observed during all active movements. Depending on the specific kind of dyskinesis, they may be divided into type I (prominent inferior angle of the scapula), type II (prominent medial border of the scapula), and type III (prominent superior medial angle of the scapula). In addition, check for a possible protracted scapular position and rounded shoulder posture.

### Passive examination

This consists of forward flexion, abduction, external rotation in neutral position, internal rotation from neutral, and horizontal adduction (Fig. 24.7). Check for ROM, pain and end feel. Be aware of the specific pattern in case of adhesive capsulitis: both rotations limited, as well as abduction in the frontal plane, and a stiff end feel. Loss of ROM and/or pain during passive examination indicate articular, capsular or ligamentous injury or stiffness in the surrounding muscles.

### Resistance examination

In this stage, isometric resistance is given against forward flexion, extension, abduction and adduction, external and internal rotation, elbow flexion and extension, all with

(b)

(a)

(c)

the shoulder in the neutral positions (Fig. 24.8). Pain and/or weakness are noticed, and might reflect injury to the musculotendinous system. Pain without weakness often is the result of tendinopathy, whereas weakness is the result of muscle tears. However, be aware that the patient might exhibit protective muscle inhibition in case of an injury with high irritability, possibly leading to a false diagnosis of muscle tear. In that case, resistance tests will be weak and painful. Weakness without pain might be the result of a complete but asymptomatic tear (e.g. external rotation

(a)

(b)

in a total tear of the infraspinatus), sport-specific weakness of the antagonist (e.g. external rotators in overhead athletes) or a neurological problem (e.g. weak abduction due to an axillary nerve injury).

After the basic clinical examination, and based on the hypothesis of tissue injury, tissue-specific palpation may be performed. In overhead athletes, check routinely for tenderness of the supraspinatus, infraspinatus, subscapularis,

AC joint line, and the LHB tendon, as well as myofascial pain in the upper trapezius, levator scapulae, pectoralis minor and rhomboids. Palpation has been shown to have similar sensitivity and specificity as to some clinical tests; however, accuracy depends upon the palpation skills of the examiner. Since the special tests, described below, often tend to irritate or impinge the tendons, it is advisable to perform palpation after the basic clinical examination and before the special tests. Repeat the tissue-specific palpation at the very end of the examination.

### Special tests—diagnostic testing and symptom modification tests

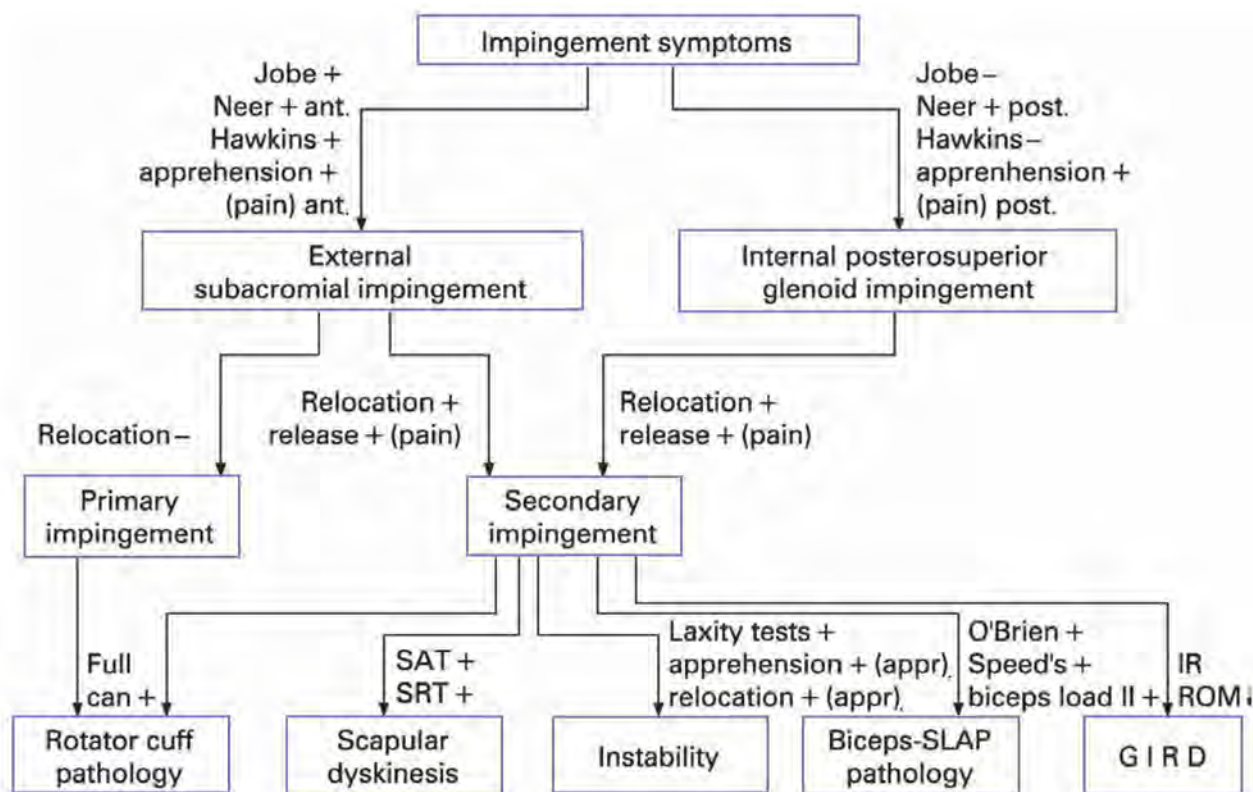

Although a large number of special tests are described for examination of the shoulder, it is not feasible to undertake all of them in every examination. Here we present and discuss an algorithm for clinical reasoning and physical examination testing to assist the clinician in the assessment of impingement-related shoulder pain (Fig. 24.9).<sup>10</sup> Clinical tests are selected based on the available evidence regarding their diagnostic accuracy

(Table 24.2); however, given the large number of available clinical tests, also based on the examiner's preference. Any test in the algorithm may be substituted by another one, as long as the purpose of the test and its diagnostic value are comparable. In general, in the interpretation of clinical tests, latest evidence and systematic reviews suggest it is favourable to interpret a 'best-test combination' instead of a solitary test.

### Impingement tests

Of the various provocative impingement tests, the most popular are the Jobe, Hawkins and Neer tests. In the Jobe test or empty can test, the shoulder is put in 90° elevation in the scapular plane in maximal internal rotation (empty can position) and manual resistance is given against further elevation (Fig. 24.10a). The test is positive for subacromial impingement if the patient reports pain. The test will be negative if the patient has posterosuperior glenoid impingement.

In the Hawkins test, passive internal rotation is performed with the shoulder in 90° of forward flexion (Fig. 24.10b).

Table based on Hegedus et al.<sup>11</sup> and Hanchard et al.<sup>12</sup>

A painful test is an indication for subacromial impingement; the test will be negative in case of internal impingement.

The Neer test consists of forced maximal forward flexion in internal rotation with the scapula fixed into depression (Fig. 24.10c). Pain at the front of the shoulder is an indication for subacromial impingement, whereas patients with internal impingement will exhibit pain

at the posterior aspect of the shoulder (slightly change testing position into neutral rotational position/external rotation and fixing the scapula to front).

It is suggested that interpretation for subacromial impingement should be based on five tests: the three impingement tests described above, painful and/or weak external rotation against resistance, and a painful arc

during active elevation. Sensitivity and specificity are the highest when a cut-off value of three positive tests on five is used (Table 24.2).

Besides these impingement tests, instability tests are often used as provocation tests for impingement. In the apprehension position, the shoulder is placed passively in maximal external rotation and horizontal abduction (Fig. 24.10d). Pain at the anterior aspect of the shoulder suggests subacromial impingement; pain at the posterior aspect implies posterosuperior glenoid impingement. It might be necessary to change the position into more or less elevation to elicit subtle symptoms in the overhead athlete. In the relocation test, the investigator manually performs a dorsal glide on the humeral head in the apprehension position (Fig. 24.10e). The test is positive if the pain exhibited during the apprehension test disappears. The relocation test allows us to identify primary versus secondary impingement. If the test is positive, this means that the impingement pain is secondary, based on excessive anterior translation of the humeral head. A negative test suggests primary impingement, not dependent on the position of the humeral head.

### Rotator cuff tests

To define the involvement of rotator cuff pathology in the impingement symptoms, the full can test is a valuable tool. The test consists of resisted elevation in the scapular plane with the thumbs up (Fig. 24.10f). Research has indicated that rotator cuff muscles are also highly active in this position, like in the empty can (or Jobe) test. If both tests are painful, rotator cuff pathology is present. If only the empty can test is painful, and the full can test is negative, the patient probably suffers from impingement symptoms, but not primarily related to rotator cuff pathology.

In the presence of rotator cuff pathology, the examiner can perform a number of specific tests for the supraspinatus, subscapularis and infraspinatus to find out whether one of more tendons are ruptured. Although recent research indicates isolation of rotator cuff muscles in a clinical setting is very difficult,<sup>13</sup> the Gerber lift-off test, and the belly press test may be useful for subscapular tears, and the lag sign is often used to detect infraspinatus tears. In the Gerber lift-off test, the patient is asked to lift their hand from their back in a maximally internally rotated position (Fig. 24.10g); during the belly press test, the quality of movement is observed when the patient pushes his hand into his stomach (Fig. 24.10h). A positive external rotation lag sign occurs when the patient is unable to maintain the position of external rotation in a slightly abducted position and the shoulder rotates internally (Fig. 24.10i).

### Scapular involvement tests

Scapular involvement in impingement-related shoulder pain may be examined by the scapular assistance test (SAT) and the scapular retraction test (SRT). The SAT, in which scapular movement quality is examined, consists of manual assistance of correct scapular movement during elevation of the arm (Fig. 24.10j). Reduction of pain during this movement compared to non-assistance confirms scapular involvement in the shoulder complaints.

In the SRT, in which scapular stability is examined, the empty can test is performed while the examiner stabilises the patient's scapula and shoulder in a position of retraction by placing the forearm along the medial border of the scapula (Fig. 24.10k). The test is positive for scapular involvement when the initial pain, present in the empty can position disappears during the SRT. Since the diagnostic value of these tests for shoulder pathology is low, they should be considered as symptom modification tests (see below) rather than diagnostic tests.

### Instability tests

The clinical tests to examine shoulder instability can be divided into provocative tests and laxity tests. Commonly used provocative tests for instability are the apprehension and relocation tests, described earlier (Fig. 24.10d, e). In case of instability, patients will exhibit symptoms, such as apprehensive muscle tension and subluxation, rather than pain.

Distinct from the provocative tests, the laxity tests assess humeral translation with respect to the glenoid fossa. For anterior laxity, the load and shift test may be used (Fig. 24.10l). In this test, the humeral head is loaded in such a way as to centre it congruently within the glenoid fossa. Subsequently, the humeral head is manually shifted anteriorly, relative to the glenoid fossa, and the amount of translation is graded from 1 (translation up to, but not beyond the glenoid rim), over grade 2 (translation beyond the glenoid rim with spontaneous reduction after releasing the humeral head) to grade 3 (subluxation without spontaneous reduction). The sulcus sign allows examination of inferior laxity. In this test, inferior subluxation is produced by downward traction on the arm (Fig. 24.10m).

For posterior laxity, the posterior subluxation test is described. This test is performed by placing the patient's arm in adduction, internal rotation and 70–90° flexion. The examiner applies a posteriorly directed force along the arm, and then slowly moves the shoulder to horizontal abduction and external rotation (Fig. 24.10n). The test is considered to be positive if a clunk is felt during the latter movement, indicating the humeral head is relocated in the glenoid after being subluxed posteriorly.

(p)

(q)

**Figure 24.10 (cont.)** (p) Passive compression test (q) Biceps load II test

### Biceps pathology and SLAP lesion tests

Numerous SLAP and biceps tests exist in the literature. However, we prefer the Speed test, the O'Brien test, the passive compression, and the biceps load II tests. The Speed test is performed by resisting downwardly applied pressure to the arm when the shoulder is positioned in 90° of forward flexion with the elbow extended, and forearm supinated; a positive test result should produce pain into the biceps region.

In the O'Brien test, resistance is tested with the arm forward flexed to 90° and adducted 10° with the thumb pointing down (Fig. 24.10o-i). Pain is lessened or disappears when the test is repeated in the same shoulder position but with the thumb pointing up (Fig. 24.10o-ii).

During the passive compression test, the clinician rotates the patient's arm externally with 30° of abduction and then pushes the arm proximally while extending the shoulder, which results in the passive compression of the superior labrum onto the glenoid (Fig. 24.10p).

The biceps load II test consists of applying resistance against elbow flexion with the shoulder in 120° of abduction and the elbow in 90° flexion (Fig. 24.10q). The test result is considered positive if the patient complains of pain during the resisted elbow flexion.

A best-test combination consisting of three tests (two sensitive and one more specific test) has been recommended for the interpretation (Table 24.2).<sup>11</sup>

### Clinical evaluation of GIRD

The assessment of glenohumeral internal rotation deficit (GIRD) is performed by measuring glenohumeral internal rotation range of motion, preferably in the supine position with the shoulder abducted 90° and the scapula stabilised against the table (Fig. 24.11). Goniometric/inclinometric

**Figure 24.11** Clinical assessment of GIRD

assessment as well as interpretation of the 'end feel' is described as criteria for GIRD evaluation. A side difference of 20° is considered to be positive for GIRD. However, in view of a possible shift in rotational range of motion due to bony adaptations, GIRD may be associated with a gain in external rotation ROM. Therefore it is imperative to measure internal as well as external rotation, interpreting the total range of motion (TROM). Besides the measurement in an abducted position, additional evaluation of GIRD with the shoulder in 90° forward flexion may even give the clinician a better impression of the posterior stiffness, since there is more stretch on the posterior aspect of the shoulder.

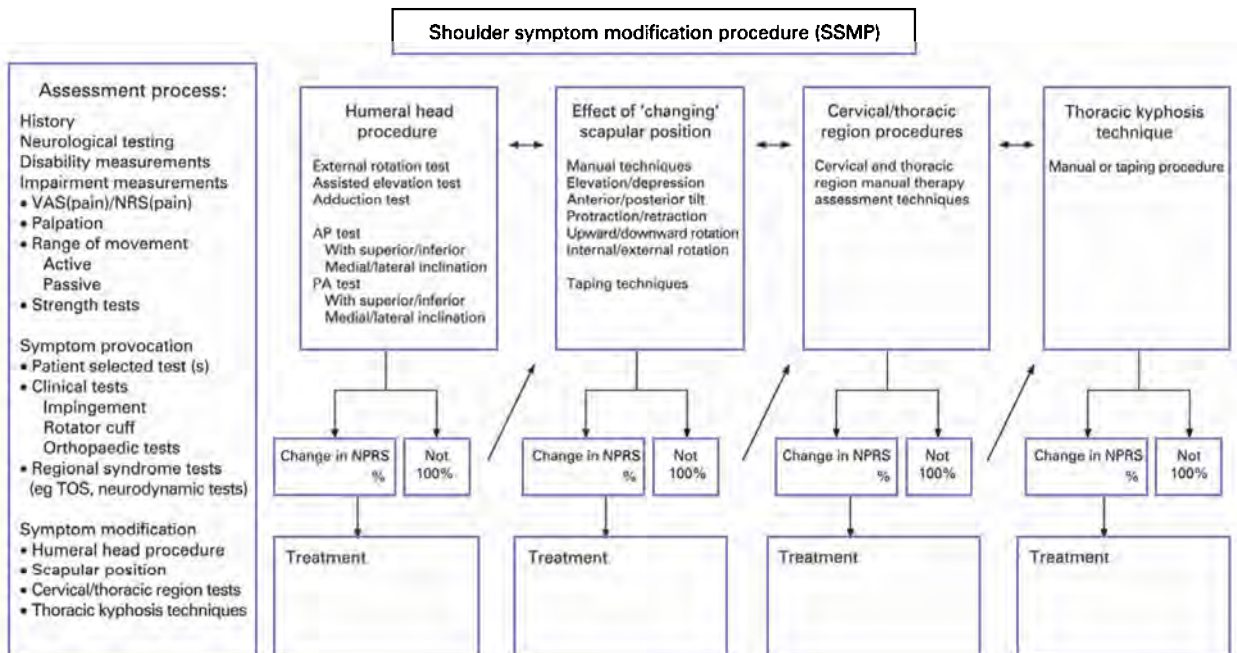

### Shoulder symptom modification procedure

In view of the limited diagnostic accuracy of the existing clinical tests (Table 24.2), as well as the relevance of the rest of the kinetic chain, it is important to perform symptom modification tests. Once the movement or

activity that reproduces the shoulder symptoms has been agreed upon (and assessed during the clinical examination), the shoulder symptom modification procedure (SSMP) is applied.

The SSMP is a series of mechanical techniques that are applied while the patient performs the activity or movement that most closely reproduces the symptoms experienced by the patient (Fig. 24.12). These techniques may be applied on different levels of the kinetic chain, starting with the shoulder locally, going to the scapula (see scapular tests), thoracic and cervical spine and posture, lumbar spine and the lower extremities. Modifications may include correcting posture (for instance sitting versus standing or correcting thoracic kyphosis), ensuring correct muscle contraction (for instance scapular correction, core stability) or mechanically correct kinematics (for instance posterior glide humeral head).

The basic principles, however, are always similar: (a) define a position or movement that causes the

Abbreviations: AP (anterior-posterior), PA (posterior-anterior), VAS (visual analogue scale), NPRS (numerical pain rating scale), TOS (thoracic outlet syndrome)

**Figure 24.12** Shoulder symptom modification procedure (SSMP)

FROM LEWIS 2009.<sup>16</sup> REPRODUCED WITH PERMISSION FROM *BRITISH JOURNAL OF SPORTS MEDICINE*

symptoms, based on the clinical exam, (b) correct the possible cause of the symptoms, based on biomechanics or arthrokinematics, and (c) observe possible change in symptoms. Based on this procedure the clinician will know the key points in the rehabilitation program and advise the patient. As stated by the authors, the SSMP is not meant as a replacement for current clinical practice but as an adjunct to help support the clinical decision-making process by identifying factors that alleviate the patient's shoulder symptoms.<sup>14-16</sup>

### Additional shoulder tests

Depending on the history and the results of the basic clinical examination, the clinician may need to perform additional special tests to those described in the previous section. In particular, neurologic, neurodynamic and/or vascular examination might be necessary in case of a suspicion of for instance thoracic outlet syndrome (TOS) or neurodynamic upper limb pathology. The Roos test (Fig. 24.13a) is a very sensitive and specific test for TOS and easy to perform: ask the patient to open and close their hands for at least 60 seconds with the shoulders abducted and externally rotated and the shoulder girdle in depression. Motor deficits, change of colour of the hands, numbness, and slowing down of the movement are considered to be signs of TOS. For the neurodynamic examination, the basic upper limb neurodynamic tests (ULNT) may be performed, evaluating the mechanosensitivity of the nervous system in the upper quarter (Fig. 24.13b). The tests are considered positive if they provoke or reproduce the symptoms, or are in a relevant distribution to the nerve being tested. The second feature of a positive test is that the response received (sensory symptoms, ROM or resistance perceived by the examiner) is different from the asymptomatic limb, and different from what is known to be a normal response. Cervicogenic shoulder involvement needs to be assessed by a cervical spine screening and differential diagnostic tests such as the Spurling test (Chapter 23).

### Screening of the kinetic chain

Regardless of the SSMP, screening of the kinetic chain is imperative in overhead athletes. Quick screening of kinetic chain variables consists of:

- observation of spinal curves and general posture (forward head posture, hyperlordosis cervical spine, hyperkyphosis and protracted shoulders, sway back, hyperlordosis or hypolordosis, flexed position of the hips, knee position into valgus or varus, foot position)
- single-leg/double-leg squat observe hip and core stability

(a)

(b)

**Figure 24.13** Additional tests for shoulder pain (a) Roos test for thoracic outlet syndrome (b) Upper limb neurodynamic tests

- bilateral deep squat: observe quality of movement, repetitive movements to evaluate lower limb strength and endurance
- trunk ROM into rotation, flexion and extension
- ROM of the hips, in particular into extension and rotation.

The clinician may use some specific testing protocols, such as the functional movement screen or the 9+<sup>17</sup> (Chapter 46) or a similar standardised screening program, looking at ROM as well as strength and stability, and at the trunk as well as the extremities.

## Key outcome measures

There are numerous patient-reported outcome measures to assess functional status, treatment effect and return-to-play criteria for people with shoulder pain. The clinician's selection should be based on the specific clinical outcome to be measured (body structures, function, activity, participation), the specific pathology (instability, rotator cuff pathology) and whether disease-specific,

region-specific or generic outcome is required. Table 24.3 summarises the most commonly used outcome scales for shoulder pain patients.

## INVESTIGATIONS

We discuss the principles of shoulder investigations (including diagnostic arthroscopy) as it is a critical element of efficient management of the patient with shoulder pain.

### Objective measurements of the shoulder

The assessment of the ROM into rotation of the shoulder can be measured with a goniometer or an inclinometer, and in many positions of the body and the shoulder. A comprehensive reliability study showed good to excellent inter- and intra-tester reliability for a variety of test positions and equipment.<sup>18</sup> Based on the results of this study, no specific procedure can be acknowledged as superior to another. However, the clinician has to take into account that large variability exists in literature regarding shoulder position (for instance scapular or frontal plane) and the specific method of scapular stabilisation (none, hand on shoulder top, or specific fixation of coracoid), and therefore be consequent in repeated measurements. Based on the above-mentioned reliability study and in view of optimal standardisation of body and shoulder position, the authors advise the procedure supine, arm 90° in frontal plane, palpation of the coracoid process, performed with digital inclinometer (Fig. 24.11).

Regarding rotator cuff strength, isokinetic (Fig. 24.14a) as well as isometric (Fig. 24.14b) and eccentric (Fig. 24.14c) strength measurements may be performed. Absolute side differences as well as muscle balance ratio between external and internal rotators are to be interpreted. In general, with respect to cut-off values distinguishing a healthy shoulder from a shoulder at risk, an isokinetic ER/IR ratio of 66% or an isometric ER/IR ratio of 75% (when measured in neutral or in abduction 90° and external rotation 90°), or  $\pm 100\%$  (when measured in 90° abduction and 0° rotation) and 60–80% (when measured in 90° abduction and 90° external rotation) is advised, with a general rotator cuff strength increase of 10% of the dominant throwing side<sup>19</sup> compared to the non-dominant side. The preferential functional eccentric/concentric ratio (eccER/concIR) depends on the speed and specific procedure tested. For the eccentric test with the hand-held dynamometer (HHD), values slightly higher than 100% (114–121%) were found in a sample of 201 adult overhead athletes from volleyball, tennis and handball.<sup>19</sup> All procedures have been found to show high to excellent reliability.

*Scapular performance or behaviour* can be evaluated by measuring scapular inclination (upward rotation), scapular muscle strength (isokinetic or isometric testing) and muscle length (pectoralis minor).

Scapular inclination may be measured using an inclinometer in several arm elevation positions (Fig. 24.15). In

(c)

**Figure 24.14 (cont.)** (b) Isometric testing with a hand-held dynamometer (c) Eccentric testing with a hand-held dynamometer—the assessor performs an internal rotation of the shoulder while the patient maximally resists against this pressure

**Figure 24.15** Measurement of scapular inclination using an inclinometer along the spine of the scapula

general, an upward inclination of approximately  $60^\circ$  should be reached at full active arm elevation.

For the scapular muscles proper intermuscular and intramuscular balance should be assessed. Isokinetic protraction/retraction ratio (Fig. 24.16) should be 100% in a healthy population, with slight changes in overhead athletes who have slightly stronger protractors. When measured isometrically with an HHD, it is advisable to use standardised positions<sup>20</sup> and to be consistent doing a make or a break test, since results might differ significantly. In bilateral sports (swimming, rowing, gymnastics) there should be no side

(a)

**Figure 24.16** Isometric strength testing of the scapular muscles (a) Protraction

(b)

**Figure 24.16 (cont.)** (b) Retraction

differences in scapular muscle strength, in one-handed overhead sports an increase of scapular muscle strength of 10% is advised on the dominant side. In particular, the lower trapezius and serratus anterior should receive special attention, since these muscles are shown to be susceptible to weakness in injured athletes. However, a statement saying that scapular behaviour should be symmetrical in overhead athletes is not supported by data. On the contrary, in volleyball, as well as in handball players, asymmetry in resting scapular posture is often found. Therefore clinicians should be aware that some degree of asymmetry in resting scapular posture is often found. It should not be considered automatically as a pathological sign but rather an adaptation to sports practice and extensive use of the upper limb.

Tightness of the pectoralis minor may be clinically observed by evaluating shoulder position with the patient supine (with more protracted shoulder position in case of short pectoralis minor) and objectively measured by determining the distance between the coracoid process and the fourth rib at the sternum (Fig. 24.17a). When normalised to body height (pectoralis minor index (PMI) = pectoralis length/body height), the PMI should not be below 7.65, indicating a short pectoralis minor.<sup>21</sup>

*Functional performance tests* for shoulder function are gaining interest, although not yet fully explored in clinical practice. The seated medicine ball throw (SMBT) (Fig. 24.17b) and the Y-balance test for the upper extremity (Fig. 24.17c) have been described for evaluation of the front chest throwing performance and static weight-bearing shoulder stability, respectively. However, normative data and cut-off values for injury prevention and return to play are lacking. Recently, it was shown that the SMBT and isokinetic shoulder, and elbow strength correlate highly, whereas no significant correlation between the Y-balance test and these isokinetic strength measures was found.<sup>22</sup>

**Radiography**

Plain X-rays are important in the diagnosis of shoulder abnormalities. Routine views (AP with internal and external rotation and axillary lateral) provide a good overview of the region. A 'true' AP view is useful for assessing joint space narrowing, (i.e. arthritis). In cases of trauma, an adequate axillary view may not be possible and a true lateral film must be obtained to exclude dislocation. The following can be identified on plain films: calcific tendinopathy, glenohumeral joint arthritis, impingement (sclerosis of anterior and/or lateral acromion, sclerosis of greater tuberosity), proximal humeral head migration (severe rotator cuff dysfunction) and fractures.

Special views have been described to evaluate instability and impingement. Supraspinatus outlet views and down-tilted acromial films are obtained to evaluate impingement. In cases of instability, special views such as the West Point view or the Stryker notch view are used to better detect Bankart and Hill-Sachs' lesions.

**Arthrography**

Detailed anatomical information is obtained when arthrography (joint injected with dye) is combined with CT of the shoulder (CT arthrogram) or MR arthrography (see below). This examination gives excellent detail of capsular attachments and of the labrum. Small avulsion fractures of the glenoid rim (Bankart lesion) and the humeral head (Hill-Sachs' lesion) are clearly defined.

**Ultrasound**

High-resolution ultrasound, in the hands of an experienced operator, is a reliable non-invasive technique for imaging the rotator cuff and adjacent muscles, the bursae and the long head of the biceps muscle. The examination may be performed as a static or dynamic investigation. Tendon swelling, thickening of the bursa, abnormal fluid collection or calcific tendonitis may be detected, as may a partial or complete rotator cuff tear. It is important to define the size and location of the tear, and if there is any supraspinatus muscle atrophy (indicating a chronic and usually irreparable rotator cuff tear). If there is a partial thickness tear it is important to determine the thickness of the tear—as a percentage of the thickness of the tendon—as tears over 50% usually progress and are less likely to respond to non-operative treatment. It is also important to determine if the partial thickness tear is on the bursal side, under surface or intrasubstance. A dynamic examination performed while the patient is actively abducting the shoulder may confirm the presence of impingement (see tendinopathy management).

**Magnetic resonance imaging**

MRI allows multiplanar, non-invasive examination of the shoulder and is used to detect a rotator cuff tear. Bone detail is not defined as well as with CT and examination with shoulder movement is not possible. MR arthrogram with contrast is well suited to evaluate labral tears or instability.

## Diagnostic arthroscopy

Arthroscopy of the shoulder, as well as being therapeutic, can provide useful diagnostic information. Shoulder arthroscopy permits inspection of the glenohumeral joint and the subacromial space in turn. Arthroscopy of the glenohumeral joint cavity is particularly useful as it:

- enables inspection of the glenoid labrum for evidence of a Bankart lesion or a SLAP lesion
- permits assessment of the state of the articular cartilage
- will demonstrate the presence of a Hill-Sachs' lesion
- allows inspection of the shoulder capsule and synovium (a red synovium and thickened capsule are characteristic of adhesive capsulitis)
- will identify a drive-through sign for laxity
- permits inspection of the under surface of the rotator cuff tendons, the biceps tendon and the subacromial bursa
- enables inspection and probing of the bursal surface of the rotator cuff.

Arthroscopy of the subacromial space allows assessment of:

- bursitis
- coracoacromial ligament ossification (spur formation)
- lateral spurs
- os acromiale
- bursal side rotator cuff tears
- full thickness rotator cuff tears.

The examination under anaesthesia (EUA) performed in conjunction with arthroscopy may sometimes be helpful to assess the presence, direction and severity of shoulder laxity, and to assess shoulder range of motion.

It is important to remember that these sophisticated investigations are only an adjunct to the clinical findings. In many cases of shoulder pain, the clinical findings provide sufficient information to diagnose the cause of the shoulder pain.

## GENERAL TREATMENT AND REHABILITATION GUIDELINES FOR THE MOST COMMON SHOULDER INJURIES IN ATHLETES

It is important to note that shoulder pain may have several underlying causing factors, structural and functional. The treatment approach must be based on the results of the clinical examination and the diagnostic imaging, and may comprise several of the treatment strategies described below. In case several factors are identified within the kinetic chain, it is imperative to start the treatment dealing with correcting the most proximal parts in the kinetic chain.

In general, four phases can be recognised in the rehabilitation of the overhead athlete:<sup>54</sup> (1) acute phase, (2) intermediate phase, (3) advanced strengthening phase, and (4) return-to-play phase. In the acute phase, the goals are to

diminish pain and inflammation, normalise motion, delay muscle atrophy and restore dynamic stability. Strengthening exercises focus on rotator cuff and scapular retractors. Functional loading is limited until full range of motion is restored. During the intermediate phase strengthening exercises progress into isotonic training of the shoulder girdle and the core, and flexibility is controlled by intensive stretching exercises, in particular of the posterior shoulder structures. The advanced strengthening phase consists of more aggressive strength training, including power and endurance enhancement. A plyometric program, endurance drills and controlled throwing are initiated. In the return-to-play phase, the athlete progressively increases the throwing program, continues flexibility drills and prepares to return to competitive throwing.

## ROTATOR CUFF INJURIES

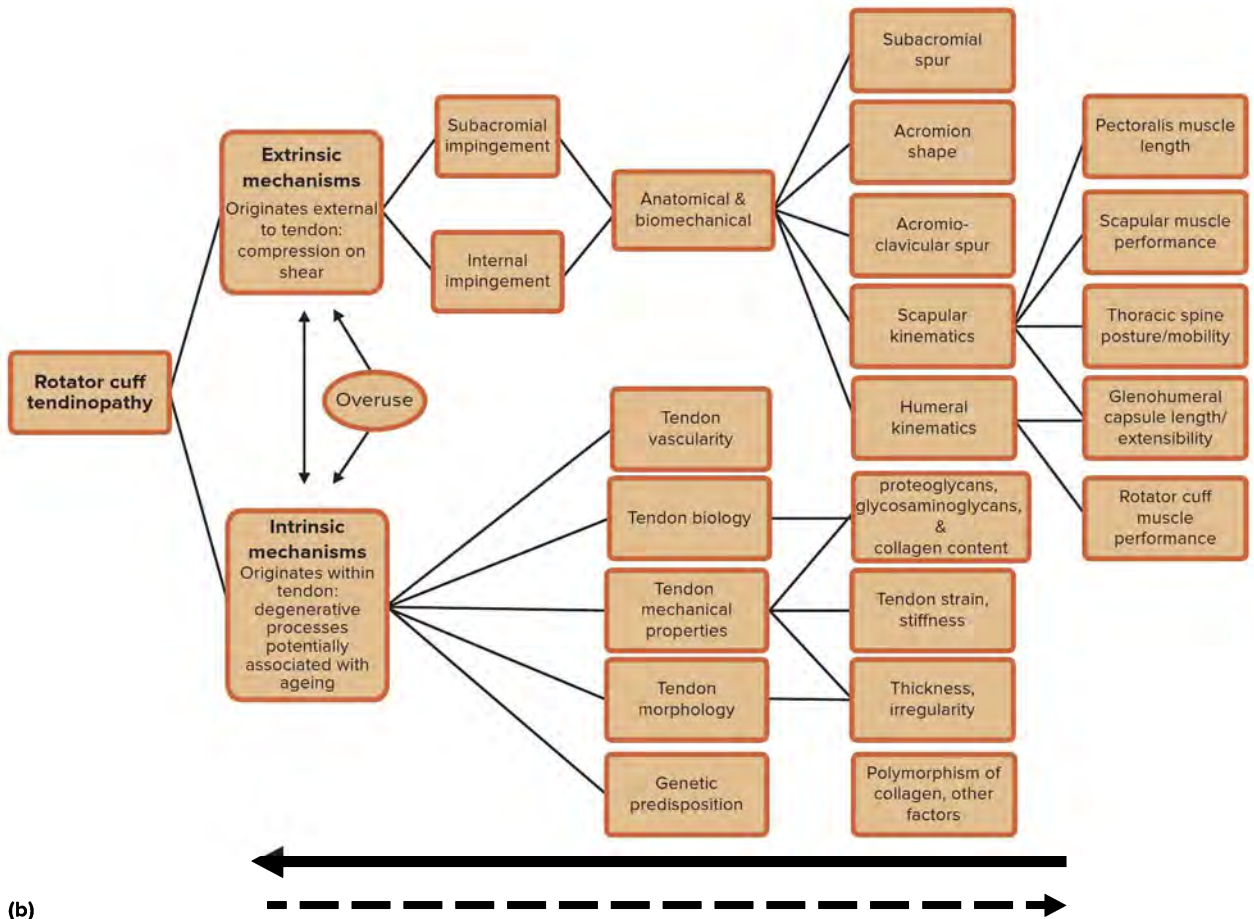

Rotator cuff injuries consist of tendinopathy and tears (complete or partial), often associated with an underlying tendinopathy.

### Rotator cuff tendinopathy

The aetiology of rotator cuff tendinopathy (Fig. 24.18a) is multifactorial, and has been attributed to both extrinsic and intrinsic mechanisms. Extrinsic factors that encroach upon the subacromial space (subacromial impingement) or against the posterosuperior rim of the glenoid (internal

**Figure 24.18** Rotator cuff tendinopathy (a) Pathology generally begins on the inferior (articular) surface of the tendon and may be associated with a partial tear

**Figure 24.18 (cont.)** (b) Intrinsic and extrinsic factors contributing to rotator cuff tendinopathy<sup>6</sup>  
PG = proteoglycans; GAG = glycosaminoglycans

impingement), include anatomical variants of the acromion, alterations in scapular or humeral kinematics, postural abnormalities, rotator cuff and scapular muscle performance deficits, and decreased extensibility of the pectoralis minor or posterior shoulder. Intrinsic factors that contribute to rotator cuff tendon degradation with tensile/shear overload include alterations in biology, mechanical properties, morphology and vascularity. An overview of extrinsic and intrinsic mechanisms contributing to rotator cuff tendinopathy is given in Figure 24.18b.

### Clinical features

The athlete with rotator cuff tendinopathy complains of pain with overhead activity such as throwing, swimming and overhead shots in racquet sports. Activities undertaken at less than 90° of abduction are usually pain-free. On examination, there may be tenderness over the supraspinatus tendon proximal to or at its insertion into the greater tuberosity of the humerus. If the infraspinatus is involved, there is also tenderness on the insertion dorsally

on the greater tuberosity. Active movement may reveal a painful arc on abduction between approximately 70° and 120°. Symptoms can be reproduced with impingement tests and in the apprehension position, and also the full can test and external rotation against resistance may be painful. The investigation of choice in rotator cuff tendinopathy is MRI arthrogram (Fig. 24.19). This may also identify a partial tear of the rotator cuff. Ultrasound can rule out a full thickness tear; define a partial thickness tear; identify a thickened subacromial bursa and rule in or out 'impingement' of the bursa under the lateral acromion as the arm is abducted.

### Treatment of rotator cuff tendinopathy

Treatment should be considered in two parts. The first part is to treat the tendinopathy symptomatically. The patient should avoid the aggravating activity and apply ice locally. There is no level 2 evidence (Chapter 2) to support NSAIDs, ultrasound, interferential stimulation, laser, magnetic field therapy or local massage.

**Figure 24.19** MR axial view showing supraspinatus tendinopathy (green arrow), with non-focal T2 signal increase not equal to that of fluid

Clinical dogma has suggested a corticosteroid injection into the subacromial space may reduce a patient's symptoms and allow him or her to begin shoulder rehabilitation. However, randomised trials have failed to support this position. The body of evidence in sports medicine is that corticosteroid injection provides short-term pain relief but impairs long-term recovery for tendinopathies<sup>55</sup> (Chapter 17).

In choosing a management plan, clinicians should consider patient preference, availability of practitioners and other health care use. If a patient prefers a more active or self-management approach, manual physical therapy, exercise and referral to a physiotherapist should be discussed. There is systematic review evidence for the benefits of exercise therapy.<sup>56</sup>

The second part of treatment should consist of rehabilitation exercises of the rotator cuff itself. Several kinds of exercises can be applied, the selection depends upon the irritability of the tendons, the goal of the program, and the specific sport the athlete is involved in.

- Strengthening the rotator cuff (Fig. 24.20): based on EMG studies the following exercises are advised to strengthen the rotator cuff:<sup>57, 58</sup> elevation in the scapular plane (supraspinatus, infraspinatus and subscapularis) (Fig. 24.20a), external rotation (supraspinatus, infraspinatus and teres minor) (Fig. 24.20b), internal rotation (subscapularis) (Fig. 24.20c), horizontal abduction

with external rotation (infraspinatus) (Fig. 24.20d). In overhead athletes special attention needs to go to the external rotators, since weakness of this muscle group is often present as a sport-specific adaptation.

- Eccentric training of the rotator cuff: evidence on structural changes in the rotator cuff tendons after eccentric training is currently lacking but clinical improvement was established.<sup>59, 60</sup> Moreover, it needs to be recognised that the rotator cuff functions very much in an eccentric mode during sports activity, which strengthens the argument to include eccentric training in rehabilitation of the overhead athlete with rotator cuff tendinopathy. Exercises may be performed in a controlled slow manner, avoiding the concentric phase to allow maximal loading of the eccentric phase (Fig. 24.21), in a more plyometric way (Fig. 24.22), or accentuating the stretch-shortening cycle (Fig. 24.23).

(a) Starting position (b) Increasing load (c) Ending position

**Figure 24.22** Plyometric catching exercise

**Figure 24.23** XCO-Trainer® exercise

Management of calcific tendinopathy can be difficult. In general the presence of calcifications in the rotator cuff is not always associated with symptoms of impingement. The aetiology is unclear, and seems to be rather a biochemical intratendinous process in particular in the supraspinatus tendon. Calcifications are not related to rotator cuff tears or glenohumeral arthritis. In some cases ESWT (extracorporeal shock wave therapy) may be indicated, supported by evidence; however, evidence regarding the effects in non-calcific rotator cuff disease is inconclusive.<sup>61</sup> In some cases, chronic symptomatic calcific tendinopathy is treated arthroscopically.

### Rotator cuff tears

Complete and partial tears of the rotator cuff tendon are commonly seen in older athletes who present with shoulder pain during activity. These patients often complain of an inability to sleep on the affected shoulder. Examination reveals positive impingement signs and sometimes weakness on supraspinatus testing. Diagnosis is confirmed on MRI (Fig. 24.24) or ultrasound.

If the tear is small and of partial thickness, treatment may be conservative. Full thickness rotator cuff tears in young athletes require surgical repair; however, athletic performance often does not return to preoperative levels.<sup>62</sup>

**Figure 24.24** MR axial view showing partial thickness intra-substance supraspinatus tear (yellow arrow), with focal T2 signal equal to that of fluid

In older patients, still active in overhead sports, the choice for surgery or conservative treatment depends upon the degree of discomfort and pain during daily and sports activities as a result of the shoulder pain, and the expectations of the patient. Given the increasing age of people performing (overhead) sports at a recreational but also at a senior competitive level, the management of rotator cuff tears including return to sports in older athletes gains interest. Analysing the definition of a master athlete as: 'Active individual aged 50 years or older, who desires optimal levels of performance or wishes to exercise for general health and has high expectations for sports medicine care, including return to sport or activity after injury', achieving these goals is a huge challenge for all healthcare professionals involved with older athletes.

Although there is no general consensus on the approach of rotator cuff tears, there seems to be a shift towards conservative treatment.<sup>63, 64</sup> Although not proven to be efficient, we advise to perform exercises with minimal load on the rotator cuff, and maximally aim to restore function, in order to postpone the 'final match'. Exercises improving function (elevation) with minimal load on the rotator cuff are:

- semi-closed chain exercises with increasing gravity impact and increasing resistance<sup>65</sup> (Fig. 24.25)
- shoulder balance exercises in increasing elevation<sup>66</sup> (Fig. 24.26).

## SHOULDER INSTABILITY

Based on the cause, direction and typical clinical presentation of instability, patients may be divided into three groups: the TUBS (traumatic unidirectional instability with Bankart lesion, for which surgery is often needed), AIOS (acquired instability due to overstress syndrome), and AMBRI (atraumatic multidirectional instability with bilateral laxity, in which rehabilitation is mandatory, but in case of failure inferior capsular shift surgery is performed). On the field these types may be combined, for instance a gymnast with general laxity (AMBRI) may develop overuse instability (AIOS), or a volleyball player with sports-specific minor instability (AIOS) may experience an acute trauma and dislocation (TUBS).

### Traumatic shoulder instability—TUBS

One of the most common traumatic sports injuries is acute dislocation of the glenohumeral joint (Fig. 24.27a, b). In almost all cases, this is an anterior dislocation and it results from the arm being forced into excessive abduction and external rotation. Most anterior dislocations damage the attachment of the labrum to the anterior glenoid margin (Bankart lesion) as shown on MRI (Fig. 24.27c).

(a)

(b)

**Figure 24.25** Semi-closed chain exercises against external resistance (a) Without gravity (b) Against gravity

**Figure 24.26** Shoulder balance exercise

An associated fracture of the anterior glenoid rim, a bony Bankart lesion (Fig. 24.27d) may be demonstrated on X-ray (Fig. 24.27e) or CT scan (Fig. 24.27f).

A compression fracture of the humeral head posteriorly (Hill-Sachs' lesion) (Fig. 24.27g) or tearing of the posterior or superior labrum may also be present. The history is usually one of acute trauma, either direct or indirect, associated with sudden onset of acute shoulder pain. A patient may describe a feeling of the shoulder 'popping out'. On examination, the dislocated shoulder has a characteristic appearance with a prominent humeral head and a hollow below the acromion. There is a loss of the normal smooth contour compared with the uninjured side. Anterior dislocations of the glenohumeral joint are occasionally associated with damage to the axillary nerve, resulting in impaired sensation on the lateral aspect of the shoulder and deltoid weakness. This should be assessed in any acute dislocation.

### Management of anterior dislocation

In a hospital setting, the dislocated shoulder should be X-rayed prior to reduction as a fracture may be present. In most cases this is not practical and the dislocation should be reduced as soon as possible. In these cases, a post-reduction film should be obtained. The sooner the dislocated shoulder is reduced, the easier it usually is to relocate. There are a number of methods to relocate the humeral head onto the glenoid cavity. One method is demonstrated in Figure 24.27h. Injection of 10–15 mL of xylocaine into the joint can reduce pain and muscle spasm and aid reduction.

Once the shoulder has been reduced, it is usually stable unless placed in gross abduction and external rotation. A traditional sling should not be used—when the arm is internally rotated, the Bankart lesion worsens by becoming detached from bone. It is better to position the arm in 30° external rotation (i.e. an external rotation pillow or splint). Non-operative treatment in such a brace for 3 weeks, day and night, reduced the incidence of recurrent dislocation. However, we acknowledge it is awkward for patients to have the arm in external rotation for several weeks and many surgeons do not insist on this rehabilitation method.

### Recurrent dislocation and Bankart repair

Shoulder dislocations in young athletes have a high rate of recurrence, leading to chronic shoulder instability. Because of this high incidence of recurrent dislocation, arthroscopy should be considered after shoulder dislocation in the younger athlete. If a Bankart lesion is found at arthroscopy, this should be repaired, either arthroscopically or as an open surgical procedure. Arthroscopic repair of a Bankart lesion can reduce the rate of redislocation to <5%.

Following a Bankart repair, the patient may commence pendular movements with the arm within 24 hours, and maintain the arm in a sling for 3–4 weeks. Once the initial pain from the procedure has subsided, active external rotation movements, to just short of the limit of rotation achieved on the operating table, are commenced. It may be helpful to place the arm in a splint in some abduction and external rotation to limit the amount of anterior capsular shortening. Active rotation exercises and stabilisation exercises can be gradually introduced as pain subsides. By 6 weeks, active strengthening can commence. Return to full sport is often achieved at 3–4 months.

The Latarjet procedure, or a bone block augmentation, is a frequently performed surgical procedure (Fig. 24.28). The choice between a Bankart repair or a Latarjet depends particularly upon the extent of bony damage to the shoulder, the type of sport and the surgeon's preference. The post-operative rehabilitation after a Latarjet procedure is similar to a Bankart repair; however, progression may be slightly quicker. Because the Latarjet procedure involves a bone block procedure it is characterised by faster tissue healing (bone to bone) than the healing of the labrum on the glenoid in the Bankart repair. After an immobilisation period of 3 weeks, gentle mobilisations are allowed, with full recovery of ROM after 8 weeks. Strengthening and stabilisation exercises can start 4–6 weeks after surgery, and return to sports, depending on the specific type of sport, from 12 weeks.

### Posterior dislocation of the glenohumeral joint

Acute traumatic posterior dislocation is far less common than anterior dislocation. It occurs either as a result of direct trauma or due to a fall on the outstretched arm that is in some degree of internal rotation or adduction. It may also be caused by a seizure of any cause (e.g. electric shock or epileptic fit). The cardinal sign of posterior dislocation is limited external rotation. Suspicion of this diagnosis should be based on the mechanism of injury and the presence of pain and impaired function. Posterior dislocation can easily be overlooked in the AP X-ray. X-ray must include a true lateral or, if possible, axillary view.

### Acquired sport-specific instability—AIOS

Overhead athletes very often exhibit acquired glenohumeral instability, characterised by laxity of the anterior capsule, as a result of the extreme use of their shoulder during overhead throwing or smashing activities. This type of acquired instability is often referred to as acquired instability overuse syndrome (AIOS). This kind of 'minor' instability may induce the hyperangulation phenomenon during throwing by excessive anterior translation of the humeral head, causing posterosuperior

A small weight may be held in the hand to facilitate reduction

(g)

(h)

**Figure 24.28** Latarjet procedure—one important element of the Latarjet procedure is repositioning the horizontal part of the coracoid to restore bone at the previously damaged anterior inferior margin of the glenoid

impingement. The clinical features comprise recurrent shoulder pain during throwing, possible but not always recurrent subluxations, 'dead arm' syndrome, meaning the athlete reports a sudden inability to throw or smash and a feeling of a 'dead arm'. Chronic pain usually arises from impingement of the rotator cuff tendons, as a result of abnormal humeral head translations, leading to subacromial as well as internal impingement. These recurrent episodes of functional impingement lead to rotator cuff tendinopathy. Apprehension and relocation tests might be painful and/or causing subluxations. These athletes very often show in addition some scapular dyskinesis, GIRD and clinical signs of labral pathology (SLAP lesion).

### Atraumatic multidirectional instability—AMBRI

Multidirectional instability of the glenohumeral joint involves a combination of two or three instabilities— anterior, posterior or inferior. Most commonly, multidirectional instability is an atraumatic type of instability, often associated with generalised ligamentous laxity throughout the body. However, it may also result from repetitive trauma, especially at the extremes of motion or, rarely, from a direct blow.

Generalised ligamentous laxity can be assessed by examination of the wrists, thumbs, elbows and knees to determine the presence of hyperextensibility, or obtaining the Beighton score for general laxity.<sup>67</sup> On examination of the shoulder, besides the functional deficits during active movements and hypermobility during passive

movements, two or three laxity tests will be positive. During the basic clinical examination, one might also find external rotation up to 90° and glenohumeral abduction >90° (Fig. 24.29).<sup>68</sup>

One of the major characteristics of multidirectional instability is that pain in translation occurs in the mid ranges of motion. This indicates a prominent role of altered muscle activation. Lower trapezius and serratus anterior activity is decreased, while pectoralis minor and major and latissimus dorsi increase, creating a position of scapular protraction and glenoid tilting. Frequently the symptoms and pain can be alleviated by placing the scapula in a corrected and stabilised position. Relief of symptoms and decreased translation will point to the need for a therapeutic exercise program for the scapular and shoulder stabilisers. Stretching of the muscles around the shoulder joint should be avoided. If multidirectional instability fails to respond to conservative measures, then surgical treatment may be attempted. However, the results of surgical treatment, particularly in those patients with generalised ligamentous laxity, are not as good as in post-traumatic instability.

A special kind of multidirectional instability is the posterior voluntary subluxation, frequently seen in gymnasts or swimmers with hyperlaxity. Their shoulder 'pumps out' during forward flexion posteriorly, and often the patient is able to perform this subluxation voluntarily. These patients exhibit a marked scapular dyskinesis, characterised by anterior tilting and downward rotation during arm elevation. The posterior subluxation test is positive, and they often exhibit weak external rotation strength.

**Figure 24.29** The hyperabduction test

## Rehabilitation guidelines for shoulder instability—overview

The rehabilitation guidelines for shoulder instability depend greatly upon the kind of instability the patient exhibits, and the degree or severity of the symptoms. In general, the three kinds of instabilities described need a different rehabilitation approach, described in Table 24.4. The guidelines are aimed to increase local glenohumeral stability as well as to correct aberrant muscle patterning around the shoulder.

The main differences in therapeutic approach are based on the actual best knowledge and best practice regarding muscle patterning and local neuromuscular control in the unstable shoulder, the benefits and the pitfalls of open versus closed chain exercises, and the value of kinetic chain exercises.

### Open versus closed chain shoulder exercises

In closed chain exercises, the final link of the chain, in the case of the upper limb, the hand, is supported on a surface, which is fixed or moveable. As a result of the compressive forces in the joint, the patient feels safer to preserve the local glenohumeral stability. In addition, closed chain exercises stimulate normal proprioceptive pathways, enhance local co-contraction in the stabilising muscles, and minimise translations in the midway of motion. However, in view of the functional demands of the upper extremity in daily life, in particular in overhead athletes, requiring functional stability during open chain overhead throwing or smashing, the limitation of the closed chain exercises is that they do not prepare the athlete for full return to sport, and do not load the tissues around the shoulder in the most functional way, thus jeopardising tissue-specific adaptation to training.

In open chain exercises, the hand is free to move in space (with or without an additional resistance) and shear and translational forces are caused in the glenohumeral joint, increasing the challenge for shoulder stability. It is imperative these exercises are implemented in the rehabilitation program of anterior instability (traumatic or acquired); however, only in later stages (for instance after a dislocation), or on the condition that the athlete feels safe performing the exercise (for instance in acquired instability). However, in multidirectional instability, often the only way to initiate and pursue an effective rehabilitation program is to implement mostly closed chain exercises.

### Local neuromuscular control of stabilising muscles

Several studies confirm the lack of adequate muscle activity of the local stabilisers. In anterior instability mainly the rotator cuff shows deficiencies in strength, accurate muscle activity and timing of muscle activation. Therefore the first stage in anterior shoulder instability rehabilitation should be to encourage local conscious muscle control in the rotator cuff by teaching the patient how to consciously contract the rotator cuff (with palpation, EMG feedback, local proprioceptive feedback) or by stimulating cuff activity by putting the shoulder in a controlled manner in positions challenging the cuff (Fig. 24.30). However, in AMBRI patients, it is mainly the deltoid, in particular the posterior part, that has recruitment problems. For that reason, deltoid activation should be the main focus in the first stage of the rehabilitation of AMBRI. In addition, since closed chain exercises increase glenohumeral compression, these exercises should be performed in a closed chain (Fig. 24.31). If needed, local taping techniques might facilitate deltoid activation and promote superior translation of the humeral head (Fig. 24.32).

**Table 24.4 Rehabilitation guidelines for shoulder instability**

### Progression in closed chain exercise program—practice

During closed chain exercises, progression is determined by the load (from low or no body weight, over moderate body weight, to full body weight) and whether the exercises are static or dynamic. In static exercises, the shoulder is loaded, but no shoulder movement is required, whereas in dynamic exercises the shoulder moves (from low to high elevation grades). Theoretic progression is shown in Table 24.5 and illustrated in Figure 24.33. It is the therapist's responsibility to find the appropriate progression, based on the specific capacity and instability problems of the patient.

**Figure 24.31** Deltoid co-activation in a semi-closed chain

**Figure 24.32** Local taping technique for a patient with AMBRI

**Table 24.5** Progression in closed chain exercises

(a)

(b)

(c)

**Figure 24.33** Progressively more difficult closed chain exercises (a) Low load (b) Moderate load (c) High load**Progression in open chain program—practice**

The open kinetic chain program should commence with basic rotator cuff training (see above); however, it should proceed into more functional exercises, challenging rotator cuff load, functional positions and include eccentric and plyometric exercises. We refer to the thrower's program below for the practical aspect of this progression.

**BICEPS-RELATED PATHOLOGY AND SLAP LESIONS**

Biceps-related pathologies are a common cause of shoulder pain and disability, and can result in limited work or athletic performance.<sup>69</sup>

**Pathomechanics of biceps-related shoulder pain**

Pathologic disorders can be divided into three categories: (1) inflammatory/degenerative conditions and partial tears

of the long head of the biceps, (2) instability of the biceps tendon into the bicipital groove, and (3) superior labrum anterior to posterior (SLAP) lesions.<sup>70</sup> The three categories of disorders may all present with shoulder pain, and although they differ widely in patient populations and pathogenesis, there is significant overlap among the pathologies.

The labrum is the primary attachment site for the shoulder capsule and glenohumeral ligaments. The superior aspect of the glenoid labrum also serves as the attachment site for the tendon of the long head of the biceps muscle (Fig. 24.34). Injuries to the glenoid labrum are divided into SLAP or non-SLAP lesions, and further into stable or unstable lesions. SLAP lesions are injuries to the labrum that extend from anterior to the biceps tendon to posterior to the tendon. They are divided into four types based on the severity and the instability of the biceps tendon (Fig. 24.35).

SLAP lesions are either stable or unstable depending on whether the majority of the superior labrum and the biceps

**Figure 24.34** The glenoid labrum contributes to proprioception and stability. Dr Ben Kibler compares the stability role with that of a washer (top panel). Like a washer, the deformable labrum (bottom panel), expands the depth and increases the size of the glenoid to increase stability of the interface. The labrum helps to spread load over the glenohumeral joint

tendon are firmly attached to the glenoid margin. Non-SLAP lesions include degenerative, flap and vertical labral tears, as well as unstable lesions such as Bankart lesions.

In general, repetitive overhead activity has been hypothesised as a common mechanism for producing biceps-related shoulder pathology.<sup>69, 70</sup> Although the pathomechanics are debated, the torsional compressive force on the base of the biceps during the cocking position, as well as the high eccentric activity of the biceps muscle during the follow-through phase of throwing and the impingement of the biceps tendon underneath the acromial arch during overhead activities are believed to possibly cause irritation, dysfunction and failure of the superior labral and biceps tendon complex.<sup>69</sup>

### Clinical features

The diagnosis of a glenoid labral tear relies on eliciting a history of an appropriate mechanism of injury, clinical

**Figure 24.35** Four types of SLAP lesions have been described. In type 1, the attachment of the labrum to the glenoid is intact but there is evidence of fraying and degeneration. Type 2 lesions involve detachment of the superior labrum and tendon of the long head of biceps from the glenoid rim. In type 3 injuries, the meniscoid superior labrum is torn away and displaced into the joint but the tendon and its labral rim attachment are intact. In type 4 lesions, the tear of the superior labrum extends into the tendon, part of which is displaced into the joint along with the superior labrum

assessment and appropriate investigation. The most common mechanisms of injury to the superior glenoid labrum are excessive traction on the labrum through the long head of biceps (e.g. carrying or dropping and catching a heavy object). Throwing injuries occur due to a combination of peel-back traction of the biceps on the labrum in shoulder cocking, abnormal posterosuperior humeral head translation in cocking due to glenohumeral internal rotation deficit, and excessive scapular protraction. Patients complain of pain localised to the posterior or posterosuperior joint line, especially in abduction. Pain in the shoulder is exacerbated by overhead and behind-the-back arm motions. Popping, catching or grinding may also be present.

On examination, there may be tenderness over the anterior aspect of the shoulder and pain on resisted biceps contraction. No current SLAP lesion test is able to guarantee sufficient diagnostic value when used alone, in general an interpretation of 'best-test combinations' is advised in the diagnosis of SLAP lesions (Table 24.2).

Plain radiography is usually unremarkable. MR arthrography, a further refinement of MRI by injection of contrast agent into the shoulder, yields greater detail of intra-articular shoulder structures than does conventional MRI (Fig. 24.36). MR arthrography is particularly useful for the detection and assessment of not only glenoid labral tears, but also small loose bodies, or cartilage flaps. Interpretation of MR arthrograms of the shoulder is best performed by a radiologist with particular expertise in the area, as interpretation is complicated by a wide range of normal anatomical variants. The static MRI is well complemented by dynamic tests which provide a context for interpreting the clinical importance of the MRI.

### Treatment of SLAP lesions

In recent clinical guidelines, it is suggested that the vast majority of overhead athletes with shoulder pain should be initially treated with non-operative methods.<sup>70</sup> Only certain diagnoses, such as traumatic injuries with documented structural damage such as unstable labral

tears, dislocations or rotator cuff tears, may warrant earlier and more aggressive operative intervention.<sup>70</sup>

Only a few studies examined the results of conservative treatment in SLAP lesions. Edwards et al.<sup>71</sup> showed that 50% of the conservatively treated athletes returned to play, with similar return to sports as those who had surgery. Fedoriw et al.<sup>72</sup> concluded from their case series that non-surgical treatment correcting scapular dyskinesia and GIRD had a reasonable success rate in professional baseball players with documented SLAP lesions.

Arthroscopic repair of SLAP lesions results in good to excellent results in patients who are not involved in sports. However, results of surgery in overhead athletes are much less predictable, with a return to previous level of play ranging between 20% and 94%.<sup>72, 73</sup> In particular, the rate of return to previous performance levels seems to be rather low among specialist throwing athletes such as baseball pitchers.

Rehabilitation of biceps-related shoulder pain and SLAP lesions (conservative and postoperative) should follow the general guidelines containing a phased progression of rotator cuff exercises, scapular exercises and stretching. However, tension on the long head of the biceps should be implemented carefully and increased gradually, with early protection of the site of the injury. In addition, in post-operative rehabilitation programs after SLAP repair, biceps activity needs to be controlled during the first 12 weeks following surgery, with no resisted biceps activity during the first 8 weeks to protect the healing of the biceps anchor, and no aggressive strengthening of the biceps for 12 weeks following surgery.<sup>74</sup>

A progressive program consisting of selected rotator cuff and scapular exercises with low to moderate load on the biceps (based on EMG analysis) was proposed, giving the clinician the opportunity to select the appropriate exercises based on the goal and the load on the biceps.<sup>75</sup> In this continuum of exercises with an increasing level of EMG activity in the biceps, exercises targeting the trapezius resulted in less load on the biceps compared with exercises for the serratus anterior. In addition, exercises with an internal rotation component showed low activity in the biceps, and exercises meant to target the biceps—such as the uppercut exercise (Fig. 24.37a) or resisted forward flexion in supination (Fig. 24.37b)—showed the highest levels of activity in the biceps.

In the advanced stages of rehabilitation, higher load on the biceps is needed to increase its strength in order to prepare the athlete to return to sport, by performing eccentric exercises in throwers or pull-up exercises in gymnasts or pole jumpers.

## PATHOLOGICAL GLENOHUMERAL INTERNAL ROTATION DEFICIT

### Pathomechanics of GIRD

Posterior shoulder stiffness is the most common adaptation seen at the dominant side of overhead athletes of multiple sports disciplines.<sup>76</sup> This manifests clinically as decreased glenohumeral cross-body adduction and internal rotation mobility and is believed to be the result of both capsular tightness and muscular contracture. It is hypothesised that the cumulative loads onto the posterior shoulder during the deceleration phase of the throwing motion cause microtrauma and scarring of these soft tissues.

Posterior shoulder stiffness therefore has been suggested to be a causative or perpetuating factor in shoulder impingement and labral pathology.<sup>3,54,77</sup> Abnormal humeral head translations, caused by selective tightening of the posterior-inferior capsule may decrease the width of the subacromial space, thus causing subacromial impingement. Other studies suggest a posterior and superior translation of the humeral head during cocking with a tight posterior capsule, possibly leading to an encroachment of the rotator cuff tendons against the posterosuperior rim of the glenoid.<sup>78</sup>

In addition, posterior shoulder tightness seems to affect kinematics of the scapula and the humeral head and is associated with a decreased acromiohumeral distance.<sup>79</sup> As a result, posterior capsule shortness possibly increases the risk for internal as well as subacromial impingement in the overhead athlete.<sup>19, 23, 26</sup> A study of elite handball players found that for every 5° increase in total rotational motion, the odds of shoulder injury were reduced by 23%.<sup>3</sup>

### Treatment of GIRD

Given the evidenced impact of posterior shoulder tightness on shoulder kinematics, increasing posterior shoulder flexibility is advisory when mobility deficits exceed the limits associated with increased injury risk. In baseball, reduced internal rotation ROM of 18–25° and reduced total range of motion of 5° are considered to increase the risk for shoulder injury.<sup>80, 81</sup> Both the cross-body stretch (Fig. 24.38a) and the sleeper stretch (Fig. 24.38b) can be recommended to decrease posterior shoulder tightness.<sup>81, 82</sup> It was shown that a 6-week daily sleeper stretch program (three reps of 30 seconds) is able to significantly increase the acromiohumeral distance in the dominant shoulder of healthy overhead athletes with GIRD.<sup>79</sup> Additional joint mobilisation performed by a physiotherapist has a small but non-significant advantage over a home stretching program alone.<sup>83</sup> No difference in mobility gain was seen after angular (sleeper stretch and horizontal adduction stretch) and non-angular (Fig. 24.39) joint mobilisation by a physiotherapist.<sup>84</sup> Muscle energy techniques (hold-relax) during the sleeper stretch and

(a)

(b)

**Figure 24.38** (a) The cross-body stretch (b) The sleeper stretch

the horizontal adduction stretch have proven useful to immediately increase internal rotation range of motion.<sup>85</sup> Two studies<sup>84, 86</sup> showed symptom relief after a stretching program in a population of overhead athletes with impingement-related shoulder pain.

(a)

(b)

**Figure 24.39** (a) Dorsal and (b) Caudal glides

GIRD in the overhead athlete is often associated with acquired instability (AIOS), both leading to imbalances in shoulder kinematics and hyperangulation during cocking. Therefore, in most athletes stretching exercises of the posterior shoulder should be combined with rotator cuff strengthening.

A valuable treatment tool in the mobilisation of the shoulder joint, however, until now, not fully explored or investigated in scientific literature, is mobilisation with movement (MWM). In these techniques, active or passive angular shoulder movements are performed, accompanied by a translational mobilisation of the glenohumeral joint. In view of the arthrokinematic characteristics of impingement, with abnormal anterior and superior translation of the humeral head, in particular dorsal (Fig. 24.40a) and inferior (Fig. 24.40b) glides during active movements are of interest in the treatment of these patients.

(a)

(b)

**Figure 24.40** (a) Mobilisation with movement—dorsal glides during forward flexion (b) Inferior glides during scapular elevation

Additional taping to correct humeral head position, as described by McConnell,<sup>87</sup> might be useful (Fig. 24.41a). However, this should result in immediate symptom relief. In addition, in case of hypertonicity in the infraspinatus, taping with elastic tape (Fig. 24.41b) and dry needling of the infraspinatus (Fig. 24.41c) may relax muscle and

help restore ROM. Home exercises may include using a foam roller (Fig. 24.41d). After resolution of symptoms, the athlete should continue the home stretching program, together with external rotator strength training.

### SCAPULAR DYSKINESIS

Most of the studies investigating scapular dyskinesis in relation to shoulder pain have been performed in patients with impingement symptoms and rotator cuff pathology. In general, the identified deviations can be summarised as a lack of scapular upward rotation, posterior tilting and external rotation, increased clavicular elevation and retraction, or characterised by scapular asymmetry in rest or during movement (abnormal scapulohumeral rhythm).

Several authors have demonstrated altered muscle activity patterns in the scapular muscles in patients with shoulder impingement. In particular, researchers consistently demonstrated decreased strength in the serratus anterior, hyperactivity and early activation of

(a)

(b)

**Figure 24.41** (a) Shoulder taping to correct humeral head position (b) Elastic tape on the infraspinatus

(c)

(d)

**Figure 24.41 (cont.)** (c) Dry needling of the infraspinatus  
(d) Foam roll exercise for the latissimus dorsi

the upper trapezius (resulting in a shrug—excessive elevation of the shoulder girdle during arm elevation), and decreased activity and late activation of the middle and lower trapezius muscle part. Although some of these studies were performed on non-athletic populations, many of the possible causes for scapular dyskinesis have been established in overhead athletes, and have been suggested to be a contributing and perpetuating factor in the development of impingement symptoms in athletes performing overhead sports.

With respect to soft tissue inflexibility, tightness of the pectoralis minor and posterior glenohumeral capsular stiffness have been established in relation to abnormal scapular position. Increased scapular internal rotation, as

well as increased anterior tilting, has been demonstrated in subjects with a short pectoralis minor or posterior shoulder stiffness. These alterations in scapular position are similar to the scapular deviations established in patients with impingement symptoms, and possibly put the shoulder at more risk for developing shoulder pain.

#### PRACTICE PEARL

**There is no consensus about the cause–consequence relationship between scapular dyskinesis and shoulder pain.**

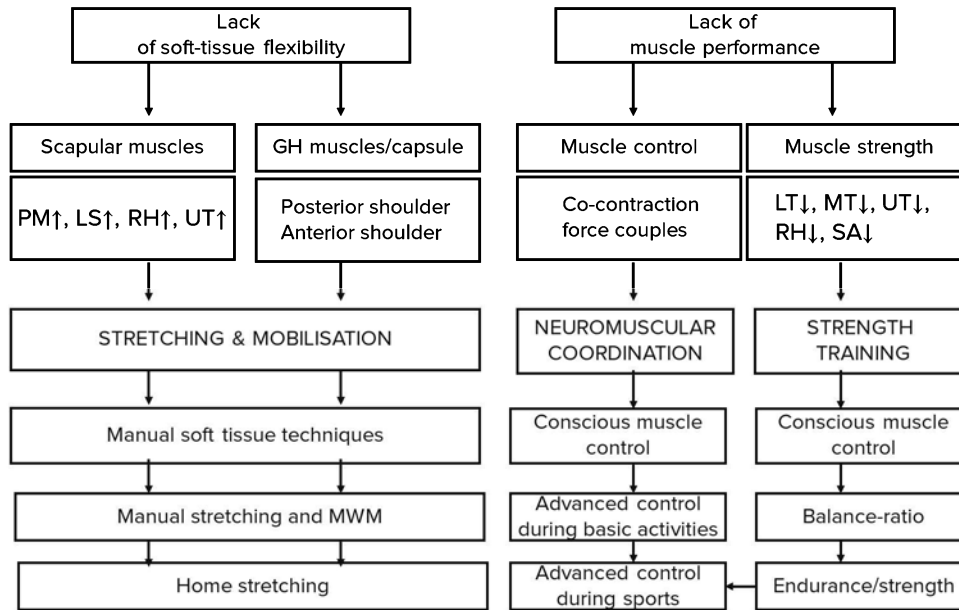

At least six biomechanical mechanisms can potentially alter scapular kinematics. These include pain, soft tissue tightness, muscle activation or strength imbalances, muscle fatigue and thoracic posture. It is unclear whether the alterations found in scapular kinematics are compensatory or contributory to shoulder impingement symptoms and rotator cuff pathology. Regardless of whether the scapular dyskinesis is the cause or the result of painful shoulder conditions, the clinician should focus on scapular evaluation and rehabilitation prior to the treatment of the shoulder. Scapular dyskinesis tends to change the relationship between the glenoid and humerus, to decrease the width of the subacromial space, to jeopardise the fulcrum of the humeral head into the glenoid fossa, and to alter the length–tension relationship of the rotator cuff muscles, hence possibly leading to glenohumeral instability. Moreover, scapular dyskinesis may interrupt the kinetic chain, in particular during overhead throwing and athletic activities.

During overhead movements, the scapula plays a very important role as a link between the trunk and the arm, transferring and increasing the energy and power from the lower extremities and the trunk into the rapidly moving arm. To fulfil this task, the scapula has to be in the correct position and all scapular muscles should be activated at the right time and sufficiently to allow the ground reaction forces to transfer into the shoulder, and finally into the most distal link of the chain, the hand.

### Rehabilitation of scapular dyskinesis—a scapular rehabilitation algorithm

The algorithm presented in Figure 24.42 guides the progression of exercises for rehabilitation of scapular dyskinesis.<sup>88</sup> The upper part of the algorithm summarises the possible causes of scapular dyskinesis, divided in flexibility and muscle performance deficits. The lower part of the algorithm offers guidelines for progressive rehabilitation. Since scapular dyskinesis nearly always is caused by both kind of deficits, the rehabilitation program

## Dr Ann Cools' Scapular Rehabilitation Algorithm

**Figure 24.42** Scapular rehabilitation algorithm

COOLS ET AL.<sup>88</sup> REPRODUCED WITH PERMISSION FROM *BRITISH JOURNAL OF SPORTS MEDICINE*

is multifactorial, including stretching as well as muscle recruitment and strengthening exercises.

### Rehabilitation of flexibility deficits

Several stretching techniques have been described to increase pectoralis minor length. Superior effects of the 'unilateral corner stretch' (performing passive horizontal abduction with the shoulder in 90° of abduction and external rotation) over 'sitting manual stretching' (in which the therapist performs scapular retraction with the shoulder in a neutral position) and 'supine manual stretch' (similar to the unilateral corner stretch, but performed by the therapist with the patient in a supine position) were established in a study on healthy subjects.<sup>89</sup> However, from a clinical perspective, these stretches (with the exception of the 'sitting manual stretching') put the athlete's shoulder into a position, possibly causing pain in the case of subacromial or internal impingement.

Therefore in clinical practice, the pectoralis minor might be stretched by performing passive retraction and posterior tilting of the scapula with the shoulder in a neutral or small elevation position and slight external rotation. In particular, direct pressure on the coracoid process provides an intense stretching effect on the

pectoralis minor (Fig. 24.43a). In healthy athletes, the corner stretch might be advised, taking care not to stretch the anterior shoulder capsule too much. An alternative self-stretch exercise, resulting in scapular retraction and posterior tilt is given in Figure 24.43b.

With respect to stretching techniques of the posterior capsule, we refer to the previous section.

### Rehabilitation of muscle performance deficits

In view of the new insights and research findings on the role of the scapula in shoulder pathology, current exercise protocols emphasise scapular muscle training as an essential component of shoulder rehabilitation. In the early stage of scapular training, conscious muscle control of the scapular muscles may be necessary to improve proprioception and to normalise scapular resting position. To selectively activate the scapular stabilisers, the 'scapular orientation exercise' has been described.<sup>90</sup> Prior to high-intensity strength training, the clinician should focus on facilitating correct timing and control of muscle recruitment. Strength training in the presence of faulty scapular control probably might reinforce poor kinematics and fail to reduce pain or improve function.

(a)

(b)

**Figure 24.43** (a) Direct manual stretching of the pectoralis minor—therapist performs a posterior tilt of the scapula with direct pressure on the coracoid process (b) Home stretching for the pectoralis minor

Depending on the results of the clinical examination, the therapist may decide in the second stage of scapular muscle training to focus more on muscle control (appropriate co-activation of the scapular force couples) or muscle strength (in case of isolated strength deficit in one or more scapular muscles).

Following the scapular orientation exercises, scapular co-contraction may be trained in basic positions, movements and exercises, activating the key scapular-stabilising muscles without putting high demands on the shoulder joint. In this stage of scapular rehabilitation, very often closed chain exercises are used. They are believed to improve dynamic glenohumeral stability through stimulation of the intra- and periarticular proprioceptors, and enhance co-contraction of the rotator cuff, thus being beneficial in case of shoulder instability. However, open chain functional exercises are also imperative in this stage. Exercises with an external rotation component tend to improve proper scapular muscle recruitment (Fig. 24.44).

For patients with a strength deficit and muscle imbalance in the scapular muscles, selective activation of the weaker muscle parts with minimal activity of the hyperactive muscles is an important component in the second stage of scapular muscle rehabilitation. Because of relative inactivity in lower trapezius (LT) and serratus anterior (SA), often combined with excessive use of upper trapezius (UT), exercises with a low UT/LT, UT/MT and UT/SA ratio are particularly important (Figs 24.45, 24.46).<sup>91</sup> Several studies have examined the effectiveness of a scapula-based rehabilitation program.<sup>60, 92, 93</sup> Although there are those who advocate for the primacy of treating scapular mechanics, there is no evidence to suggest this has clinical benefits over a comprehensive shoulder treatment program as outlined in this chapter.

In the third stage of scapular rehabilitation, in which the treatment goal is to exercise advanced scapular muscle control and strength during sport-specific movements,

(a)

(b)

**Figure 24.44** Examples of exercises with glenohumeral external rotation component (a) During elevation, (b) Combined with core stability and hip abductor training

special attention is given to integration of the kinetic chain into the exercise program, implementation of sport-specific demands by performing plyometric exercises and eccentric exercises. Scapular control should be automatic and integrated into all sport-specific exercises. Throwing athletes should perform exercises in which the external rotators are eccentrically loaded (see thrower's program in Chapter 8).

On the other hand, swimmers should not focus on plyometrics, but rather train in sport-specific positions such as lying prone or supine in situations demanding a lot of core stability and demanding a large number of repetitions. Gymnasts and athletes performing climbing sports should perform high-level closed chain exercises, such as side- and prone-bridging, and sling exercises might

(a)

(b)

**Figure 24.45** Four exercises to improve UT/MT and UT/LT ratio (a) Side-lying external rotation, (b) Side-lying forward flexion

(b)

**Figure 24.46** Two exercises to improve UT/SA ratio  
(a) Elbow push-up, (b) Serratus push-in closed chain

be added to their program. These exercises have been shown to highly activate the large glenohumeral muscles compared to exercises on a stable surface.<sup>92</sup>

Throughout the rehabilitation program, and given the evidence that scapular dyskinesis is often related to thoracic kyphosis or flexed thoracic postures, thoracic posture should also be addressed in the rehabilitation of patients with shoulder pain and related scapular dyskinesis. This includes correction of posture into extension, and also mobilisation exercises into extension (Fig. 24.47a) and rotation (Fig. 24.47b), and core-stability training and muscle training of the trunk muscles. The use of therapeutic tape (Fig. 24.48) can be helpful in this stage of the rehabilitation, since it has been shown that taping the thoracic spine and the scapula into extension, posterior tilting and retraction improves trunk posture and shoulder range of motion.

## FRACTURES OF THE CLAVICLE

Clavicle fractures are usually caused by either a fall onto the point of the shoulder, for example in horse riding or cycling, or by direct contact with opponents in sports such as football.

The clavicle usually fractures in its middle third with the outer fragment displacing inferiorly and the medial fragment superiorly. It is extremely painful. On examination, there is localised tenderness and swelling and the bony deformity may be palpated. With clavicular shortening or angulation, the scapula will assume a protracted position.

Radiography reveals the fracture. There has been a change in perspective about imaging clavicle fractures as it is sometimes difficult to assess true clavicle position using radiographs. Thus, overlap and shortening need to be carefully monitored for the first 3–4 weeks of non-operative management because significant deformity can occur.

The principles of treatment are to provide pain relief. Clavicle fractures almost always heal in 4–6 weeks. However, often the ends overlap and the clavicle is foreshortened. A foreshortened clavicle is associated with significant functional deficits. A figure-of-eight bandage is designed to prevent foreshortening and has significant advantages over a sling or collar and cuff. During this time the patient should perform self-assisted shoulder flexion to a maximum of 90° to prevent stiffness of the glenohumeral joint.

These fractures<sup>94</sup> are best managed conservatively and usually heal well. Early surgical fixation is indicated if there is compromise of the skin by bony fragments or foreshortening of greater than 1–2 cm. Occasionally, non-union of a fracture of the clavicle may occur with a fibrous pseudoarthrosis forming. This is treated surgically by open reduction and internal fixation with a dynamic

(a)

(b-i)

(b-ii)

**Figure 24.47** (a) and (b-i, ii) Exercises promoting trunk rotation

**Figure 24.48** Taping technique to promote scapular posterior tilt and retraction

compression plate and bone chips to ensure the length of the clavicle is maintained.<sup>94</sup>

Distal clavicle fractures comprise 12-15% of all clavicle fractures. Many of these fractures involve disruption of the AC joint and/or coracoclavicular ligaments. These fractures are more prone to non-union and delayed union. Classification for these fractures is shown in Table 24.6

Generally, fractures medial to the ligament attachments have greater displacement of fracture fragments and this is associated with increased risk of delayed or non-union if treated non-operatively.<sup>94</sup>

Minimally displaced fractures distal to the coracoclavicular ligament attachments (type I) may be treated with a sling for comfort and early range of motion and isometric strengthening exercises. If displacement is present, then rehabilitation should progress slowly, with active range of motion exercises only introduced when pain resolves and healing has begun radiographically.

Treatment of the more medial (type II) fractures is more controversial.<sup>94</sup> As there is a high rate of non-union, surgical treatment is often recommended. Distal intra-articular fractures (type III), if stable, should be treated non-surgically as they tend to heal with minimal dysfunction.

**Table 24.6 The American Shoulder and Elbow Society classification of distal clavicle fractures**

Type	Pathology
I	Fracture distal to coracoclavicular ligaments with little displacement
IIa	Fracture medial to coracoclavicular ligaments
IIb	Fracture between coracoclavicular ligaments
III	Intra-articular fracture without ligament disruption

### Special note—immature skeleton

The treatment of distal clavicle fractures in the immature adult is different from that in the adult. Even fractures that present with significant displacement are stable and will eventually heal in an anatomical position. This is due to the fact that, although the fracture is medial to the coracoclavicular ligament attachment, the periosteal envelope remains attached to the coracoclavicular ligaments. The haematoma and subsequent new bone formation stimulated by the periosteum results in remodelling and complete union.

### ACROMIOCLAVICULAR JOINT INJURIES

The AC joint is another common site of injury in athletes who fall onto the point of the shoulder. Stability of the AC joint is provided by a number of structures. In order of increasing importance, these are the joint capsule, the AC ligaments and the coracoclavicular ligament comprising the conoid and trapezoid ligaments (Fig. 24.49).

### Acute acromioclavicular joint injuries

A modified classification system by Rockwood describes six different types of AC joint injuries (Fig. 24.50). Type I injury corresponds to sprain of the capsule of the joint and is characterised clinically by localised tenderness and pain on movement, especially horizontal flexion. Type II injuries correspond to a complete tear of the AC ligaments with sprain of the coracoclavicular ligaments. On examination, as well as localised tenderness, there is

**Figure 24.49** The acromioclavicular joint

a small palpable step deformity. Type III and V injuries consist of complete tears of the coracoclavicular ligaments, the conoid and trapezoid. In type III and V injuries, a marked step deformity is present (Fig. 24.51).

Type V injuries can be distinguished from type III injuries radiographically by the amount of displacement. A type V injury has between three and five times greater coracoclavicular space than normal, whereas a type III injury has 25–100% greater coracoclavicular distance than the uninjured side. Type V injury typically involves much greater soft tissue injury and includes damage to the muscle fascia and occasionally the skin. Type IV injuries are characterised by posterior displacement of the clavicle and type VI injuries have an inferiorly displaced clavicle into either a subacromial or subcoracoid position. Type IV, V and VI injuries also have complete rupture of all the ligament complexes and are much rarer injuries than types I, II and III.

Management is based on the general principles of management of ligamentous injuries. Initially, ice is applied to minimise the degree of damage and the injured part is immobilised in a sling for pain relief. This may be for 2–3 days in the case of type I injuries or up to 6 weeks in severe type II or type III injuries. Isometric strengthening exercises should be commenced once pain permits. Return to sport is possible when there is no further localised tenderness and full range of pain-free movement has been regained. The athlete may feel more comfortable on return to sport by taping the AC joint (Fig. 24.52).

The major functional problems in a high grade (III–IV) injury result from loss of strut function to stabilise the scapula, glenohumeral joint and arm. Most type III AC separations showed an alteration of scapular mechanics.<sup>95, 96</sup> Thus, much more consideration should be given to reconstruction in those patients exhibiting altered scapular mechanics.

#### PRACTICE PEARL

The treatment of type III injuries is controversial. Historically, most of these injuries have been treated surgically. However, most clinicians now consider conservative management to be equally effective.

Surgery is clearly indicated for type IV, V and VI injuries and those type III injuries that fail to respond adequately to conservative management.<sup>97</sup>

### Chronic acromioclavicular joint pain

Chronic AC joint pain may occur as a result of repeated minor injuries to the AC joint or following a type II or

**Figure 24.50** Classification of acromioclavicular joint injuries

type III injury. This can damage the fibrocartilaginous meniscus situated within the AC joint.

Another cause of chronic AC joint pain, osteolysis of the outer end of the clavicle, is seen occasionally, especially in weightlifters performing large numbers of

bench presses. X-ray in this condition shows a 'moth-eaten' appearance of the distal end of the clavicle (Fig. 24.53). Horizontal flexion is painful. Rotator cuff impingement may occur due to the abnormal scapular position that results from loss of the clavicle strut. Treatment consists

**Figure 24.51** Marked step deformity at the acromioclavicular joint in type III injury

**Figure 24.52** Taping after acromioclavicular joint injury

of physiotherapy, including pain relieving modalities and mobilisation, combined with muscle strengthening.

Osteoarthritis of the AC joint may occur as a result of recurrent injuries. This is characterised by a typical radiographic appearance with sclerosis and osteophyte formation (Fig. 24.54).

AC joint pain is usually localised over the joint. Symptoms may be reproduced by AC joint compression using O'Brien's test (with both test positions giving symptoms) or cross-arm adduction. An injection of local anaesthetic and corticosteroid into the AC joint can confirm the diagnosis and provide effective symptom relief.

**Figure 24.53** Osteolysis of the outer end of the clavicle, showing a 'moth-eaten' appearance

**Figure 24.54** Post-traumatic osteoarthritis of the acromioclavicular joint showing a spur and bony irregularity on the acromion

Persistent AC joint pain may require arthroscopic distal clavicle excision.<sup>98</sup> The surgeon must take care not to disrupt the ligamentous attachments to the distal clavicle. More than 5 mm resection alters the joint loads and removes the bony attachments.<sup>98</sup>

## LESS COMMON CAUSES OF SHOULDER PAIN

As shown in Table 24.1, there are a number of less common causes of shoulder pain. These include other muscle tears, adhesive capsulitis, neurovascular injuries, other fractures and the 'snapping scapula'.

### Other muscle tears around the shoulder

Other muscle tears around the shoulder include the long head of biceps, pectoralis major and subscapularis.

### Rupture of the long head of the biceps

Rupture of the loaded long head of the biceps muscle may occur in the older athlete and is usually accompanied by immediate sharp pain and a tearing sensation.

The deformity is obvious—the muscle is detached from its proximal attachment and bunches up in the distal arm. The deformity is accentuated by contraction of the biceps. Often there is little ongoing pain. Surprisingly, biceps strength is almost fully maintained. Imaging is via MRI or ultrasound. Those who do not rely on their upper arm in sport are generally satisfied with reassurance and require no definitive treatment. In those who perform power sports, surgery may be indicated.

### Pectoralis major tears

Pectoralis major tears may be partial ruptures (grades I-II) or complete (grade III).<sup>99</sup> Complete rupture occurs at the site of its insertion to the humerus. This is usually seen in weight training, especially when performing a bench press. The typical history is of sudden onset of pain on the medial aspect of the upper arm. Examination reveals localised tenderness and swelling. Resisted contraction of the pectoralis major is weak and may be painful.

A partial tear is treated conservatively with ice and a strengthening program over a period of 4–6 weeks. A complete tear of the pectoralis major should be treated by surgical repair.<sup>100</sup> It is usually possible to differentiate between a partial and a complete tear clinically. Ultrasound or MRI examination may assist in this differentiation.

### Subscapularis muscle tears

Tears of the subscapularis muscle can occur with sudden forceful external rotation or extension applied to the abducted arm. There is usually no associated instability. The main complaint is pain, and range of motion may be maintained or even increased. On examination, the patient will have increased passive external rotation with the shoulder adducted at the side, weakness of internal rotation and a positive lift-off sign (Fig. 21.2h). MRI and ultrasound will confirm the diagnosis. Treatment should be immediate surgical repair.

## Adhesive capsulitis—'frozen shoulder'

Glenohumeral joint stiffness is not uncommon after significant trauma, for instance, a fracture or surgery. It may also follow an injury to the neural structures in the neck or it may occur spontaneously.

The age group in which spontaneous shoulder stiffness, commonly referred to as adhesive capsulitis, occurs is between 40 and 60 years of age. Idiopathic adhesive capsulitis more commonly affects the non-dominant shoulder and is more prevalent in women than men (1.3:1). Adhesive capsulitis is more common in patients with diabetes and there is an association with thyroid disorders and drugs that involve inhibition of matrix degradation.

The diagnosis of shoulder stiffness is relatively easy to make by evaluating passive external rotation with the elbow at the side. Care should be taken to stabilise the scapula when examining for shoulder stiffness as significant range of motion can occur at the scapulothoracic articulation. Surgical or post-traumatic scapular stiffness usually resolves within 12 months and further surgical intervention is rarely necessary. Physiotherapy may be valuable.

Idiopathic adhesive capsulitis is a self-limiting condition that resolves, on average, over 1.5 years.<sup>101</sup> There is no evidence that intensive physiotherapy, injections<sup>102</sup> or drugs change the outcome of idiopathic adhesive capsulitis. However, pain-relieving techniques and modalities, as well as patient education during the painful phase are useful and appreciated by the patient. During the resolving phase, graded mobilisation and a home stretching and strengthening program assist the patient in the natural recovery process.

Arthroscopic capsular release to divide the thickened shoulder capsule and an early aggressive supervised range of motion program are not effective at restoring motion and relieving pain in patients with idiopathic adhesive capsulitis.<sup>103, 104</sup>

## Neurovascular injuries

### Suprascapular nerve entrapment

The most common entrapment is of the suprascapular nerve.<sup>105</sup> The suprascapular nerve is derived from the upper trunk of the brachial plexus formed by the roots of the C5 and C6 nerves. The course of the nerve is shown in Figure 24.55. The nerve passes downwards beneath the trapezius to the superior border of the scapula. Here it passes through the suprascapular notch. The roof of this notch is formed by the transverse scapular ligament. After passing through the notch, the nerve supplies the supraspinatus muscle as well as articular branches to both the glenohumeral and AC joints. The nerve then turns around the lateral edge of the base of the spine of

**Figure 24.55** Course of the suprascapular nerve

the scapula (the spinoglenoid notch) to innervate the infraspinatus muscle. Entrapment of the suprascapular nerve may occur at either the suprascapular notch or the spinoglenoid notch.

The patient usually complains of pain that is deep and poorly localised. It is often felt posteriorly and laterally in the shoulder, or referred to the arm, neck or upper anterior chest wall. The patient may describe shoulder weakness. On examination, there may be wasting of the supraspinatus and/or infraspinatus muscles accompanied by weakness on abduction and external rotation. Tenderness over the suprascapular notch may also be present.

The site of entrapment in cases of combined supraspinatus and infraspinatus weakness is the suprascapular notch. The nerve may be stretched and kinked in this position by extremes of scapular motion associated with the throwing action. It may also occur in tennis players who complain of weakness and lack of control over backhand volleys. Diagnosis is made on the clinical symptoms and confirmed by an abnormal electromyogram. Surgical decompression of the nerve at the site of entrapment is occasionally required.

Isolated infraspinatus weakness and wasting may occur when the suprascapular nerve is trapped at the spinoglenoid notch. This condition has been seen in volleyball players who use the 'float' serve<sup>106, 107</sup> and in weight lifters. It can also arise due to a cyst that results from superior glenoid labral tears compressing the nerve. Treatment should be directed to repairing the labral tear.

The main task of the coach and sports physician is to monitor external rotation strength on a regular basis (for instance using a hand-held dynamometer) in an athletic population known to be at risk for suprascapular nerve pathology such as volleyball players, and to give an external rotator strengthening program in the injury prevention program. In particular, focusing on external rotation strength training in several positions (neutral, abduction, forward flexion) guarantees sufficient training of all external rotators, infraspinatus as well as teres minor.<sup>108</sup>

### Long thoracic nerve injury

The long thoracic nerve is formed from the roots of the C5, C6 and C7 nerves. The nerve passes behind the brachial plexus to perforate the fascia of the proximal serratus anterior, passing medial to the coracoid with branches throughout the length of the serratus anterior. Long thoracic nerve palsy causes paralysis of the serratus anterior, with winging of the scapula. The nerve may be injured by traction on the neck or shoulder or by blunt trauma. Isolated long thoracic nerve palsy may also follow viral illnesses.

Clinical features include pain and limited shoulder elevation. Patients may complain of difficulty in lifting weights or an uncomfortable feeling of pressure from a chair against a winged scapula while sitting. They may also develop secondary impingement due to poor scapular control. The most striking feature on examination is winging of the scapula when pushing against a wall with both hands. Electromyographic studies will confirm the diagnosis. Initial treatment is conservative and most patients will recover fully. During the rehabilitation period, it is extremely important to give the patient exercises in which the winging is minimally present or suppressed. Very often, this is only possible with low load closed chain exercises. Surgical tendon transfer may occasionally be required.

### Axillary nerve injury

Axillary nerve compression or quadrilateral space syndrome is an uncommon condition caused by compression of the posterior humeral circumflex artery and axillary nerve or one of its major branches in the quadrilateral space.<sup>109</sup> The quadrilateral or quadrangular space is located over the posterior scapula in the subdeltoid region and consists of the teres minor superiorly, teres major inferiorly, the long head of triceps medially and the surgical neck of the humerus laterally. The axillary nerve and the posterior humeral circumflex artery pass through the space at a level inferior to the glenohumeral joint capsule.

Quadrilateral space syndrome is seen in throwing athletes and is characterised by poorly localised posterior shoulder pain, paraesthesia over the lateral aspect of the shoulder and arm, and deltoid and teres minor weakness. The condition may occur secondary to abnormal fibrous

**Figure 24.56** Anatomy of the thoracic outlet

bands, although traumatic causes have been described. Diagnosis is by electromyography or subclavian arteriogram, although this is associated with some risk. Treatment is initially conservative. Occasionally, surgical exploration is required.

Axillary nerve injuries can also occur with anterior dislocation of the shoulder and by blunt trauma to the anterior lateral deltoid muscle.<sup>110</sup>

### Thoracic outlet syndrome

The term thoracic outlet syndrome (TOS) refers to a group of conditions that result from compression of the neurovascular structures that course from the neck to the axilla through the thoracic outlet (Fig. 24.56). The brachial plexus and subclavian vessels are especially susceptible to compression because of their proximity to one another in the thoracic outlet. The most common site of compression is the costoclavicular space between the clavicle and the first rib (costoclavicular syndrome).<sup>111</sup> Other sites of compression are the triangle between the anterior scalene muscle, the middle scalene muscle and the upper border of the first rib (anterior scalene syndrome); and the angle between the coracoid process and the pectoralis minor insertion (hyperabduction syndrome or pectoralis minor syndrome).

This condition may occur in overhead athletes. Poor posture with drooping shoulders and scapular protraction can decrease the diameter of the cervicoaxillary canal, causing TOS symptoms.

Congenital anatomical abnormalities including complete cervical rib, incomplete cervical ribs with fibrous bands, fibrous bands from the transverse process of C7, and clavicular abnormalities, can all compress the neurovascular structures. Complete cervical ribs are rare but, if present, are often bilateral. However, only 10% of patients with cervical ribs have TOS symptoms.

Traumatic structural changes that can cause TOS include fractures of the clavicle and/or first rib, pseudoarthrosis of the clavicle, mal-union of clavicle fractures, exuberant callus formation or a crush injury of the upper thorax. TOS symptoms are common in patients with chronic scapular dyskinesis. They have tight pectoralis minor, scalene and upper trapezius muscles, with weak serratus anterior and lower trapezius muscles; this causes excessive anterior tilt and protraction.

### Clinical features

While patients with TOS occasionally present with a pure arterial, venous or neurogenic picture, most often the picture is mixed. The patient with TOS may complain of pain in the neck or shoulder, or numbness or tingling involving either the entire upper limb or the forearm and hand. The patient may state that the arm feels weak or easily fatigued. There may be venous engorgement or coolness of the involved arm.

Physical signs may be absent. A patient with arterial compression may have a positive Adson's test. The patient begins the test with the head laterally rotated to the side of the symptoms and extended. The patient then abducts the involved arm and inspires deeply. A positive test obliterates the radial pulse and reproduces symptoms. The sensitivity of this test can be greatly increased by the use of Doppler flow patterns during the manoeuvre. The most sensitive provocation test is the Roos hyperabduction/external rotation test (Fig 24.13a), in which the patient opens and closes his or her hands for 1–3 minutes with elbows bent and arms abducted to 90° and externally rotated in an attempt to reproduce the symptoms. Evaluation of scapular motion and position can help to rule scapular dyskinesis in or out.

### Treatment

Treatment for any subset of TOS focuses on the specific area compromised. However, certain treatments apply to all forms of TOS. Correction of drooping shoulders, poor posture and poor body mechanics is vital. The patient should be taught proper positioning while sitting, standing and lying down. Physiotherapy should include pectoral and scalene stretching and trigger point treatment, and soft tissue mobilisation of restricted tissues, as well as scapular and scapulothoracic mobilisation. Joint mobilisation of the first rib can restore accessory motion of the sternoclavicular

and AC joints. Therapeutic exercise, education and manual therapy can correct forward head posture. Thoracic extension and brachial plexus neuromobility exercises are added as tolerated.

Surgical consultation and treatment is warranted for patients who have neurogenic TOS that does not respond to aggressive conservative management and for patients who have vascular compromise or thrombus formation.<sup>112</sup> Arterial compression caused by a complete cervical rib is usually treated by first rib resection.

### **Axillary vein thrombosis ('effort' thrombosis)**

Axillary vein thrombosis is also known as 'effort' thrombosis because of its frequent association with repetitive, vigorous activities or with blunt trauma that results in direct or indirect injury to the vein. The axillary vein can be compressed at various sites along its path, most significantly in the costoclavicular space. Compression most often occurs when the patient hyperextends the neck and hyperabducts the arm simultaneously, or when the patient assumes a military brace position with a backward thrust of the shoulders. Compression can also occur between the clavicle and the first rib, the costocoracoid ligament and first rib, or the subclavian muscles and first rib.

Patients complain of dull, aching pain, numbness or tightness, and heaviness of the upper arm and shoulder, along with fatigue after activities involving the extremity. In axillary vein thrombosis, the entire upper extremity will be swollen, the skin may be mottled and cold, and superficial veins may be prominent. The diagnosis is confirmed on venography.

Treatment involves immediate anticoagulant therapy. Most patients make a full recovery and are able to resume sporting activities.<sup>113</sup>

### **Less common fractures around the shoulder**

Stress fractures around the shoulder joint are uncommon. Stress fracture of the coracoid process is associated with the sport of trapshooting. Patients with this stress fracture have localised tenderness over the coracoid process and a focal area of abnormality on MRI or isotopic bone scan. Another specific site of stress fractures is anterolateral rib fractures in rowers, probably due to excessive activation of the serratus anterior (see Chapter 9).

Scapular fractures are usually due to a crushing force, either a fall on the shoulder or direct violence. Examination reveals marked tenderness and swelling. X-rays should be taken to exclude other associated injuries, such as a rib fracture, dislocated shoulder or dislocated sternoclavicular joint. Scapular fractures usually heal well, even if displaced. A broad arm sling is worn for comfort and active movements are commenced as soon as pain permits.

Fracture of the neck of the humerus is caused by a fall on the outstretched hand or direct violence.<sup>114</sup> It is seen in adolescents, young adults and the elderly. Fractures involving more than two fragments displaced by more than 1 cm or associated with shoulder dislocation require surgical assessment. Minimally displaced or angulated fractures may be treated conservatively. Impacted fractures heal rapidly and can be supported in a broad arm sling. Displaced fractures are best treated in a collar and cuff that allows gravity to correct any angulation. For the first 2 weeks the arm should be kept in a sling under a shirt. After 2 weeks, pendular movement exercises of the shoulder joint should be commenced. From 4 weeks, a collar and cuff may be worn outside the clothes and gradually removed in stages over the following 2 weeks.

An unusual fracture is seen among throwing athletes. These athletes sustain a closed external rotation spiral fracture of their humerus immediately below the insertion of the deltoid muscle at the junction of the middle and lower thirds of the humerus or along the radial groove. Many, but not all, patients with this fracture give a history of pain at the site of the fracture so it may be regarded as a rapid-onset stress fracture. The fracture heals well in a cast or functional brace.

### **Snapping scapula**

The scapula is surrounded by a number of scapular bursae to allow smooth movement over the thoracic wall. Snapping scapula syndrome or scapulothoracic bursitis is a condition characterised by periscapular crepitus and pain during arm movements. While some patients are mildly symptomatic, others may complain of severe pain and poor shoulder function even with simple tasks.

Snapping scapula is the result of a lack of congruence between the concave scapula and the convex thoracic wall, which can occur from anatomic predisposition, space-occupying skeletal lesions, fibrotic bursae, poor thoracic posture or scapular muscle control.<sup>115</sup> Often the scapulothoracic bursitis is the result of combined structural (fibrotic bursae, elastofibroma) and functional (tightness of surrounding musculature, for instance pectoralis minor) deficits.

Regardless of the aetiology, current data support initial conservative treatment in patients with symptomatic snapping scapula. Non-operative treatment consists of non-steroidal anti-inflammatory medications, therapeutic injections of steroids and local anaesthetics into the inflamed bursa, activity modification and physiotherapy. Surgical treatment, bursectomy, is indicated after failure of conservative management. However, if anatomical lesions or deformities capable of producing scapular snapping are identified on imaging, primary surgical intervention is the favourable treatment option. Radiographic evaluation of the

snapping scapula is important to rule out osseous deformity, tumours or other bony causes of the patient's pain. Three-dimensional CT and MRI aid in detecting muscle, bony and soft tissue abnormalities.<sup>116</sup>

### SPECIAL CONSIDERATIONS FOR THE OVERHEAD ATHLETE

In any overhead athlete with a shoulder injury, the role of the kinetic chain (Chapter 8) must be considered.

#### Kinetic chain integration

It is important to re-establish the kinetic chain early in the rehabilitation process. While the shoulder is recovering from the injury or surgery, leg and trunk exercises can be prescribed so that when the shoulder is ready for rehabilitation, the base of the kinetic chain is also ready for linked activity. After the shoulder is

ready for rehabilitation, sport-specific activation of the kinetic chain patterns restores the force-dependent motor activation patterns and normal biomechanical positions. This then allows normal link sequencing to generate velocity and force.

The athlete's kinetic chain is highly sport-specific, and varies for every athlete. In ground-based sports, like baseball, tennis or cricket, all of the activities of the shoulder work within a kinetic chain linkage from the ground through to the trunk, mostly in a diagonal pattern. These athletes benefit from diagonal pattern exercises in a closed chain for the lower extremities. In addition, performing shoulder exercises standing on the contralateral leg enhances scapular muscle activity<sup>117</sup> (Fig. 24.57a). However, sports like volleyball, gymnastics and swimming have totally different movement patterns, and thus different demands from their kinetic chain. Volleyball players load their shoulder the most

(a)

(b)

**Figure 24.57** (a) Diagonal external rotation exercise standing on the contralateral leg (b) Throwing exercise on an unstable surface

(c)

**Figure 24.57 (cont.)** (c) Progressive 'training hanging' for gymnasts

during smashing, when their feet are off the ground. They should train the smashing and decelerating capacity of their shoulders with minimal input from the ground, for instance on an unstable surface (Fig. 24.57b). Gymnasts should train in hanging (Fig. 24.57c) or high load closed chain positions mimicking their sport-specific positions. Swimmers should focus on endurance in a concentric manner in a prone (Fig. 24.58) and supine position. Tennis (for the two-handed backhand), hockey and golf players should additionally pay attention to movements using both hands. Athletes who have to be able to 'fall' (diving in volleyball, goal keepers in soccer) should be trained to do so, for instance using sliding boards (Fig. 24.59).

#### PRACTICE PEARL

It is important to correct any inflexibilities of the hamstrings, hip and trunk; weakness or imbalances of the rotators of the trunk, flexors and extensors of the trunk and hip; and any subclinical adaptations of stance patterns or gait pattern.

(a)

(b)

**Figure 24.58** Prone exercise W-V—patient moves the arms from (a) Elbow in the back pockets (W) up to (b) High elevation (V)

**Figure 24.59** Exercise training for impact on a gliding surface

In ground-based sports, rehabilitation of the legs and hips should be concerned with generating appropriate sport-specific force and velocity from the lower extremity and should be done in a closed chain. This pattern, which is done with the foot on the ground, simulates the patterns that exist in the throwing or hitting activities. Eccentric patterns should also be emphasised to absorb the load from jumping forward movement or stopping of the plant leg in the baseball throw. Combined patterns of hip and trunk rotation in both directions, hip and shoulder diagonal patterns should also be emphasised. Integration of the scapular retraction muscles to the hip is very important because these reactions tend to be coupled in the cocking phases

of throwing. Hip extension and trunk stability should be trained performing squatting exercises.

Endurance activities in the legs should also be emphasised, as should aerobic endurance for recovery from exercise bouts and anaerobic endurance for agility and power work. Examples include mini-trampoline exercises, agility drills with running and jumping, jumping jacks and slider or fitter boards.

When working in closed chain, the kinetic chain activity also benefits from diagonal patterns. Research has shown that lower trapezius activity is increased when, during the four-point kneeling position, the contralateral leg is extended.<sup>118</sup>

### The thrower's program

Various thrower's programs are published, all aiming at progressively training the shoulder in order to prepare the athlete to throw in baseball, serve in tennis, smash in volleyball.<sup>74</sup> The main goal is to increase the challenge versus throwing by (a) changing shoulder position from neutral to full abduction/external rotation (ABER), (b) gradually increasing speed of movement, (c) implementing sport-specific kinetic chain skills, such as diagonals and core stability, into the shoulder exercises. For the latter we refer to the previous paragraph. All the following exercises should be considered to be functional, meaning adding kinetic chain principles where appropriate, depending on the specific sports; they are described below in view of shoulder loading only.

The goals and types of exercises are summarised in Table 24.7.

**Table 24.7** Which exercises to prescribe depends on the clinician's goal

Goal	Type of exercise
Basic RC training	ER and IR in neutral
From neutral to functional ABER	ER and IR diagonal with limited load in ABER
Increasing load in ABER	'Throwing' movement slow with high load in ABER
Increasing speed in ABER—low load	Quick low-load ER and IR movements in ABER
Functional throwing and decelerating	'Throwing' movement fast with high load in ABER
Focus on eccentric strength of the external rotators	Slow high-resistance eccentric exercise (avoid or limit concentric phase to enhance eccentric loading)
Focus on deceleration of the posterior shoulder muscles	'Catching' exercises
Focus on stretch-shortening phase of throwing	Use material that challenges plyometric cycle of throwing

RC = rotator cuff; ER = external rotation; IR = internal rotation; ABER = abduction external rotation

The program starts with IR and ER exercises with the shoulder in neutral position (Fig. 24.21b and c) or in slight elevation in the scapular plane. These positions put no strain on the shoulder capsule and allow strengthening in a safe position; however, they should be considered as non-functional from a sport-specific point of view. ER may also be performed with the athlete side-lying, to enhance proper UT/LT muscle balance (Fig 24.45a). If allowed (depending on the injury), eccentric drills in neutral may be performed, with side-lying catching exercises (Fig. 24.60). This exercise can be performed in the early stage, for instance in labral injury or instability, however, in case of muscle or tendon strain or overload injury, it should be postponed to a later stage.

The next stage of exercises brings the athlete's shoulder from neutral position to higher elevation angles and towards the throwing position; however, with limited load in that position. Examples are IR and ER diagonals towards or starting at the contralateral hip, standing sideways to the point of resistance (Fig. 24.61a and b). In addition, side-lying forward flexion and prone horizontal abduction with external rotation may be performed (see scapular rehabilitation). Eccentric exercises for the infraspinatus/trapezius may be implemented performing

side-lying catching exercises with the shoulder in 90° of forward flexion.

- To increase the challenge of the shoulder towards throwing positions, the load in this position is increased by facing the point of resistance (for ER) (Fig. 24.62a), or standing backwards towards it (for IR) (Fig. 24.62b), and performing slow throwing movements.
- After these rather slow exercises, speed is implemented in two steps: first, quick movements are performed in the ABER (abduction-external rotation) position into

**Figure 24.60** Side-lying plyometric catching exercise

(a)

(b)

**Figure 24.61** Diagonal (a) Internal and (b) External rotation with moderate load

(a)

(b)

**Figure 24.62** The load is increased by facing the point of resistance (a) For ER or (b) Standing backwards towards it for IR

IR and ER without explosive strength, later on more explosive exercises, challenging the stretch-shortening cycle and plyometric nature of throwing are performed. During the first step, endurance is the exercise goal, and the athlete is encouraged to perform the exercise at two or more reps per second for 30 to 60 seconds consecutively. At the end of this stage, the athlete should also be able to perform catching exercises prone with the shoulder in ABER (Fig. 24.22).

- In the final stage of basic throwing exercises, the patient performs quick throwing movements against resistance to train the acceleration as well as the deceleration mechanism. In addition, the stretch-shortening cycle may be trained by the use of equipment that 'decelerates' the turning point between IR and ER (Fig. 24.23).
- In line with specific shoulder training, the therapist should not forget to pay additional attention to the elbow and the wrist and grip strength muscles.

### Return to play following shoulder injury

According to the decision-based return-to-play model<sup>119</sup> (Chapter 19), three steps need to be taken prior to full return to sports. In the first step, the health status of the athlete is evaluated, including assessment of symptoms and a battery of analytical and functional tests, for instance strength and flexibility, and throwing performance. Then the clinician evaluates the participation risk, based on the type of sport, level of competition and ability to protect the shoulder. Finally, some factors might modify the decision such as the timing in the season, pressure from the athlete or the environment. However, little evidence exists regarding the physical return-to-play criteria of the shoulder after injury. In particular, for each of the described risk factors, from a clinical perspective, there is a need for cut-off values to be used as criteria for return to train and return to play. In addition, the clinician needs objective and valid assessment tools applicable on the field or the

training area of the athlete, and finally, once deficits are assessed, there is a need for science-based training programs to restore normal values.

The following return-to-play criteria (Table 24.8), although not extensively supported by scientific evidence, may be used.<sup>120, 121</sup>

**Table 24.8 Return-to-play (RTP) criteria for the overhead throwing athlete following shoulder injury**

Return-to-play criterion	Specific details
No/little pain	Self-report
Full ROM	Side difference GIRD <20°, TROM <5°
Normal strength	Dominant side 10% stronger in throwers, equal in strength in symmetric sports ER/IR ratio 66% (isokinetic), 75% (HHD in neutral), 95% (HHD in 90° abduction)
Normal scapular function	Slight scapular asymmetry allowed in resting position Scapular upward rotation +/– 60° in full elevation Dominant side 10% stronger in throwers, equal in strength in symmetric sports
Normal functional ability	Seated medicine ball throw Y-balance test Endurance test rotator cuff (elastic band, X-CO Trainer®)
Normal sport-specific skills	Having completed the thrower's program or another sport-specific program (non-throwing sports)

ROM = range of motion; GIRD = glenohumeral internal rotation deficit; TROM = total range of motion

# Elbow and arm pain

with BILL VICENZINO, ALEX SCOTT, SIMON BELL and NEBOJSA POPOVIC

*Throwing warmup pitches to start the bottom of the second inning, Hudson felt some tightness around his elbow. On the second pitch that inning, he felt that something was seriously wrong. His fastball dipped to about 85 mph, and he became hittable. He stayed in the game and completed the inning . . . but that . . . would be Hudson's last pitch for another year.*

Report on Major League Baseball pitcher Daniel Hudson's return from two ulnar collateral ligament surgeries

A well-functioning elbow is essential for upper limb use in sports. Elbow injuries may even interfere with an athlete's everyday activities. Tennis was the classic cause of elbow pain, but the double-handed backhand has reduced the prevalence of 'tennis elbow' dramatically. Elbow pain remains a problem in golf and in sports such as volleyball and handball, which involve forceful elbow hyperextension.

To approach elbow pain in clinical practice, consider which of the following categories describes your patient's elbow pain:

- lateral elbow pain, with a particular focus on extensor tendinopathy
- medial elbow pain
- posterior elbow pain
- acute elbow injuries
- forearm pain
- upper arm pain.

### ANATOMY

The elbow is situated between two highly mobile joints, the shoulder and the wrist, and comprises three distinct articulations—the ulna-humeral, radio-capitellar and proximal radio-ulnar joints. The first two provide flexion (150°) and extension (0°) of the elbow and the third provides pronation/supination (85°/85°) of the forearm. The proximal radio-ulnar joint works in conjunction with the distal

radio-ulnar joint at the wrist to achieve forearm pronation-supination. With the forearm in full extension and supination there will be a physiological valgus (carrying angle) of 9–14° in men or 12–17° in women. Any increase or loss of this physiological angle is a sign of pathology (instability, mal-union or overuse). Elbow stability is provided by the osseous anatomy, capsuloligamentous structure and musculotendinous units that cross the elbow.

### Ligaments

The ligaments of the elbow are divided into lateral and medial collateral ligament complexes. The medial collateral ligament complex is composed of discrete bands; the lateral collateral ligament complex consists of complex ligament fibres.

The medial collateral ligament complex (MCLC) is composed of the anterior oblique, posterior and transverse bands. The anterior band is the primary constraint against valgus stress, contributing 55 to 70% of valgus stability of the elbow. There are two elements of the anterior band: the anterior non-isometric and posterior isometric bundles. There is sequential tightening of these bundles proceeding from anterior to posterior when the elbow is flexed from full extension. The fan-shaped posterior band of the MCLC is a thickening of the capsule that is best defined with the elbow flexed at 90°. The posterior band does not contribute significantly to valgus stability of the elbow except in near terminal flexion. The transverse band

(TB) does not cross the joint, but exists as a thickening of the most caudal portion of the joint capsule. The TB contributes little to elbow stability because it originates from and inserts on the ulna.

The lateral collateral ligament complex (LCLC) consists of four components—the annular ligament, radial collateral ligament, lateral ulnar collateral ligament and accessory lateral collateral ligament—as well as the anconeus muscle (which acts as a dynamic stabiliser). These ligaments provide varus and external rotation stability to the elbow. This ligament complex is isometric throughout the normal range of flexion and extension with little change in the distance between ligament origin and insertion as the ligament complex is near the axis of rotation. There is controversy about the function of the different components of the LCLC.

## Muscles

Four muscle groups control elbow dynamic stability: the flexors and extensors of the elbow and the pronators and supinators of the proximal radio-ulnar joint. The flexor and extensor muscles provide some compression across the joint, increasing the inherent stability provided by the congruent articular surfaces.

The brachialis and triceps muscles have broad cross-sectional areas and their insertions are close to the axis of elbow joint rotation, providing a bulk effect to gain further stability of the joint. The overall effect of these muscle contractions on the stability of the elbow is likely to be important, but the magnitude of these effects has yet to be determined.

The muscles that cross the medial side of the elbow joint have an alignment favouring dynamic protection of the MCLC. On the medial side of the elbow the flexor carpi ulnaris (FCU) is the most important dynamic stabiliser, with the flexor digitorum superficialis (FDS) being less important. The FCU and FDS are optimally positioned to provide secondary valgus stability of the medial side of the elbow, especially at between 90 and 120° of elbow flexion (the position of cocking in throwing).

## LATERAL ELBOW PAIN

The lateral side is the most common site of elbow pain (Fig. 25.1). Some diagnoses that should be considered are lateral elbow tendinopathy, referred pain from the cervical and upper thoracic spine, synovitis of the radiohumeral joint, radiohumeral bursitis, osteochondritis dissecans of the capitellum and radius, posterolateral elbow instability and combinations of these problems (Table 25.1).

If your patient is between 30 and 60 years of age with local lateral elbow pain with or without some spread into the forearm, but no pain in the neck, arm and beyond the wrist, then lateral elbow tendinopathy is the likely

diagnosis. Although evocative, the term 'tennis elbow' is unsatisfactory as it gives little indication of pathology; in fact, sports medicine clinicians are more likely to see this condition in non-tennis players than in tennis players. The term 'lateral epicondylitis' is not accurate as the primary pathology is not inflammatory as implied by the suffix 'itis'. The term epicondylitis is also problematic, as not all patients will present with degenerative changes implied by the suffix 'osis' (Chapter 4). Lateral elbow tendinopathy or lateral elbow pain are more general terms that do not assume a given pathology or an exact source of symptoms and thus better reflect the clinical situation.

## History

Begin by eliciting the characteristics of the patient's lateral elbow pain. The pain of lateral extensor tendinopathy is typically located around the lateral epicondyle and proximal forearm. Occasionally the pain may radiate into the forearm extensor muscle mass, but it never extends into the hand and fingers or proximally into the upper arm. The onset of pain is often insidious but may be acute.

(a)

**Figure 25.1** Anatomy of the lateral elbow (a) Surface anatomy of the lateral elbow

(b)

**Figure 25.1 (cont.)** (b) Anatomy of the lateral elbow from behind

There may have been recent changes in training load, technique, duties or equipment used in sports or work.

The severity of pain ranges from relatively trivial to almost incapacitating, keeping the patient awake at night. It is important to note whether the pain is aggravated

by light everyday activities, such as picking up a cup, or requires repeated heavy activity to become painful.

Pain in the lateral aspect of the forearm may also implicate entrapment of the posterior interosseous nerve or irritation of other nerves. If pain is closely related to the activity level, it is more likely to be of a mechanical origin. If pain is persistent, unpredictable or related to posture, consider a source of pain from other anatomical structures, non-musculoskeletal pathologies or abnormal central nervous system functioning (e.g. complex regional pain or neuropathic pain states). Lateral elbow tendinopathy is typically painful with gripping or wrist extension, whereas referred pain may be provoked by prolonged postures such as in lengthy periods seated at a desk or in a car. Associated sensory symptoms, such as pins and needles, also suggest a neural component. Presence of neck, upper thoracic or shoulder pain should be noted, especially when symptoms extend beyond the lateral elbow and forearm.

Often patients presenting to sports medicine clinicians will have undergone a variety of treatments. It is important to note the response to each of these.

An activity history should also be taken, noting any recent change in the level of activity. In tennis players, note any change in racquet size, grip size or string tension and whether or not any comment has been made regarding the patient's technique. This is also relevant to occupations involving manual tool handling tasks.

## Examination

Examination involves:

1. Observation from the front
2. Active movements
  - a. elbow flexion/extension
  - b. supination/pronation
  - c. wrist flexion (forearm pronated) (Fig. 25.2a)
  - d. wrist extension
3. Passive movements
  - a. as above
4. Resisted movements
  - a. wrist extension (Fig. 25.2b)

**Table 25.1 Causes of lateral elbow pain**

Common	Less common	Not to be missed
Extensor tendinopathy Referred pain <ul style="list-style-type: none"> <li>• Cervical spine</li> <li>• Upper thoracic spine</li> <li>• Myofascial</li> </ul>	Synovitis of the radiohumeral joint Radiohumeral bursitis Posterior interosseous nerve entrapment (radial tunnel syndrome)	Osteochondritis dissecans (in adolescents) <ul style="list-style-type: none"> <li>• Capitellum</li> <li>• Radius</li> </ul>

- b. extension at the third metacarpophalangeal joint (Fig. 25.2c)
  - c. grip test (Fig. 25.2d)
- 5. Palpation
  - a. lateral epicondyle (Fig. 25.2e)
  - b. extensor muscles (Fig. 25.2f)
- 6. Special tests
  - a. neurodynamic tests
  - b. cervical spine examination (Chapter 23)

- c. thoracic spine examination (Chapter 28)
- d. periscapular soft tissues (Fig. 25.2g).

### Investigations

Investigations are usually not performed in a straightforward case of lateral elbow pain. However, in longstanding cases, plain radiograph (AP and lateral views) of the elbow may show osteochondritis dissecans, degenerative joint changes or evidence of heterotopic calcification.

(a)

(c)

(b)

(d)

**Figure 25.2** Examination of the patient with lateral elbow pain (a) Active movement—wrist flexion with forearm fully pronated (b) Resisted muscle testing—patient resists the clinician's pressure by extension of the wrist (c) Resisted muscle testing—extension at third metacarpophalangeal joint (d) The patient (in sitting or standing position) raises his or her arms up to horizontal, keeping the elbows extended and the palms facing down to the floor, then grips the examiner's two radial fingers as firmly as possible with the unaffected side, followed by the affected side until painful. A positive test is indicated by markedly reduced force to pain onset

(e)

(f)

(g)

**Figure 25.2 (cont.)** (e) Palpation—lateral epicondyle. Attempt to locate painful site distal to lateral epicondyle (f) Palpation—extensor muscles. Pincer grip is used with passive flexion and extension to provide exact feel of damaged tissue (g) Periscapular soft tissues—palpation of active trigger points and changes in muscle tone and length in the periscapular soft tissues

Ultrasound examination may be helpful.<sup>1</sup> It may demonstrate the degree of tendon or ligament damage<sup>2</sup> as well as the presence of a bursa; MRI identifies tendinopathy<sup>3</sup> but is not indicated routinely. It may provide valuable anatomic detail when the diagnosis is challenging.

### Lateral elbow tendinopathy

For this major sports medicine condition, we review the pathology, outline the clinical presentation and then discuss evidence-informed and clinically-reasoned treatment.

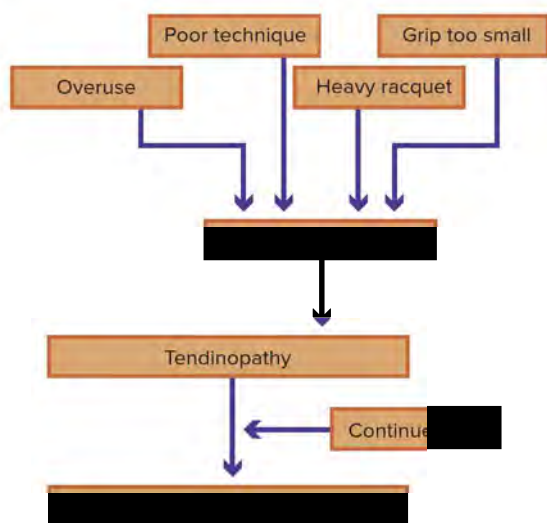

### Clinically relevant pathology

The extensor carpi radialis brevis (ECRB) tendon is the most common tendon to become problematic, but the extensor digitorum (or extensor carpi ulnaris) may be

implicated if the middle finger extension test is more provocative than the wrist extension test.<sup>4</sup> In addition to locating which muscle is involved, the tendon may be affected at its origin<sup>5</sup> or mid-substance. The latter is characterised on light microscopy as an excess of both fibroblasts and blood vessels.<sup>6-8</sup> The vessels appear consistent with what Alfredson calls 'neovessels',<sup>9</sup> pathologists call 'angiogenesis' and Nirschl called 'angiofibroblastic hyperplasia'.<sup>7</sup> With continued use, the lesions may extend into microscopic partial tears.<sup>10</sup> Conversely, a tear may be the primary abnormality, with degenerative changes being secondary. A summary of the processes leading to extensor tendinopathy is shown in Figure 25.3.

Manual tasks that require wrist stabilisation, such as gripping, or that require wrist extension movements,

**Figure 25.3** Processes leading to the development of lateral elbow tendinopathy

place considerable load on the ECRB tendon. The highest stresses occur in the ECRB tendon when the elbow is extended and the forearm pronated—the most provocative position to reproduce a patient's pain and test grip force.

Pain-free grip force is reduced in lateral elbow tendinopathy and there is altered motor control of the gripping action. In lateral elbow tendinopathy during a low force gripping action, there is a relatively lower activation of the ECRB and a relatively greater activation of the long finger flexors and extensors.<sup>11</sup> Associated with this, the wrist is held in a more flexed position.<sup>12</sup> The only muscle that is not weaker in this condition is the extensor digitorum longus.<sup>13</sup> Taken together, this evidence points to altered control mechanisms of the wrist in lateral elbow tendinopathy.

This abnormal gripping action was also present on the unaffected elbow side in unilateral tendinopathy, suggesting central neural mechanisms at play.<sup>14</sup> Consistent with these findings are impaired reaction time and speed of movement that are bilaterally present in unilateral tendinopathy.<sup>12, 15</sup> Most intriguingly, tendinosis-like tissue changes can also be triggered bilaterally in response to unilateral overuse as documented in a recent animal model.<sup>14</sup> These discoveries provide a basis for the clinician to be alert to potential central mechanisms and to carefully evaluate, and possibly treat, both sides even when the presentation is unilateral.

### Clinical features

Lateral elbow tendinopathy occurs in association with repeated gripping and/or wrist extension actions and

activities. These tasks includes sports, such as tennis, squash and badminton, as well as occupational and leisure pursuits, such as carpentry, bricklaying, sewing and knitting. Keyboard use is also associated with the condition.<sup>16</sup> The peak incidence is between the ages of 40 and 60 years, but the condition may affect any age group, in which case careful attention to differential causes of the symptoms is imperative.

### History

There are two distinct clinical presentations of lateral elbow tendinopathy. The most common is an insidious onset of pain, which occurs 24-72 hours after unaccustomed activity involving repeated wrist extension. This occurs typically after a person spends the weekend engaged in manual activity such as laying bricks or using a screwdriver, or after prolonged sessions of sewing or knitting. In the tennis player, it may occur following the use of a new racquet; playing with wet, heavy balls; or overhitting, especially when hitting into the wind. It also occurs when the player is hitting 'late' (getting into position slowly), so that body weight is not transferred correctly and the player relies excessively on the forearm muscles for power (see also discussion of specific tennis biomechanics in Chapter 9).

The other clinical presentation is a sudden onset of lateral elbow pain associated with a single instance of exertion involving the wrist extensors, for example lifting a heavy object, or in tennis players attempting a very forceful single-handed backhand with too much reliance on the forearm and not enough on the trunk and legs. The insidious onset is thought to correspond to microscopic tears within the tendon, whereas the acute onset may correspond to larger macroscopic tendon tears.

### Physical examination

On examination, insertional versus mid-substance lesions will be differentiated by the site of maximal tenderness, with the latter being approximately 1-2 cm distal to the lateral epicondyle. Palpation of the entire tendon and the associated muscle(s) will provide valuable information on tissue tightness or hypersensitivity, which is useful in guiding treatment.

Typically, the pain is reproduced by resisted wrist extension, especially with the elbow extended and forearm pronated. Resisted extension of the middle finger is also painful (Fig. 25.2c). It is thought that the ECRB tendon is preferentially stressed in this position as it contracts synergistically to anchor the third metacarpal to allow extension to take place at the digits.

The upper limb neurodynamic or neural provocation test (Chapter 15), especially with radial nerve bias, may

reproduce lateral elbow pain or show restriction of movement compared with the other side. In either situation, this may implicate a neural component to the pain.

Examination of the cervical spine will frequently detect decreased range of movement, especially lateral flexion. The cervical and upper thoracic spine may be stiff to palpation and tender both centrally and over the painful apophyseal joint, usually around the C5–6 level.<sup>17</sup> Active trigger points can occur in the periscapular soft tissues (Fig. 25.2g). In chronic cases, it is not uncommon to find decreased joint play in the elbow joints.

### Treatment

No single treatment is totally effective and it is most likely that the patient will be best served through a combination of different treatments selected on the basis of the patient's clinical presentation<sup>18</sup> and preferences, and informed by current best evidence.

The basic principles of treating soft tissue injuries apply, with a specific focus on addressing the grip strength deficit and coordination impairments of the upper limb and specifically at the wrist. These deficits are best addressed through exercise. There must be control of pain (e.g. ice, analgesic medications, relative rest, electrotherapy), encouragement of the healing process, restoration of any flexibility deficit, correction of any predisposing factors and a gradual return to activity.

Treatment of any spinal or neural dysfunctions often speeds up resolution<sup>19</sup> and is highly recommended if there is concomitant neck pain.<sup>20, 21</sup>

#### PRACTICE PEARL

Exercise is the key to managing lateral elbow tendinopathy. Other treatments are adjunctive, mainly to resolve pain and facilitate tissue healing.

### Exercises for strengthening and coordination

We recommend the following exercises:

- Progressively graduated exercise to improve strength and endurance capacity (Fig. 25.4) as well as normalise flexibility of the forearm muscles (Fig. 25.5).
- Exercises geared at improving coordination (Fig. 25.6) should also be considered.<sup>22</sup>

It is unknown how much pain should be experienced during exercise without compromising resolution, but experience indicates that it should be minimised through careful selection of load and type of exercise. For example, in very painful elbows, isometric low load exercise with taping, and/or mobilisation with movements (Fig. 25.7)

**Figure 25.4** Strengthening exercises for wrist extensors.

Exercises can be isometric, concentric (raising the weight, black arrow), eccentric (lowering the weight, white arrow) or functional

**Figure 25.5** Stretching the extensor carpi radialis brevis tendon

**Figure 25.6** Coordination exercise focusing on supination/pronation at an early stage in rehabilitation of lateral elbow tendinopathy. The patient oscillates the body blade with the shoulder in a position that approximates the scapular plane

**Figure 25.7** Mobilisation with movement

to improve endurance should be favoured initially, with progression in load and complexity (concentric, eccentric) as pain subsides to emphasise strengthening.

Exercise is supported by clinical trials<sup>23, 24</sup> and in one particular study,<sup>21</sup> long-term benefits and prevention of recurrence were seen in patients who had previously failed common treatments such as corticosteroid injections and oral medications.

### Electrotherapeutic modalities

Electrotherapeutic modalities such as laser, extracorporeal shockwave therapy (ESWT), TENS and ultrasound are often used in practice for these conditions despite mixed evidence on their effectiveness. In some part

related to this mixed evidence is the fundamental issue of what constitutes an appropriate dosage, which can be challenging to the practitioner. For example, laser administered at a wavelength of 904 nm (but not 820 and 1064 nm) offers short-term pain relief and a reduction in disability, applied either in isolation or in combination with exercise.<sup>25</sup>

A modality where a perplexing situation arises is ESWT, which is effective at some sites of tendinopathy but not for lateral elbow tendinopathy,<sup>26</sup> though the issue of dose for this modality has perhaps not been adequately explored. Interestingly, TENS, which is a scientifically developed modality for the reduction of pain, has only recently been considered in clinical trials of tennis elbow.<sup>27</sup> Practitioners should be aware that dosage plays an important role in delivering beneficial outcomes;<sup>28</sup> high frequencies (e.g. 85–110 Hz) and pulse durations of approximately 200  $\mu$ s delivered at a strong but sub-noxious intensity are recommended.

Therapeutic ultrasound (i.e. not diagnostic ultrasound), which tends to be widely used in clinics for many musculoskeletal conditions, has very little evidence to support its use.<sup>29</sup> A recent clinical trial showed that while therapeutic ultrasound reduced pain over time, as did the comparator laser treatment, the patients did not rate their condition as being sufficiently improved.<sup>30</sup>

### Manual therapy

Specific manual therapy applied to the joints or soft tissues of the elbow and forearm is beneficial for lateral elbow tendinopathy.

There is evidence of benefit with elbow mobilisation with movement<sup>31</sup> (Fig. 25.7), in combination with exercise,<sup>32</sup> and with the addition of cervical and thoracic spine treatment to elbow treatment.<sup>33</sup>

Cervical mobilisation (Fig. 25.8), thoracic mobilisation and neural stretching (Fig. 25.9) are commonly used as adjuncts to other forms of treatment.

Transverse frictions are frequently advocated at the site of the lesion; however, there is little evidence that these are beneficial. There is some evidence that they are less effective than supervised exercise, when frictions are combined with Mill's manipulation, which is a small-amplitude, high-velocity thrust performed at end of elbow extension while the wrist and hand are flexed.<sup>33–35</sup>

There is little evidence to support the use of digital ischaemic pressures and myofascial massage, though it may be trialled to judge whether the individual patient will benefit from its application. A critical aspect of such soft tissue manual therapy techniques is targeting them to areas exhibiting increased resistance, tightness

**Figure 25.8** Cervical mobilisation

**Figure 25.9** Neural tissue mobilisation positioned at end of range

or thickening to digital pressure in the absence of severe pain. In this situation the tissues are usually placed under various conditions of stretch while digital pressure is applied, either sustained (Fig. 25.10a) or longitudinally directed in motion (Fig. 25.10b).

These techniques usually produce pain during application, but this pain should be within the patient's tolerance, not be severe and not outlast the treatment. The presence of severe pain and very little or no resistance, tightness or thickening are contraindications to high force/load soft tissue techniques.

#### Trigger points

In patients with lateral elbow pain, active trigger points associated with muscle shortening are frequently found in the forearm extensor muscles—brachioradialis, extensor carpi radialis longus, ECRB, extensor digitorum, extensor carpi ulnaris, extensor digiti minimi and anconeus, as well as the periscapular area.<sup>36</sup> Digital ischaemic pressure or dry needling of these trigger points may help in the treatment.

#### Acupuncture

There is some evidence of short-term (2–8 weeks) benefit with the use of acupuncture for lateral elbow pain.<sup>37</sup>

#### Bracing and taping

Counterforce bracing (Fig. 25.11) increases forearm extensors' stretching pain tolerance, but it does not appear to influence neuromuscular parameters such as strength or proprioception of these muscles.<sup>38</sup> If a brace is to be used, it should demonstrably reduce pain on gripping or on resisted tests of wrist and middle finger extension. In these cases, the brace should be worn during the performance of pain provocative tasks, such as on returning to an aggravating activity like tennis. The brace should be correctly applied approximately 10 cm below the elbow joint. Tensioning the brace up to 50 N has been found to be beneficial.<sup>38</sup>

A deloading taping technique has been shown to initially improve pain-free gripping<sup>39</sup> and to reduce tissue stress within the taped area. Our clinical experience

(a)

(b)

**Figure 25.10** Soft tissue techniques (a) Sustained longitudinal pressure to the extensor carpi radialis brevis muscle in the position of maximum elbow extension and wrist flexion (b) Digital ischaemic pressure to deep muscle fibres in the shortened position

indicates that it is very useful in patients who have severe pain and pain at night (Fig. 25.12).

### Iontophoresis

There is insufficient evidence from clinical trials to support or refute the use of corticosteroids delivered by iontophoresis.

### Corticosteroid injection

#### PRACTICE PEARL

The use of corticosteroid injection in the treatment of this condition requires careful consideration because the best evidence to date indicates that while it is very effective in the short term (i.e. >80% success rate), there are unfavourable consequences later (i.e. >6–12 months), such as delayed recovery and a 62% greater recurrence rate than if the patient were advised to adopt a wait and see approach.<sup>40</sup>

**Figure 25.11** Counterforce brace

(a)

(b)

**Figure 25.12** The diamond tape technique

(a) The anchor point X marks the site from which the tape is tensioned longitudinally (along the solid-line arrow) and laid onto the skin. The skin should be pulled towards the site of pain (dotted-line arrow)

(b) Note the overlapping ends of the tape and the orange-peel effect on the skin with the diamond tape, resulting in a translation of skin away from the tape towards the site of pain (O) as shown by the arrows

FROM VICENZINO ET AL<sup>39</sup>

Combining physiotherapy with an injection does not seem to improve this situation.<sup>41</sup> Thus, it is prudent to consider using this injection within a more comprehensive management framework as illustrated (Fig. 25.13).

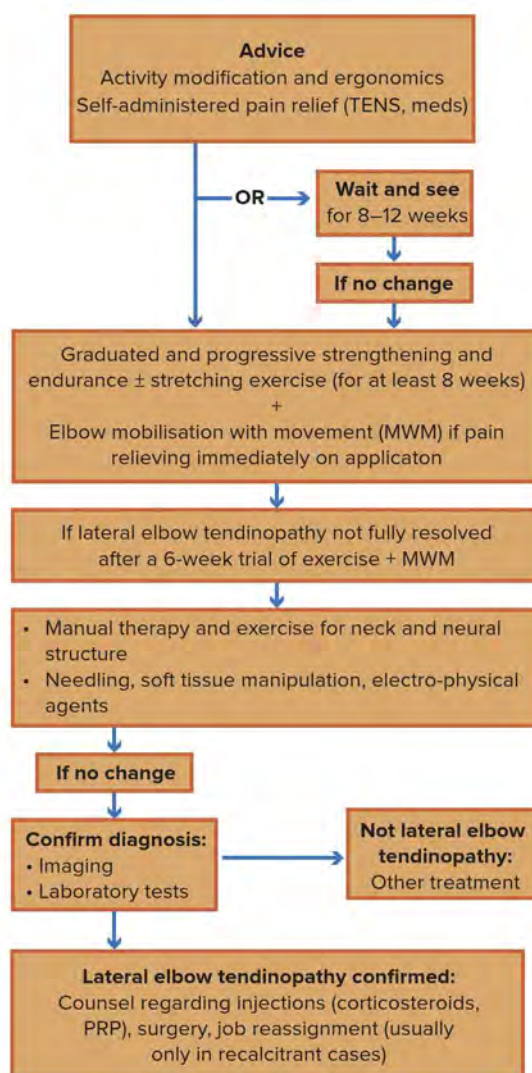

Prior to any injection, the clinician should fully inform the patient of likely short- and long-term outcomes, as adopting a wait and see policy will result in approximately 80% success rate at 12 months, with much lower risk of recurrences.<sup>42</sup> When corticosteroid and local anaesthetic agents are injected, the aim should be around the ECRB tendon, directly over the point of maximal tenderness but not into the tendon substance itself.

### PRACTICE PEARL

A comprehensive program for the management of lateral elbow pain (Fig. 25.13) would include implementing a graduated progressive exercise program over 8 weeks, pain relief if required, ergonomic advice and activity modification.<sup>42</sup>

### Nitric oxide donor therapy

Initial studies of lateral elbow, Achilles and supraspinatus tendinopathies provided level 2 evidence that nitric oxide donor therapy (glyceryl trinitrate [GTN] patches applied locally, 1.25 mg/day) improved outcomes within

**Figure 25.13** Treatment algorithm

**Figure 25.14** Nitric oxide donor therapy—one quarter of a 0.5 mg/24 h glyceryl trinitrate (GTN) patch in place over the most tender site of extensor tendinopathy

3–6 months<sup>43</sup> (Fig. 25.14). One mechanism by which this treatment might work is through enhanced collagen synthesis. However, a recent dose-ranging clinical trial for lateral elbow tendinopathy failed to confirm the initial findings, but highlighted that the type of exercise (strengthening as opposed to stretching) is a significant consideration.<sup>44</sup>

Pragmatically, the practitioner and patient need to be aware that 4–5% of patients will develop headaches or skin rash that are severe enough to discontinue treatment with GTN and that this seems to be dose dependent. Thus it is important to carefully meter the dose and monitor response.

### Botulinum toxin

Historically used for neuromuscular conditions, botulinum toxin (Botox<sup>®</sup>) injection is a new and unproven treatment of tendinopathy. There is evidence that it produces short-term improvement in pain when compared to placebo,<sup>40, 45</sup> though it is important to counsel the patient prior to the treatment that there will be a high likelihood (92% at 8 weeks post injection)<sup>46</sup> of an extensor muscle lag. This treatment-induced extensor weakness is an important consideration for athletes who need good grip strength.

### Autologous blood, platelet-rich plasma and autologous cell injections

with ROBERT-JAN DE VOS

Autologous blood and platelet-rich plasma (PRP) are increasingly proposed as treatment for lateral elbow tendinopathy.<sup>47</sup> The rationale behind these treatments is improvement of tendon healing through delivery of growth factors and cytokines present in blood.<sup>48, 49</sup> There are various protocols for preparation and injection of these blood products.

A relatively high number of clinical trials have been performed on patients with longstanding lateral elbow tendinopathy. One recent qualitative systematic review, concluded that there is strong evidence against the use of PRP.<sup>50</sup> Also after pooling of data in a Cochrane review, there was no significant improvement after PRP treatment compared to other treatments for this condition.<sup>51</sup> There is a lot of discussion about the interpretation of these results; nonetheless, the data are clearly not in favour of PRP treatment.<sup>52</sup> One case series showed pain reduction and functional improvement after an injection with autologous tenocytes for longstanding lateral elbow tendinopathy.<sup>53, 54</sup> However, due to the study design, this conclusion has limited value.

Consequently, there is currently insufficient evidence to recommend injections with autologous blood, PRP or autologous tenocytes in patients with chronic lateral elbow tendinopathy.

### Correct predisposing factors

Probably the most important factor to be avoided is exposure to activity levels for which there is inadequate preparation (e.g. inappropriate training load, poor technique). In tennis players, a major cause is a faulty backhand technique with the elbow leading (Fig. 25.15). Other technique faults that may predispose to the development of extensor tendinopathy include excessive forearm pronation while attempting to hit topspin forehands and excessive wrist flick (flexion) movement while serving. Correction of these faults requires the assistance of a qualified tennis coach. Other factors, such as racquet type, grip size, string tension, court surface and ball weight, may influence the amount of shock imparted to the elbow (Chapter 9). A mid-sized racquet with a large 'sweet spot' and a grip size that feels comfortable should be used. Care should be taken to avoid using racquets with excessively large or, especially, small grips.

### Surgery

Surgery might be considered occasionally in cases with a long history (e.g. >18 months) of lateral elbow pain that is recalcitrant to the treatment strategies outlined above. Surgery is varied, but most recent approaches involve ECRB tendon release from the lateral epicondyle with or without some degree of excision of the degenerative tissue within the common extensor tendon. A recent systematic review concluded that there is a lack of quality evidence to recommend one surgical approach over others.<sup>55</sup>

### Graduated return to activity

As with all soft tissue injuries, it is important to return gradually to activity following treatment. The tennis

(a)

(b)

**Figure 25.15** Backhand technique (a) Incorrect (b) Correct

player should initially practice backhand technique without a ball, then progress slowly from gentle hitting from the service line to eventually hitting full length shots. Depending on the severity of the condition and the

length of the rehabilitation program, this graduated return should take place over a period of at least 3–6 weeks.

### Other causes of lateral elbow pain

Other causes of lateral elbow pain may occur in isolation or in conjunction with the previously mentioned conditions. Radiohumeral bursitis is occasionally seen in athletes. This may be distinguished from extensor tendinopathy by the site of tenderness that is over the radiohumeral joint and distal to the lateral epicondyle, maximally over the anterolateral aspect of the head of the radius. The presence of this bursitis may be confirmed on ultrasound examination. Injection with a corticosteroid agent is the most effective form of treatment.

Osteochondritis of the capitulum or radial head may occur in younger athletes (Chapter 44) involved in throwing sports. This is a significant condition as it can cause an enlarged, deformed capitulum that may predispose to the development of osteoarthritis. The treatment of this condition involves avoidance of aggravating activities.

The lateral elbow is a common site of referred pain, especially from the cervical and upper thoracic spine and periscapular soft tissues. Most patients with chronic lateral elbow pain are likely to have some component of their pain emanating from the cervical and thoracic spine (Chapters 23 and 28). Any associated abnormalities of the cervical and thoracic spine should be treated and the patient's signs reassessed immediately after treatment. If there is a noticeable difference, this may indicate a significant component of referred pain.

### MEDIAL ELBOW PAIN

Patients who present with medial elbow pain can be considered in two main groups. One group has pain associated with excessive activity of the wrist flexors. This is the medial equivalent of lateral elbow tendinopathy, with a similar pathological process occurring in the tendons of pronator teres and the flexor group. This condition will be referred to as 'flexor/pronator tendinopathy'.

The second group of patients has medial elbow pain related to excessive throwing activities. Throwing produces a valgus elbow stress that is resisted primarily by the anterior oblique portion of the medial collateral ligament (MCL) and secondarily by the stability of the radiocapitellar joint. Repetitive throwing, especially if throwing technique is poor (Chapter 8), leads to stretching of the MCL and a degree of valgus instability. A fixed flexion deformity of the elbow may develop as a result of scarring of the MCL. Subsequently, there may be some secondary impingement of the medial tip of the olecranon onto the olecranon fossa, producing a synovitis or loose

body formation. With valgus stress, the compressive forces may also damage the radiocapitellar joint. Several of these pathological entities may be present in combination.

In children, repetitive valgus stress may result in damage to the medial epicondylar epiphysis with pain and tenderness in this region. This usually responds to a period of rest followed by a gradual return to throwing activity, but may progress to avulsion with continued activity. This condition, commonly known as 'little leaguer's elbow', is considered in Chapter 44. The causes of medial elbow pain are shown in Table 25.2.

### Flexor/pronator tendinopathy

This condition is not as common as its lateral equivalent, accounting for 9–20% of all epicondylalgia diagnoses.<sup>56</sup> It is seen especially in golfers ('golfer's elbow') and in tennis players who use a lot of topspin on their forehand. The primary pathology exists in the tendinous origin of the forearm flexor muscles, particularly in the pronator teres tendon.<sup>57</sup> Ultrasound is sensitive and specific for detecting clinically defined medial epicondylitis, with focal hypoechoic areas of tendinosis being the most common finding, followed by partial tears—that is, identical to lateral tendinopathy ultrasound findings.

On examination, there is usually localised tenderness just at or below the medial epicondyle with pain on resisted wrist flexion and resisted forearm pronation (Fig. 25.16).

Treatment is along the same lines as treatment of lateral elbow tendinopathy (Fig. 25.13). Particular attention should be paid to the tennis forehand or the golf swing technique. Due to its close proximity to the medial epicondyle, the ulnar nerve may become irritated or trapped in scar tissue. This should be treated with neural mobilisation.

### Medial collateral ligament sprain

Sprain of the MCL of the elbow may occur as an acute injury, which is discussed below, or as the result of chronic excessive valgus stress due to throwing. This occurs particularly in baseball pitchers, javelin throwers, and water polo, handball, tennis and cricket players.

Throwing is a highly dynamic activity (see Chapter 8) where body segments move through long arcs of motion at high speed. Large joint forces and torques are generated

**Figure 25.16** Medial elbow pain reproduced with resisted wrist flexion and forearm pronation

at the medial side of the elbow. In general, the throwing motion is similar among various sports and the overuse pathology of the medial side of the elbow is similar.

Medial elbow stability between 20 and 120° of elbow flexion is provided primarily by the MCL. The static function of the MCL is to serve as the primary restraint to valgus strains in this functional range of motion. During each throw the elbow is subject to tremendous forces and functional demands. The elbow is designed for planar motion whereas the act of throwing relies on a peak rotatory power to propel the ball.

Biomechanical studies of pitching have shown arm rotation speeds of >7000°/second and arm extension velocity of 2300°/second. The anterior bundle of the MCL is the primary static restraint against valgus stress at 30 to 90° of flexion with an average load to failure of 260 N. Muscle contraction during throwing can reduce the stress on the MCL by compressing the joint and adding some stability. Because of the intensity of activity in these athletes with high numbers of repetitions (in some sports, up to 60 000 throwing motions per year), the abnormal forces over time can lead to subtle microscopic tearing within the soft tissues of the medial side of the elbow with imperfect healing. This chronic attenuation of the MCL with repeated high valgus stress can result in acute rupture of the MCL.

**Table 25.2** Causes of medial elbow pain

Common	Less common	Not to be missed
Flexor/pronator tendinopathy Medial collateral ligament sprain <ul style="list-style-type: none"> <li>• Acute</li> <li>• Chronic</li> </ul>	Ulnar nerve compression Avulsion fracture of the medial epicondyle (adolescents) Apophysitis—'Little Leaguer's elbow' (adolescents)	Referred pain

The athlete with an acute MCL injury typically describes the sudden onset of pain with throwing. In approximately 50% of cases the patient will report hearing or feeling a 'pop' and is typically unable to continue throwing. More chronic injuries may not present as obviously.

They will likely be described as a gradual onset of pain localised to the medial elbow that worsens in the late cocking or early acceleration phase of throwing. A decrease in maximum velocity is also typically reported in chronic cases. Local inflammation of the unstable ligamentous complex can lead to other common elbow complaints such as ulnar nerve symptoms secondary to irritation of the nerve within the cubital tunnel (see below), flexor-pronator mass strain or medial epicondylitis.<sup>58</sup>

On examination, there will be localised tenderness over the ligament *just distal to the medial epicondyle* and mild pain/instability on valgus stress (Fig. 25.17a). The *milking manoeuvre* or the moving valgus stress test is a useful test to access partial tear of MCL. The milking manoeuvre is performed by pulling on the patient's thumb in order to apply valgus stress while the patient's shoulder is forward elevated to 90° and elbow flexed beyond 90°.<sup>59</sup>

There will often be associated abnormalities such as a flexion contracture of the forearm muscles, synovitis and loose body formation around the tip of the olecranon, as well as damage to the radio-capitellar joint. However, many throwers demonstrate a flexion contracture without concurrent MCL pathology.<sup>60</sup> Ultrasound and MRI are the preferred imaging modalities in these athletes.

Treatment in the early stages of the injury involves modification of activity, correction of faulty technique, local electrotherapeutic modalities (just as with lateral elbow tendinopathy, little research exists) and soft tissue therapy to the medial ligament. Medial strapping of the elbow may offer additional protection (Fig. 25.17b). Specific muscle strengthening should be commenced, concentrating on the forearm flexors and pronators (Fig. 25.18).

#### PRACTICE PEARL

**Surgery is indicated for the throwing athlete with elbow pain associated with medial dynamic valgus instability that precludes participation in sport at the pre-injury level.**

The first successful UCL reconstruction surgery was performed in 1974 by Dr Frank Jobe on Los Angeles Dodgers pitcher, Tommy John. Prior to this surgery, a UCL tear was considered to be a career-ending injury. Tommy John's return to baseball in 1976 changed the way this injury was viewed and sparked an evolution of surgical techniques that would take place over the next 40 years.

(a)

(b)

**Figure 25.17** (a) Assessment of integrity of the medial collateral ligament with humerus fully internally rotated and controlled for pro/supination. Laxity should not exceed 5°  
(b) Elbow stability tape

Most MCL reconstruction techniques ('Tommy John surgery') use a free autograft tendon (e.g. palmaris longus) placed in ulnar and humeral bone tunnels. Transmuscular splitting approach to the medial elbow is used to expose the MCL. Time to return to throwing is about 1 year for full competition. Current techniques allow competitive throwing athletes to return to their previous levels of sport in more than 80% of cases.<sup>61</sup>

#### Ulnar nerve entrapment/neuritis

The ulnar nerve pierces the intermuscular septum in the middle of the arm and then passes deep to the medial head of the triceps muscle into a superficial groove (ulnar sulcus) between the olecranon and medial epicondyle. It enters the forearm between the humerus and the ulnar heads of the flexor carpi ulnaris muscle.

**Figure 25.18** Strengthening exercises for the forearm flexors and pronators

Inflammation of the ulnar nerve can occur as a result of a combination of any of four factors.<sup>62</sup>

1. Traction injuries to the nerve may occur because of the dynamic valgus forces of throwing, especially when combined with valgus instability of the elbow.
2. Progressive compression can occur at the cubital tunnel secondary to inflammation and adhesions from repetitive stresses, or where the nerve passes between the two heads of the flexor carpi ulnaris due to muscle overdevelopment secondary to resistance weight-training exercises.
3. Recurrent subluxation of the nerve due to acquired laxity from repetitive stress or direct trauma. A subluxing ulnar nerve is present in about 8% of the population. Can be an important differential diagnosis—the athlete feels a ‘click’ and might have some pain at the same time.
4. Irregularities within the ulnar groove, such as spurs commonly seen from overuse injuries in older throwers.

The patient presents with posteromedial elbow pain and sensory symptoms such as pins and needles or numbness along the ulnar nerve distribution—the ulnar border of the forearm and the ulnar one and a half fingers. The nerve may be tender behind the medial epicondyle (Fig. 25.19) and tapping over the nerve may

**Figure 25.19** Palpation of the ulnar nerve

reproduce symptoms in some cases. Placing the elbow in maximum flexion, the forearm in pronation and the wrist in full extension for one minute may reproduce medial elbow pain and tingling/numbness in the ring and little finger if ulnar neuritis is present. Patients with clinical features of ulnar nerve involvement should undergo nerve conduction studies.<sup>56</sup> Reports of snapping sensation should lead one to suspect ulnar nerve subluxation, which can be confirmed with dynamic ultrasound examination.<sup>63</sup>

Treatment of this condition depends on the initiating factor.

1. Traction injuries related to valgus instability from throwing are best served by treating the instability to reduce the ongoing nerve irritation.
2. If adhesions are felt to be present, treatment may include local soft tissue therapy to the nerve in the ulnar groove to mobilise soft tissue that may be compressing or tethering the nerve. Neural mobilisation is often beneficial.
3. Recurrent subluxation of the ulnar nerve should be referred to a neurologist or surgeon experienced in managing this condition in active individuals. Management will depend on the degree of symptoms, electrophysiological evidence of nerve injury and local management expertise (in relation to nerve transposition surgery).
4. Bony irregularities may be amenable to arthroscopic debridement.

## POSTERIOR ELBOW PAIN

The main causes of posterior elbow pain are olecranon bursitis, triceps tendinopathy and posterior impingement. Gout should always be considered.

### Olecranon bursitis

Olecranon bursitis may present after a single episode of trauma or, more commonly, after repeated trauma, such as

falls onto a hard surface affecting the posterior aspect of the elbow. This is commonly seen in football goalkeepers and in basketball players 'taking a charge'. It is also seen in individuals who rest their elbow on a hard surface for long periods of time and is known as 'student's elbow'. The olecranon bursa is a subcutaneous bursa that may become filled with blood and serous fluid (Fig. 25.20).

Treatment in acute traumatic cases consists initially of ice, rest, firm compression and NSAIDs. If this fails, then aspiration of the contents of the bursa and injection with a mixture of corticosteroid and local anaesthetic agents will usually be effective. The needle should be inserted at an oblique angle to reduce the risk of sinus formation.

(a)

(b)

**Figure 25.20** Olecranon bursa (a) Palpation site of bursa (b) Olecranon bursitis

Although this is considered a straightforward procedure among experienced clinicians, there is a trend to do this with ultrasound imaging support to increase the accuracy of needle insertion. If recurrent bursitis does not respond to aspiration and injection, surgical excision of the bursa should be considered.

Occasionally, olecranon bursitis can become infected. This is a serious complication that requires immediate drainage, immobilisation and antibiotic therapy. Osteomyelitis and septic arthritis can follow. Excision of the bursa is occasionally required.

### Triceps tendinopathy

Tendinopathy at the insertion of the triceps onto the olecranon is occasionally seen. Standard conservative measures for treatment of tendinopathy should be used. Soft tissue therapy including self-massage with a Styrofoam™ roll and dry needling to reduce excessive tightness of the triceps musculotendinous complex may be helpful.

### Posterior impingement

Posterior impingement is probably the most common cause of posterior elbow pain. It occurs in three situations. In the younger athlete there is the 'hyperextension valgus overload syndrome'. Repetitive hyperextension valgus stress to the elbow results in impingement of the posterior medial corner of the olecranon tip on the olecranon fossa. Over time this causes osteophyte formation, exacerbating the impingement and leading to a fixed flexion deformity. Valgus instability can be a primary driver of posterior impingement as the olecranon will then no longer be fitting into the olecranon fossa, but will impact more medially.

In the older patient the most common cause is early osteoarthritis, which often predominantly affects the radiocapitellar joint. Generalised osteophytes form through the elbow. Impingement of these osteophytes posteriorly results in posterior pain. The main clinical feature in athletes with posterior impingement is a fixed flexion deformity of some degree and posterior pain with forced extension (Fig. 25.21).

Treatment may include strategies to minimise hyperextension forces such as taping or bracing, along with a strength and flexibility program and graduated return to sport or activity. If lost range is the only problem, surgery is rarely indicated.

If conservative measures fail, then arthroscopic removal of the impinging posterior bone and anterior capsule release is very effective in relieving symptoms and improving extension especially in elderly patients. Acute painful locking however is an indication for surgery. The patient must be counselled that sometimes the loose bodies can be hard to find in the elbow, and the surgeon may miss one or more.

**Figure 25.21** Posterior impingement. The elbow is forced into end-range extension. If posterior pain is produced then posterior impingement is present

## ACUTE ELBOW INJURIES

Acute elbow injuries include fractures, dislocations and ligament or tendon ruptures. Elbow dislocation associated with fracture can lead to long-term instability and must be recognised early.

### Fractures

As the complication rate for elbow fractures is higher than with fractures near other joints, it is essential that fractures in this region be recognised and treated early and aggressively. Those who are fully able to extend the elbow are unlikely to have a fracture, though they should be followed up in 7–10 days if symptoms have not resolved. A clinical protocol has been proposed to detect the presence of a fracture.<sup>64</sup> Plain radiography is the first line of investigation.

#### PRACTICE PEARL

Patients who cannot fully extend their elbow after injury should be referred for plain radiography because there is a 50% chance of fracture.

Unstable fractures, usually those associated with displacement, should be referred early for orthopaedic management. When the articular or cortical surface has less than 2 mm of vertical or horizontal displacement, the fracture can be regarded as stable and treated conservatively.<sup>65</sup>

The most common complication of elbow fractures is stiffness, particularly loss of terminal extension. Prompt diagnosis and treatment that includes an early rehabilitation program can help avoid loss of extension. Thus, treatment of

elbow fractures must be aggressive. Surgically stabilising a displaced adult elbow fracture allows early commencement of a post-operative range of motion program.

A stable fracture that involves no significant comminution, displacement or angulation may be treated conservatively. In adults, immobilising the arm for a few days, even up to a week, is generally well tolerated. Then the arm should be placed in a removable splint and early motion commenced. The fracture should then be protected for 6–8 weeks, with early and frequent radiographic checks to ensure the reduction stays anatomical.

Heterotopic ossification is the other main complication of elbow fractures, particularly in high energy injuries. This usually appears within the first month after surgery and plateaus after 4–6 months. Traumatized elbows that are forcefully or passively manipulated may also be at greater risk of this complication.<sup>66</sup> Therefore, gentle, active assisted range of motion and pain-free stretching exercises are preferred. Mobilisation with movements, applied correctly in a pain-free manner, may be helpful in restoring motion.<sup>31</sup> Heterotopic bone formation has also been associated with elbow fracture-dislocation treated surgically 1–5 days after injury or treated with multiple surgical procedures. Thus, surgery should be performed in the first 24 hours after injury or after 5–7 days.

### Supracondylar fractures

Supracondylar fractures are more common around the age of 12 than in adults. They often occur from a fall on an outstretched arm, either from a height or a bicycle. As they are rotationally unstable and have a high rate of neurovascular complications, these fractures should be regarded as an orthopaedic emergency.

For fractures that are unstable, displaced or cannot be reduced without jeopardising the blood supply, the treatment of choice is closed reduction in the operating room under general anaesthesia. Percutaneous pins placed across the fracture maintain the reduction and prevent late slippage. The arm is initially placed in a splint and then several days later in a cast. The pins are removed after 4–6 weeks. Stiffness is typically not a problem in children recovering from fractures.

### Olecranon fractures

Olecranon fractures occur from a fall onto an outstretched hand or from direct trauma to the elbow. If the fracture is non-displaced and stable, the patient should be able to extend the arm against gravity. Treatment consists of immobilising the arm for 2–3 weeks in a posterior splint and then in a removable splint, and commencing a range of motion program. If the patient is unable to extend the elbow against gravity or if radiographs show significant displacement, open reduction with internal fixation by

tension-band wiring is preferred.<sup>67</sup> Early motion is started within one week of surgery.

### Radial head fracture

The most common fracture around the elbow in athletes is the radial head fracture, almost always resulting from a fall onto an outstretched hand. The radial head can be considered a multifunctional stabiliser of the elbow. In the frontal plane its contribution to valgus stability may be as high as 30% even with the intact MCL. In disruption of the MCL, the radial head becomes a critical secondary stabiliser of the elbow with up to 70% of resistance to valgus stress. In the sagittal plane, the radial head contributes to preventing posterior elbow dislocation in association with the coronoid process, lateral and medial ligament complex. In the longitudinal plane, the radial head prevents proximal migration of the radial shaft along with the interosseous membrane.

The main mechanism of injury in contact sports is a fall onto the outstretched hand—the radial head may fail under compressive axial or valgus loads. If there is a rotatory component it may cause a marginal shearing fracture. High energy injuries are more likely to provoke an associated fracture (capitellum, coronoid or even olecranon). MCL ligament injuries are very frequently associated.

AP, lateral and oblique elbow radiographs usually provide sufficient information for diagnosis and deciding on treatment. CT scan of the elbow in some cases can be very useful if surgery is needed, or in doubtful cases after plain radiography (for more complex cases).

Radial head fractures have been classified by Mason.<sup>68</sup>

- Type I—undisplaced
- Type II—displaced wedge fragment
- Type III—comminuted fracture
- Type IV—fracture associated with elbow dislocation.

Most radial head fractures are minimally displaced or non-displaced (type I) and are very difficult to see on radiographs. Sometimes the only clue is the fat pad sign, which appears as a triangular radiolucency just in front of the elbow joint. Early aspiration, splinting with an easily removable device and early commencement of a range of motion program will yield excellent results. Complete healing can be expected within 6–8 weeks.

Open reduction and internal fixation of displaced type II radial head fractures should only be attempted when anatomic reduction, restoration of articular congruity and initiation of early motion can be achieved. If these goals are not obtainable, open reduction and internal fixation may lead to early fixation failure, non-union, and loss of elbow and forearm motion and stability.

Comminuted radial head fractures are frequently associated with elbow dislocation and other destabilising

injuries.<sup>69</sup> The scarce literature on the subject is of little help in defining optimal treatment.<sup>70</sup> Radial head excision in young or adult athletes with comminuted fracture of the radial head, associated with medial, lateral or interosseous ligament injury, has a poor clinical outcome. There is currently more emphasis on preservation or replacement of the radial head, attempting to avoid radial head excision if at all possible.<sup>70, 71</sup>

### Coronoid fractures

The coronoid process provides an anterior bony buttress to resist the posteriorly directed forces that occur from the flexor/extensor muscles. Regan and Morrey in their study<sup>72</sup> showed a correlation between coronoid fragment size and a tendency for elbow dislocation.

Coronoid fracture can be isolated, but most commonly occurs in association with radial head fracture and elbow dislocation ('terrible triad'). The injury pattern is determined by the position at the time of injury and the loading pattern across the elbow. A common mistake is to misidentify a coronoid fragment as a radial head fragment. Coronoid fractures have been classified on the base of anatomic location of the primary fracture:

- tip (anteromedial facet)
- body.

Plain AP, lateral and oblique lateral radiograph views can be helpful and CT scan is highly useful.

#### PRACTICE PEARL

Dislocated elbow with radial head fracture usually has an associated coronoid fracture. The coronoid fragment is always bigger than it appears on the radiograph because of the articular cartilage cup on the fragment.

Caution is required when treating isolated coronoid fractures as they appear benign, but usually are fracture subluxations with ligament avulsion. Many of these fractures require some form of surgical treatment by specialised elbow surgeons.

### Posterior dislocation

The most serious acute elbow injury is a posterior dislocation. This can occur either in contact sports or when falling from a height such as while pole vaulting. There is often an associated fracture of the coronoid process or radial head. The usual mechanism is a posterolateral rotatory force resulting from a fall on an outstretched hand with the shoulder abducted, axial compression, forearm in supination and then forced flexion of the elbow.<sup>73</sup>

There are three grades of elbow dislocation:<sup>73</sup>

1. subluxation of the elbow in the posterolateral direction
2. incomplete elbow dislocation with the coronoid perched on the trochlea
3. complete posterior dislocation of the elbow, so that the coronoid rests behind the trochlear
  - a. where the anterior band of the MCL is intact and the elbow is stable to valgus stress following reduction
  - b. where the MCL is completely disrupted so the elbow is unstable in all directions after reduction.

This pattern of dislocation is associated with progressive soft tissue disruption that commences laterally and progresses around anteriorly, medially and posteriorly, termed the Horii circle described by O'Driscoll.<sup>74</sup>

The major complication of elbow dislocation is impairment of the vascular supply to the forearm. Assessment of pulses distal to the dislocation is essential. If pulses are absent, reduction of the dislocation is required urgently. Reduction is usually relatively easy. With the elbow held at 45°, the clinician stabilises the humerus by gripping the anterior aspect of the distal humerus and traction is placed longitudinally along the forearm with the other hand (Fig. 25.22). The elbow usually reduces with a pronounced clunk. If vascular impairment persists after reduction, urgent surgical intervention is required.

Following reduction, the stability of the collateral ligaments should be assessed (Fig. 25.17a). A post-reduction radiograph should also be performed. Small fractures of the coronoid process or undisplaced fractures of the radial head only require conservative treatment with support in a sling for 2-3 weeks. Large coronoid fractures, however, may result in chronic instability and should be reduced and fixed surgically. Large fractures of the radial head may be difficult to manage, but in most cases can be internally fixed. Occasionally, a large fracture of the capitellum may

**Figure 25.22** Technique for reduction of posterior dislocation of the elbow

occur. This also requires internal fixation. Sometimes a piece of bone becomes trapped in the joint after reduction. This needs to be excluded with good quality post-reduction radiographs.

Acute injuries at the elbow after subluxation or dislocation are best treated non-surgically, with brace or splint keeping the forearm in pronation to allow the lateral ligament complex to heal. Long-term loss of terminal extension is frequently a problem following elbow dislocation. Immediate active mobilisation under supervision has been shown to result in less restriction of elbow extension with no apparent increase in instability.<sup>75</sup> Professional athletes with a simple dislocation with no associated fracture or instability are able to return to sports relatively quickly after an appropriate rehabilitation program. Verrall described three cases of stable dislocations in professional footballers who returned to sport after 7, 13 and 21 days with no further complications.<sup>76</sup> Joint mobilisation (Fig. 25.23) may be required as part of the treatment.<sup>31</sup> The surrounding muscles should also be strengthened. Elbow stability taping should be applied on return to the sport (Fig. 25.17b).

Heterotopic ossification occasionally occurs following elbow dislocation. The use of NSAIDs for a period of three months following the injury may reduce the incidence of this complication.

Elbow dislocations in directions other than posterior occur occasionally. These are often associated with severe ligamentous disruption and patients should be referred to an orthopaedic surgeon immediately.

### Instability post-dislocation

When the competency of the soft tissue restraints after elbow dislocation or injury is inadequate, it can lead to recurrent elbow instability. The condition is more common in some sports than has previously been recognised. On the lateral side, instability is posterolateral and rotatory. On the medial side it is valgus.

Athletes with posterolateral rotatory instability (PLRI) usually present with the symptoms after an elbow subluxation or dislocation. Less commonly there is a history of previous lateral elbow surgery (iatrogenic) for tennis elbow. Recurrent lateral instability is always rotatory.<sup>77</sup> PLRI is defined as a posterior radial head subluxation relative to the humerus while maintaining normal relationship at the proximal RU joint. O'Driscoll et al. identified the ulnar part of the lateral collateral ligament as the key lateral soft tissue restraint preventing posterolateral rotatory instability;<sup>77</sup> however, the radial collateral ligament also contributes to both varus and posterolateral stability.

The patient with PLRI presents with recurrent painful clicking, snapping, clunking or locking of the elbow occurring in extension of the arm with the forearm in

(a)

(b)

**Figure 25.23** Examples of mobilisation with movement techniques that use a glide out of the plane of extension to improve extension (a) Sustained lateral glide applied through a belt while assisted active extension is performed (b) Sustained internal rotation

supination. Typically these symptoms are more prominent with loading of the joint in the supinated and slightly flexed position. Several provocative manoeuvres have been described, including the posterolateral rotatory apprehension test (or lateral pivot shift test)<sup>77</sup> and the chair and push-up tests.<sup>78</sup>

Chronic PLRI does not respond well to conservative treatment and usually requires ligament reconstruction with a free ligament autograft (ipsilateral palmaris longus, gracilis, semitendinosus, triceps). Published studies on the clinical outcome after surgical treatment of chronic PLRI demonstrate mostly good and excellent outcomes.<sup>79, 80</sup>

### Acute rupture of the medial collateral ligament

Acute rupture of the MCL may occur in a previously damaged ligament or in a normal ligament subjected to extreme valgus stress, for example elbow dislocation. In a study of 14 MCL injuries in American National Football League (NFL) gridiron players,<sup>81</sup> the two most common mechanisms of injury were blocking at the line

of scrimmage (50%) and the application of a valgus force with the hand planted on the playing surface (29%). The degree of laxity should be assessed by applying valgus stress to the elbow at 30° of flexion (Fig. 25.17a). If complete disruption is present with associated instability, surgical repair of the ligament is required. Incomplete tears should be treated with protection in a brace and muscle strengthening exercises for a period of 3–6 weeks, followed by graduated return to sports.

### Tendon ruptures

Acute avulsion of the biceps or triceps tendons from their insertions is a rare condition. Rupture of the distal biceps tendon insertion occurs predominantly in young or middle-aged men engaged in strength activities (e.g. weightlifting). Partial ruptures are more painful than complete ruptures, due to mechanical irritation of the remaining intact tendon. Early surgical repair of complete ruptures would be expected to lead to better outcomes, as complete rupture of tendons leads to degenerative processes due to the loss of mechanical load. Rupture of the triceps tendon occurs

most commonly with excessive deceleration force, such as occurs during a fall or by a direct blow to the posterior aspect of the elbow. Partial and complete triceps ruptures are seen in NFL linemen.<sup>34</sup> Partial tears tend to heal well without surgery. Acute complete ruptures at the insertion of either of these tendons should be treated surgically.

### Hyperextension injuries

Hyperextension injuries caused by direct force to the forearm pushing the elbow into hyperextension may be acute, in which case the athlete is usually unable to continue activity, or repetitive, when the athlete feels sudden pain but is able to continue. These injuries are probably more common than previously thought.

Kenter et al. reported that hyperextension was the most common (56%) cause of acute elbow sprain in NFL players.<sup>81</sup> Hyperextension injuries are common (75%) in goalies in handball.<sup>82, 83</sup> Hyperextension of the elbow is caused by the ball hitting the fully extended distal part of the forearm when blocking a shot. This injury is frequently bilateral. Most handball goalkeepers could usually remember their first elbow accident. The goalies routinely minimise their symptoms in an attempt to continue to play, despite the fact that the injury affects their performance. Their first symptoms (pain) usually began acutely but developed into chronic elbow pain, with intermittent pain as the chief complaint. There are reports of similar mechanisms of injuries in other sports such as water polo players, soccer goalkeepers, volleyball players, wrestlers and judo practitioners.

The force of the blow of the ball to the forearm produces a valgus load on the elbow, applying stress to the anterior band of the MCLC. Specific injuries include (i) lesions of the anterior capsule including rupture, (ii) L-shaped rupture of the flexor/pronator origin with elongation of the anterior part of the MCL, (iii) occasional incomplete rupture of the LCL and, rarely, (iv) detachment of small fragments of cartilage near the posterior edge of the olecranon. Imaging studies (ultrasound/MRI) can confirm the diagnosis.

## FOREARM PAIN

### Fracture of the radius and ulna

The bones of the forearm are commonly injured by a fall on the back or front of the outstretched hand. It is usual for both bones to break, although a single bone may be fractured in cases of direct violence or in fractures of the distal third where there is no shortening.

A displaced fracture is usually clinically obvious. Plain radiographs should be taken for post-reduction comparison and for exclusion of a concurrent dislocation. Two types of dislocation occur—the Monteggia injury (fractured ulna with dislocated head of the radius at the elbow joint) and

the Galeazzi injury (fractured radius with dislocated head of the ulna at the wrist joint).

In the child, angulation of less than 10° is acceptable. Other fractures should be reduced under local or general anaesthesia depending on the age of the child. The usual position for immobilisation is in pronation, although in proximal radial fractures and in Smith's fracture at the wrist, the forearm should be held in supination. The plaster should extend above the elbow and leave the metacarpophalangeal joints free. Depending on the age of the child, immobilisation should last 4–6 weeks. The position should be checked by radiography every 1–2 weeks depending on stability.

In the adult, perfect reduction of radial and ulnar fractures is necessary to ensure future sporting function. Most of these fractures are significantly displaced and require anatomical internal fixation with a plate and screws. Depending on the accuracy of reduction, either a cast or a crepe bandage support is required post-operatively for 8–10 weeks. Isolated fractures of the ulna are treated conservatively by an above-elbow cast in mid-pronation for 8 weeks. Monteggia and Galeazzi injuries are usually displaced and should be referred to an orthopaedic surgeon for reduction.

### Stress fractures

Stress fractures of the forearm bones occur occasionally in athletes involved in upper limb sports, such as baseball, tennis or swimming. Treatment involves rest and correction of the possible predisposing factors, such as faulty technique.

### Entrapment of the posterior interosseous nerve (radial tunnel syndrome)

The radial nerve divides into the superficial radial and the posterior interosseous nerve at the level of the radiocapitellar joint (Fig. 25.24). The posterior interosseous nerve (PIN) passes distal to the origin of the ECRB and enters the arcade of Frohse. Prior to entering the arcade of Frohse, it gives off branches to the ECRB and supinator muscles. The arcade is a semicircular fibrous arch at the proximal head of the supinator muscle, which begins at the tip of the lateral epicondyle and extends downwards, attaching to the medial aspect of the lateral epicondyle. The PIN then emerges from the supinator muscle distally, where it divides into terminal branches that innervate the medial extensors. Compression of the PIN may occur at one of four sites:<sup>84</sup>

- fibrous bands anterior to the radial head
- recurrent radial vessels
- arcade of Frohse
- tendinous margin of the extensor carpi radialis brevis muscle.

**Figure 25.24** Anatomy of the posterior interosseous nerve

It may be difficult to differentiate between lateral elbow tendinopathy and the early stages of PIN entrapment. PIN entrapment is seen in patients who repetitively pronate and supinate the forearm, whereas lateral elbow tendinopathy is more frequently associated with repetitive wrist extension. Symptoms of PIN entrapment include paraesthesia in the hand and lateral forearm, pain over the forearm extensor mass, aching wrist and middle or upper third humeral pain. It is these symptoms that critically differentiate this condition from lateral elbow tendinopathy.

Maximal tenderness is over the supinator muscle, four finger breadths below the lateral epicondyle (distal to the area of maximal tenderness in extensor tendinopathy). Reproduction of symptoms by manual palpation of these local structures and the relief of such palpation-induced symptoms by injection of local anaesthetic should be considered as part of the physical examination.<sup>85</sup> Nerve entrapment also causes marked pain on resisted supination of the forearm with the elbow flexed to 90° and the forearm fully pronated. Neurodynamic tests (with radial nerve bias) may reproduce the patient's symptoms, and nerve conduction studies may be performed to confirm the diagnosis.

Treatment consists of soft tissue therapy over the supinator muscle at the site of entrapment and neural tissue mobilisation, along with exercises targeting strength and endurance deficits in the forearm muscles. If this is unsuccessful, decompression surgery may be required.

### Pronator teres syndrome (median nerve entrapment)

The median nerve can become entrapped as it passes between the two heads of the pronator teres muscle. Median nerve entrapment presents as diffuse anterior elbow pain that radiates distally into the forearm with paraesthesia in the median nerve distribution distally and weakness of the thenar muscles. The most common cause in athletes is forceful pronation, for example throwing or racquet sports.

A similar clinical picture can be produced by cervical radiculopathy at C6–7 level, compression of the median nerve underneath the lacertus fibrosis or by the ligament of Struthers. The diagnosis can be confirmed on nerve conduction studies.

Activity modification is the first line of treatment. Surgical resection of the humeral head of pronator teres is occasionally required.

### Forearm compartment pressure syndrome

Forearm compartment pressure syndromes have been described in kayakers, canoeists, motorcyclists (popularly termed 'arm pump' in motorcross) and weight-training athletes. The flexor compartment is most usually affected. Symptoms include activity-related pain that is relieved by rest. Diagnosis requires compartment pressure testing. Treatment consists of local soft tissue therapy. Surgical fasciotomy may be required.

### UPPER ARM PAIN

An aching pain in the upper arm is a common complaint, especially among manual workers (e.g. bricklayers, carpenters) and athletes. The most common cause is myofascial pain, but stress fracture of the humerus needs to be considered.

### Myofascial pain

A dull non-specific pain in the upper arm is most likely to be myofascial in nature. The most common source of the upper arm pain is trigger points in the infraspinatus muscle (Fig. 25.25). Firm palpation of these trigger points will often reproduce the patient's pain. The cervical spine and glenohumeral joint need to be assessed for their possible involvement and treatment directed accordingly.

Treatment consists of digital ischaemic pressure or dry needling to the trigger points. Attention should also be paid to the lower cervical and upper to mid-thoracic spine. Increased muscle tone and trigger points may be found in the paraspinal muscles, and hypomobility of the intervertebral segments may be present. These abnormalities must also be treated with soft tissue techniques.

**Figure 25.25** Myofascial trigger points around the shoulder region that refer pain to the upper arm

### Stress reaction of the humerus

Stress reactions and fractures of the humerus have been described in tennis players, javelin throwers, baseball pitchers, bodybuilders and weightlifters. In a group of symptomatic elite tennis players, MRI of the humerus demonstrated bone marrow oedema and/or periostitis, and the extent of imaging changes was related to the severity and duration of symptoms.<sup>86</sup> Most of the fractures occurred in adolescents and were associated with a recent increase in activity. In a number of cases the diagnosis was made retrospectively when an acute fracture occurred and the patient admitted symptoms leading up to the acute episode.

Recommended treatment follows the general principles of management of simple stress fractures: avoidance of the aggravating activity until symptom-free with no local tenderness, then gradual resumption of the activity.

# Wrist pain

with GREGORY HOY and HAMISH ANDERSON\*

*Laura Robson admits she will have to start her career all over again after she recovers from major wrist surgery. Robson said she 'felt like a child again' in the aftermath of her operation, struggling to dress herself and cut her own food. Itching to return to action, Robson said she has been reduced to tears, at times frustrated with rehabilitation while her peers train and compete.*

Sky Sports, 20 June 2014

The wrist is frequently injured during sport.<sup>1</sup> Distal radial fractures are common, as are scaphoid fractures and tendon problems. Carpal instabilities are less frequent but often career threatening.

Men are more likely to sustain a hand or wrist injury<sup>2</sup> and children/adolescents are more likely to have a wrist injury compared with adults.<sup>3</sup> Injuries to the wrist range from acute traumatic fractures, such as occur during football, hockey and snowboarding, to overuse conditions, which occur more commonly in racquet sports, golf and gymnastics. If wrist injuries are not treated appropriately at the time of injury, they can lead to future impairments that may affect not only sporting endeavours, but also activities of daily living.<sup>4</sup>

In this chapter, we will assess wrist injuries from an anatomical viewpoint, based on the site of pain. They are:

- radial-sided wrist pain, both acute and chronic
- central wrist pain, including volar and dorsal
- ulnar-sided wrist pain.

The differential diagnoses of wrist pain are listed in Table 26.1.

### CLINICAL APPROACH

The wrist joint has multiple axes of movement: flexion/extension and radial/ulnar deviation occur at the radio-carpal and midcarpal joints, and pronation/supination occurs at the distal and proximal radio-ulnar joints. These movements provide mobility for hand function.

The anatomy of the wrist is complex (Fig. 26.1). It is helpful to know the surface anatomy of the scaphoid

tubercle, hook of hamate, pisiform, Lister's tubercle and anatomical snuffbox. The bony anatomy consists of a proximal row (lunate, triquetrum, pisiform) and a distal row (trapezium, trapezoid, capitate, hamate), which are bridged by the scaphoid bone. Normally, the distal carpal row should be stable; thus, a ligamentous injury here can greatly impair the integrity of the wrist. The proximal row permits more intercarpal movement to allow wrist flexion/extension and radial and ulnar deviation. Here, a ligamentous injury disrupts important kinematics that have been recently labelled the 'dart thrower's motion' between the radius, scaphoid, lunate and the capitate in the central column, resulting in carpal instability with potential weakness and impairment of hand function. Recognising these ligamentous injuries early is not just important for athletic performance, but also for minimisation of any subsequent post-traumatic arthritis.

### History

It is essential to determine the mechanism of the injury (if there is one) causing wrist pain. A fall on the outstretched hand may be severe enough to fracture the scaphoid or distal radius, or damage the intercarpal ligaments and/or triangular fibrocartilage complex. These injuries are commonly encountered in high-velocity activities such as snowboarding,<sup>5</sup> rollerblading<sup>6, 7</sup> or falling off a bike. A patient may fracture the hook of hamate while swinging a golf club,<sup>8</sup> tennis racquet or bat and while striking a hard object (e.g. the ground). Rotational stress to the distal radio-ulnar joint and forced ulnar deviation and rotation may tear the triangular fibrocartilage complex.

**Table 26.1** Causes of wrist pain divided into regions

Zone	Common	Less common	Not to be missed
<b>Dorsal wrist</b>			
Radial zone	Extensor carpi radialis tenosynovitis De Quervain's tenosynovitis (volleyball) Scaphoid fracture Distal radius fracture (often intra-articular in the athlete)	Intersection syndrome (rowing/paddling) Anterior interosseous nerve compression Radial sensory nerve compression (volleyball) Extensor pollicis longus impingement on Lister's tubercle with occasional rupture (gymnastics)	Carpal dislocation Radial epiphyseal stress reaction (gymnastics)
Central zone	Posterior interosseous nerve/radial nerve entrapment Ganglion cyst Scapholunate ligament sprain (football)	Impingement syndromes: lunate (gymnastics); capitate (weightlifting); triquetrohamate (racquet sports); radial styloid (golf)	Scapholunate dissociation Perilunar dislocation Kienbock's disease
Ulnar zone	Extensor carpi ulnaris tenosynovitis (golf/tennis) Triangular fibrocartilage complex tear (water skiing) Ulnar styloid fracture Triquetral fracture (boxing)	Distal radioulnar joint instability Luno-triquetral ligament sprain Ulnar fracture Extensor carpi ulnaris subluxation (cricket)	Lunotriquetral dissociation
<b>Volar wrist</b>			
Radial zone	Carpometacarpal osteoarthritis	Flexor carpi radialis tendinopathy	Carpal instability
Central zone	Carpal tunnel syndrome (motorcycling)	Pisotriquetral degenerative joint disease	
Ulnar zone	Thoracic outlet syndrome Lunotriquetral ganglion	Hook of hamate fracture (golf) Ulnar nerve compression at Guyon's canal (cycling, baseball) Flexor carpi ulnaris tendinopathy	Anterior dislocation of lunate Traumatic ulnar artery aneurysm or thrombosis (karate)

When a patient presents with gradual-onset or chronic wrist pain, the clinician should consider whether the pain may be a manifestation of a systemic condition (e.g. metabolic disorder or spondyloarthopathy, see Chapter 7). Also, the clinician should rule out an uncommon presentation of radiating pain from a more proximal problem such as a herniated cervical disc.

A detailed history will reveal whether the problem stems from an overuse condition (e.g. tenosynovitis), or from an acute injury that has not been correctly diagnosed or treated. Some patients suffer only minor discomfort at the time of an initial injury and fail to seek attention at that time. Factors that aggravate the pain provide useful information as to which structures are involved in chronic wrist pain.

Pain after repeated movement, with stiffness after a period of rest, suggests an inflammatory condition such as tenosynovitis. Pain aggravated by weight-bearing activities, such as gymnastics or diving, suggests bone or joint involvement. A history of joint clicking may be

**(a)****Figure 26.1** Anatomy of the wrist (a) Carpal bones (MC = metacarpal)

(b)

(d)

(c)

(e)

**Figure 26.1 (cont.)** (b) Surface anatomy, dorsal view (c) Surface anatomy, volar view (d) Dorsal aspect (e) Volar aspect

associated with carpal instability, triangular fibrocartilage tears or extensor carpi ulnaris subluxation. Characteristic night pain, with or without paraesthesia, is found in carpal tunnel syndrome. Associated neck or elbow symptoms suggest referred pain.

Other important aspects of the history may include:

- hand dominance
- occupation (e.g. computer-related, manual labour, food service industry)

- degree of reliance upon hands in occupation/recreation
- musician (number of years playing, hours of practice per week, change in playing, complex piece, etc.)
- gardening, crafts, hobbies.
- history of past upper extremity fractures including childhood fractures/injuries
- history of osteoarthritis, rheumatoid arthritis, thyroid dysfunction, diabetes
- any unusual sounds (e.g. clicks, clunks, snaps, etc.)
- recurrent wrist swelling raises the suspicion of wrist instability

## Physical examination

Examination involves:

1. Observation (Fig. 26.2a)  
Inspection may reveal a ganglion on the dorsum of the wrist. Swelling over the radial styloid may indicate de Quervain's tenosynovitis. Muscle wasting of the thenar or hypothenar eminence is found in the late stages of median or ulnar nerve compression, respectively.
2. Active movements
  - a. flexion/extension
  - b. supination/pronation
  - c. radial/ulnar deviation (Fig. 26.2b)
3. Passive movements
  - a. extension (Fig. 26.2c)
  - b. flexion (Fig. 26.2d)
4. Palpation  
Palpate the wrist to detect tenderness and to determine whether the pathology appears to be extra-articular (i.e. soft tissue) or articular.
  - a. distal forearm (Fig. 26.2e)
  - b. radial snuffbox (Fig. 26.2f)
  - c. base of metacarpals
  - d. lunate (Fig. 26.2g)
  - e. head of ulna (Fig. 26.2h)
  - f. radio-ulnar joint
  - g. hamate/pisiform (Fig. 26.2i)
  - h. tuberosity of trapezium

On the volar aspect of the wrist, palpate the tuberosity of the trapezium as a bony prominence at the base of the thenar eminence.
5. Special tests
  - a. Watson's test for scapholunate injury (Fig. 26.2j)
  - b. stress of triangular fibrocartilage complex (Fig. 26.2k)
  - c. ulnar fovea sign for foveal disruption and ulnar triquetral ligament injury (Fig. 26.2l)
  - d. press test for triangular fibrocartilage complex pain (Fig. 26.2m)

- e. Finkelstein's test (Fig. 26.2n)
- f. Tinel's sign for nerve entrapment (Fig. 26.2o)
- g. Phalen's test for carpal tunnel syndrome
- h. two point discrimination (Fig. 26.2p).

The clinical utility of selected assessment findings is shown in Table 26.2.

## Key outcome measures

Several valid and reliable assessment scales can quantify function of the wrist specifically or the upper extremity after an injury. These include the Patient Rated Wrist Evaluation (PRWE),<sup>15, 16</sup> the Disability of the Arm, Shoulder and Hand (DASH and QuickDASH)<sup>17, 18</sup> and the Mayo Wrist Score<sup>19</sup> (Table 26.3).

## Investigations

### Plain radiography

Plain radiographs taken should include a posteroanterior (PA) view and a PA with both radial and ulnar deviation. If ligament injury is suspected, also obtain a PA view with clenched fist. A straight lateral, with the dorsum of the distal forearm and the third metacarpal forming a straight line, permits assessment of the distal radius, the lunate (or 'intercalated segment'), the scaphoid and the capitate, and may reveal subtle instability called DISI (dorsal intercalated segment instability) or VISI (volar intercalated segment instability). Undisplaced distal radial and scaphoid fractures, however, may be difficult to see on initial radiographs; clinical suspicion warrants use of other modalities (see 'Special imaging studies', below).

The normal PA view is shown in Figure 26.3a. Inspect each bone in turn. Note the line joining the proximal ends of the proximal row of the carpus and the C shape of the midcarpal joint (Gilula's arcs). If these lines are not smooth, a major abnormality is present. Assess the size of the scapholunate gap and look for scaphoid flexion (the signet ring sign) as these are signs of scapholunate instability.

The lateral radiograph of the normal wrist can be seen in Figure 26.3b. The proximal pole of the lunate fits into the concavity of the distal radius and the convex head of the capitate fits into the distal concavity of the lunate. These bones should be aligned with each other and with the base of the third metacarpal.

A clenched fist PA view should be taken if scapholunate instability is suspected. This is indicated by a widened gap of 3 mm or greater between the scaphoid and lunate on the PA view, but this may not present until some time after a scapholunate tear.

(a)

(b)

**Figure 26.2** Examination of the patient with an acute wrist injury (a) Observation—inspect the wrist for obvious deformity suggesting a distal radial fracture. Swelling in the region of the radial snuffbox may indicate a scaphoid fracture. Inspect the hand and wrist posture, temperature, colour, muscular wasting, scars, normal arches of the hand (b) Active movement—radial/ulnar deviation. Normal range is radial  $20^\circ$  and ulnar  $60^\circ$ . Pain and restriction of movement should be noted. Always compare motion with that of the other hand (c) Range of motion—extension (the ‘prayer position’). Normal range of motion in wrist extension is  $70^\circ$  (d) Range of motion—flexion (the ‘reverse prayer position’). Normal range of motion in wrist flexion is  $80\text{--}90^\circ$

(c)

(d)

(e)

(g)

(f)

(h)

**Figure 26.2 (cont.)** (e) Palpation—the distal forearm is palpated for bony tenderness or deformity (f) Palpation—radial snuffbox. The proximal snuffbox is the site of the radial styloid, the middle snuffbox is the site of the scaphoid bone, while the distal snuffbox is over the scaphotrapezial joint (g) Palpation—the lunate is palpated as a bony prominence proximal to the capitate sulcus. Lunate tenderness may correspond to a fracture. On the radial side of the lunate lies the scapholunate joint, which may be tender in scapholunate ligament sprain. This is a site of ganglion formation. On the ulnar side of the lunate lies the triquetrolunate ligament. Tenderness and an associated click on radial and ulnar deviation of the wrist may occur with partial or complete tears of this ligament (h) Palpation—head of ulna and ulnar snuffbox. Swelling and tenderness over the dorsal ulnar aspect of the wrist is present with fractures of the ulnar styloid. Distal to the ulnar head is the ulnar snuffbox. The triquetrum lies in this sulcus and can be palpated with the wrist in radial deviation. Tenderness may indicate triquetral fracture or triquetrolunate injury. The triquetrohamate joint is located more distally. Pain here may represent triquetrohamate ligament injury

#### PRACTICE PEARL

Scapholunate instability cannot be excluded on a normal plain radiograph as the instability is initially dynamic, occurring only with grip.

#### Special imaging studies

The combination of the complex anatomy of the wrist and subtle wrist injuries that can cause substantial

morbidity has led to development of specialised wrist imaging techniques. Scaphoid views should be requested if a scaphoid fracture is suspected. A carpal tunnel view with the wrist in dorsiflexion allows inspection of the hook of hamate and the ridge of the trapezium. For suspected mechanical pathology, such as an occult ganglion, an occult fracture, non-union or bone necrosis, several modalities are useful (e.g. ultrasonography, radionuclide bone scan, computed tomography (CT) scan or magnetic resonance imaging (MRI) scan).

(i)

(k)

ulnar deviation

radial deviation

(l)

(j)

**Figure 26.2 (cont.)** (i) Palpation—the pisiform is palpated at the flexor crease of the wrist on the ulnar side. Tenderness in this region may occur with pisiform or triquetral fracture. The hook of hamate is 1 cm (0.5 in.) distal and radial to the pisiform. Examination may show tenderness over the hook or on the dorsal ulnar surface (j) Special test—Watson's test for scapholunate instability. The examiner places the thumb on the scaphoid tuberosity as shown, with the wrist in ulnar deviation. The wrist is then deviated radially with the examiner placing pressure on the scaphoid. If the athlete feels pain dorsally (over the scapholunate ligament) or the examiner feels the scaphoid move dorsally, then scapholunate dissociation is present (k) Special test—triangular fibrocartilage complex integrity. The wrist is placed into dorsiflexion and ulnar deviation and then rotated. Overpressure causes pain and occasionally clicking in patients with a tear of the triangular fibrocartilage complex (l) Special test—ulnar fovea sign for foveal disruption and ulnar triquetral ligament injury

Ultrasonography is a quick and accessible way to assess soft tissue abnormalities such as tendon injury, synovial thickening, ganglions and synovial cysts. Bone scans have high sensitivity but low specificity; thus, they can effectively rule out stress fractures, although MRI may be equally sensitive and more specific than a bone scan.

CT scanning is particularly useful for evaluating fractures that are difficult to assess fully on plain radiography, but MRI

can also provide information about soft tissue injuries. Thus, a complete scapholunate ligament tear is more effectively identified with MRI than with CT.

Arthrography of the wrist is no longer used as an investigative tool except in combination with MRI—MR arthrogram or MRA. If all imaging results are negative but clinically significant wrist pain persists, the clinician should refer the patient to a specialist for further evaluation.

(m)

**Figure 26.2 (cont.)** (m) Special test—press test (or 'sitting hands' test). Attempting to raise body weight from a chair reproduces the pain of the triangular fibrocartilage complex injury (n) Special test—Finkelstein's test to detect de Quervain's disease. The thumb is placed in the palm of the hand with flexion of the metacarpophalangeal and interphalangeal joints while the examiner deviates the wrist in the ulnar direction (o) Special test—Tinel's sign. Tapping over the median nerve at the wrist produces tingling and altered sensation in the distribution of the median nerve in carpal tunnel syndrome (p) Special test—two point discrimination. Assessment of fine sensory ability. Apply the two points with even pressure horizontally over the medial and lateral aspects of the distal phalanx, starting wide and becoming narrower, with single point comparison

## RADIAL COLUMN PRESENTATIONS

### Fracture of the distal radius

Distal radius fractures are very common peripheral fractures.<sup>23</sup> As the force required to fracture young adults' bones is great, athletes may simultaneously incur an

intra-articular fracture and ligamentous strain or rupture. The higher the forces involved (e.g. in high-velocity sports), the greater the likelihood of a complex injury involving articular structures (Fig. 26.4). Thus, thorough assessment of ligamentous injury is essential when fractures occur.

**Table 26.2 Clinical utility of selected assessment findings for wrist pain**

Test	What is a positive finding?	Sensitivity	Specificity	LR+	LR–
<b>Carpal tunnel syndrome</b>					
Phalen's test <sup>9</sup>	Reproduction of symptoms	0.92	0.88	2.68	0.54 <sup>10</sup>

(a)

(b)

**Figure 26.3** Radiograph of the wrist (a) PA view—Gilula's arcs (b) Lateral view

Initial treatment of the fracture is anatomical reduction, which should be done even if later internal fixation is contemplated, thus reducing swelling and making later anatomical alignment more likely.

Conservative management by reduction and casting with radiological follow-up at 3 and 6 weeks is appropriate for stable fractures post-reduction with minimal risk of displacement. Casts should be moulded with the wrist flexed to no more than 20° and slight ulnar deviation, and permit full finger motion. As oedema reduces, the cast should be changed. There is no evidence to support the use of thermoplastic splints or braces for acute distal radius fracture.<sup>24</sup>

Surgical intervention with early mobilisation for distal radius fracture has become the norm, with a particular emphasis on volar, locked plating. In spite of Cochrane reviews not being able to prioritise one surgical method over another, volar plating is being increasingly adopted.<sup>25</sup> Volar plating avoids the complications associated with external fixation and the surgical experience demands of fragment-specific fixation, as well as reducing the risk of extensor tendon rupture associated with dorsal plates.<sup>25</sup> Indications for open reduction are dorsal comminution, intra-articular involvement, instability on reduction, dorsal angulation of more than 20°, an articular surface step of greater than 1 mm, or radial shortening of greater than 5 mm, with anatomical alignment a necessity to avoid ongoing functional impairment.<sup>26, 27</sup>

Post-operatively, there is little published evidence for early mobilisation with reference to long-term results;<sup>24, 28</sup> however, a stable fixation, control of oedema and a controlled early mobilisation program in the athlete is crucial to an early return to sport, accompanied by suitable brace protection if appropriate. Inaccurate reduction, articular surface angulation, radial inclination or inadequate restoration of length all require early internal fixation with fixed angle-volar plating, although relative indications such as return-to-sport timelines and career goals are now just as important to the athlete.<sup>29, 30</sup> Overall, there is a trend to more aggressive treatment using volar plating and this has led to improved functional outcomes, especially in the young active adult.

### Fracture of the scaphoid

The most common carpal fracture involves the scaphoid<sup>4</sup> and the usual mechanism is a fall on the outstretched hand. As pain may settle soon after the fall, presentation may be late after injury. The key examination finding is tenderness in the anatomical snuffbox. This may be accompanied by swelling and loss of grip strength. A more specific clinical test for scaphoid fracture is pain on axial compression of

(a)

(b)

**Figure 26.4** Fracture of radius (a) Coronal CT of comminuted fracture of radius (b) Axial CT of comminuted fracture of radius

the thumb towards the radius or direct pressure on the scaphoid tuberosity with radial deviation of the wrist. Plain radiographs with special scaphoid views will usually demonstrate the fracture (Fig. 26.5a), but CT scan may be required to detect more subtle fractures (Fig. 26.5b).

Scaphoid fracture is the most commonly missed fracture leading to litigation. If there is no bony damage, scapholunate instability should also be considered (see below).

#### PRACTICE PEARL

If a scaphoid fracture is suspected clinically but the radiograph is normal, a fracture cannot be ruled out. CT is an ideal diagnostic test for an acute injury that may be cost-saving in some settings. Note that it can take 24 hours for the injury to be revealed on MRI.

#### Traditional treatment of stable and unstable scaphoid fractures

A stable scaphoid fracture (including stress fractures of the scaphoid, which occur in high-board divers and gymnasts<sup>31</sup>) may be immobilised for eight weeks in

(a)

**Figure 26.5** Scaphoid fracture (a) Plain radiograph of subtle scaphoid fracture (arrow)

(b)

**Figure 26.5 (cont.)** (b) CT requested in plane of scaphoid shows scaphoid fracture (arrow)

a scaphoid cast extending from the proximal forearm to, but not including, the interphalangeal joint of the thumb (Fig. 26.6a). Upon removing the cast, re-evaluate the fracture clinically and radiologically. Unstable, angulated ( $>15\text{--}20^\circ$ ) or significantly displaced fractures (diastasis in the fracture gap  $>1.5\text{ mm}$ ) require immediate percutaneous fixation (Fig. 26.6b) or open reduction and internal fixation. There are initial reports of using scaphoid plates but no long-term follow-up.

#### PRACTICE PEARL

##### Current treatment of scaphoid fractures

The most reliable method of achieving scaphoid union with anatomic position is with internal fixation using mixed threaded (or graduated thread) screws which compress the scaphoid.

#### Complications of scaphoid fracture

The blood supply to the scaphoid originates distally (Fig. 26.7a), so the flow to the proximal pole can be diminished, which can then be at risk of necrosis after a fracture (Fig. 26.7b). Scaphoid fractures also have a risk of delayed union or non-union. Non-union and

(a)

(b)

**Figure 26.6** Treatment of scaphoid fractures (a) Cast immobilisation (b) Surgical fixation is now first-line treatment for scaphoid fracture

osteonecrosis can occur on their own or can occur in combination.<sup>32</sup>

If there is clinical evidence of incomplete union when the cast is removed, the fracture should be immobilised for a further four to six weeks. Further immobilisation beyond this time is unlikely to prove beneficial. CT scan is the investigation of choice to detect non-union, but MRI can be used if CT is not available.

(a)

(b)

**Figure 26.7** (a) The artery to the scaphoid enters via the distal pole, so a fracture at the waist of the scaphoid compromises the proximal fragment (b) MRI showing the characteristic hypointense appearance of avascular necrosis (arrow) in the proximal pole of the scaphoid

### Contemporary management of scaphoid non-union

Contemporary treatment of non-union requires specialist hand surgeon management. Simple non-unions may be treated with fixation with bone graft (if there is a deformity or there has been bone resorption), while osteonecrosis with or without non-union may require a vascularised bone graft.<sup>33</sup>

### Post-immobilisation wrist rehabilitation

Following successful treatment of a scaphoid fracture, the athlete can gradually return to activity using a protective device. Compression tubing worn under the protective splint reduces oedema and improves comfort. Different sports have different rules about what constitutes an 'allowable' protective cast (Fig. 26.8).

### Fracture of the trapezium

Fractures of the trapezium make up 1-5% of carpal fractures. The most common pattern is a vertical, intra-articular fracture associated with axial compression from the thumb metacarpal. Rarely occurring in isolation, it often accompanies a Bennett's fracture. Presentation will be point tenderness and localised swelling, with the fracture itself best confirmed on CT scan (Fig. 26.9). Examination should be thorough because of the high

**Figure 26.8** Following a scaphoid fracture, the athlete may wear a protective cast

risk of associated fracture dislocation and/or fractures of neighbouring carpals.<sup>34</sup>

Intervention will be determined by the amount of displacement of the fracture. The risk of degenerative arthritis at the trapezial articulations is high for a displaced fracture in a young, active individual, and can lead to reduced carpometacarpal motion, with a painful pinch and grip. Surgery can involve percutaneous pinning or open reduction with screw fixation. Non-displaced fractures do well with thumb spica casting.

**Figure 26.9** CT scan of fracture of trapezium

### Radial epiphyseal injury (gymnast's wrist)

Skeletally immature athletes may place substantial compressive and shear forces across the distal radial physes, making them prone to growth arrest. Gymnasts, both elite and recreational, are particularly at risk of this injury, which occurs due to repetitive loading through a dorsiflexed wrist. It has been frequently hypothesised that this injury then puts them at risk of developing a positive ulnar variance; however, no definitive relationship has been established.<sup>35</sup>

The patient will present with dorsal wrist pain that is directly associated with activity. Radiographic changes in order of severity are haziness around the physis, cystic changes and/or metaphyseal sclerosis and widening of the physis itself (Fig. 26.10). Salter Harris V stress fracture should be considered if the growth plate is narrowed. The adolescent (ages 10–14) is more at risk than the younger athlete.<sup>36</sup>

Recovery can take several months and is activity dependent. Both athlete and family need to be aware of the long-term consequences of poor management. Treatment includes rest, adaptation of technique and forearm strengthening, particularly the flexors. Bracing to reduce hyperextension of the wrist has been shown in biomechanical studies to reduce load, and should be considered along with alternating swinging and loading skills during training.<sup>37</sup>

### De Quervain's tenosynovitis

De Quervain's tenosynovitis affects the synovium of the abductor pollicis longus and extensor pollicis brevis

tendons as they pass in their synovial sheath in a fibro-osseous tunnel at the level of the radial styloid (Fig. 26.11). This is a common radial-sided tendinopathy in athletes and occurs particularly with racquet sports, ten-pin bowlers, rowers and canoeists.

(a)

(b)

**Figure 26.10** Radial epiphyseal injury in gymnast showing widening of the radial growth plate indicating stress reaction (a) Anteroposterior wrist X-ray (b) Lateral wrist X-ray

**Figure 26.11** Site of compression in de Quervain's tenosynovitis

The left thumb of a right-handed golfer is particularly at risk because of the hyperabduction required during a golf swing. There will be local tenderness and swelling, which may extend proximally and distally along the course of the tendons. In severe cases, crepitus may be felt. A positive Finkelstein's test (Fig. 26.2n) is suggestive of the diagnosis; however, flexor carpi radialis tendinopathy also causes a positive test.

Treatment includes splinting, local electrotherapeutic modalities, stretches and graduated strengthening. Patients often find a pen build up (a rubber addition to enlarge the diameter of the pen) or golf grip widener useful as this reduces the stretch on the extensor tendons. An injection of corticosteroid and local anaesthetic into the tendon sheath will usually prove helpful.<sup>38</sup> In rare cases, surgical release is necessary.

### Intersection syndrome

Intersection syndrome is a true tendinitis that occurs between the first and second dorsal wrist tendon compartments (Fig. 26.12), just proximal to the extensor retinaculum. It may be due to friction at the site of crossing or it may also

arise from compartment syndrome of the thumb extensors, causing a tight band over the wrist extensors. Tenderness is found dorsally on the radial side, with swelling and crepitus a short distance proximal to the site of maximal tenderness in de Quervain's disease (Fig. 26.11). This condition is sometimes called 'oarsman's wrist' because of its common occurrence in rowers,<sup>39</sup> but it is also seen in canoeists and in weight training and racquet sports.

Treatment involves early intervention with corticosteroid injection into the junction. Acute surgical

(a)

(b)

**Figure 26.12** Intersection syndrome (a) Tight fascial band rubbing on tendons COURTESY OF DR GREG HOY (b) Close up of pathology COURTESY OF DR GREG HOY

decompression<sup>40</sup> and immediate return to training and events for rowers is very effective, and removes the need for changing rowing technique.<sup>39</sup>

### Radial sensory nerve compression

As the dorsal radial sensory nerve exits brachioradialis 5–7 cm proximal to the wrist, it becomes superficial and subject to damage. Compression can occur following radial styloid fracture, be caused by a tight cast or by repetitive trauma in sports like volleyball. It can also be compressed more proximally when squeezed between brachioradialis and extensor carpi radialis longus tendons during rapid, repeated pronation and supination.

It is differentiated from de Quervain's tenosynovitis by the presence of sensory changes over the radiodorsal aspect of the hand. Treatment is initially conservative with corticosteroid injection, splinting and addressing of potential causes of entrapment. Surgical decompression has good results in chronic conditions.<sup>41</sup>

## CENTRAL COLUMN PRESENTATIONS

### Ganglions

Ganglions occur in athletes of any age. They are a synovial cyst communicating with the joint space (Fig. 26.13a). They most often present as a relatively painless swelling. They occur in several common sites on both the dorsal and volar aspects of the wrist, most commonly the scapholunate space, due to the poorly named 'mucinous degeneration' of the scapholunate ligament. They may also be intracapsular or even intra-osseous.

(a)

**Figure 26.13** Ganglion cyst (a) Graphic view of the dorsum of the wrist showing the ganglion arising from the joint

(b)

(c)

**Figure 26.13 (cont.)** (b) MRI axial view of dorsal scapholunate ganglion (c) MRI axial view of volar wrist ganglion

The patient's main complaint is of intermittent wrist pain and reduced movement. Swelling may be visible intermittently or not at all, and so should not be relied upon to make the diagnosis. Ultrasonography is a useful investigation, however, T2-weighted MRI highlights ganglion cysts (Fig. 26.13b & c) and is the investigation of choice. The athlete must be reassured that the ganglion is benign, and that the average number in normal people is approximately two per wrist.<sup>42</sup>

Treatment is only indicated for a symptomatic ganglion. When symptoms persist, aspiration and/or

corticosteroid infiltration are at least temporarily effective and can be performed under ultrasound guidance where this is feasible. Some persistent symptomatic ganglions require surgery, in which the neck of the ganglion must be removed to prevent recurrence.

### Dislocation of the carpal bones

There are a number of different types of dislocation of the carpal bones, mostly involving the lunate. They are the uncommon end stage of severe ligament disruption. Failure to recognise them generally results in disastrous consequences.

#### Anterior dislocation of the lunate

In rare cases, the lunate may dislocate anteriorly as the end point of a perilunar injury. Pain is usually severe and deformity obvious. Plain radiography reveals the dislocation best in the lateral view with the lunate tilted volarly and not articulating with the capitate.<sup>43</sup> Treatment is URGENT open reduction and primary ligament repair, followed by eight weeks of cast immobilisation. Anterior lunate dislocation is often associated with severe median nerve compression and numbness in the radial three and a half digits.<sup>44</sup> This requires urgent surgical decompression.

#### Perilunar dislocation of the lunate

Perilunar dislocation is occasionally associated with a fractured waist of the scaphoid (so-called 'trans-scaphoid perilunate dislocation') when the lunate remains with the radius and the capitate is dislocated dorsally. This complex injury is often overlooked if the deformity is moderate, but the sequelae are catastrophic for the wrist, and this is a common cause of litigation when missed. It requires treatment by a hand and wrist surgeon, as long-term instability and radiographic wrist arthritis can occur.<sup>45, 46</sup>

### Scapholunate dissociation

Scapholunate dissociation is due to a complex injury involving dorsal scapholunate ligament tear and loss of secondary restraints (Fig. 26.14a). Rotatory subluxation (mainly flexion) of the scaphoid may occur as a result of disruption of its ligamentous attachments due to acute trauma (e.g. a fall on the dorsiflexed hand). Examination reveals tenderness 2 cm distal to Lister's tubercle on the radial side of the lunate. There may be little or no swelling. The key examination manoeuvre is Watson's test (Fig. 26.2j). If the test causes pain or reveals dorsal movement of the scaphoid, scapholunate instability is likely.

Conventional radiographic views may not show any abnormality, but stress films (clenched fist postero-anterior view) may reveal a scapholunate gap (Fig. 26.14b). A lateral radiograph may show an increased volar flexion of the distal pole of the scaphoid and dorsiflexion of

the lunate. If these tests are negative but the injury is suspected clinically, MRI is indicated (Fig. 26.14c).

Treatment of scapholunate dissociation is open reduction and reconstruction of the ligaments with temporary internal fixation. Many techniques are published<sup>47, 48</sup> and the main aim in athletes is return of grip strength and pain relief. Prevention of future arthritis (scapholunate advanced collapse (SLAC) wrist) is the ideal, although there is currently no significant evidence that this is achieved.

### Kienböck's disease

Kienböck's disease is otherwise known as avascular necrosis of the lunate. It is associated with repetitive microtrauma and negative ulnar variance, and it is most commonly diagnosed in adult males. However, there is a published case report of it occurring in a 14-year-old female gymnast.<sup>49</sup>

The patient will report a gradually worsening history of wrist pain. There may be swelling over the lunate which will be painful to palpate, and wrist motion will be affected. Imaging confirmation is increasingly using MRI. Interpretation of what is currently classified as Lichtman's stage 1 on MRI is controversial, with some authors arguing that this is an example of lunate overload and not Kienböck's disease.<sup>50</sup>

Surgical treatment will depend on the stage of the disease and the patient's level of function. Radial

(a)

**Figure 26.14** Scapholunate dissociation (a) Coronal graphic shows a tear of the dorsal component of the scapholunate ligament

(b)

(c)

**Figure 26.14 (cont.)** (b) In a classic case, radiograph reveals separation of the scaphoid and lunate. This can be a late sign, so normal radiography does not rule out this condition (c) Coronal MRI T2 image of scapholunate instability (arrow)

shortening osteotomy has been shown to have had good long-term results, with only slight loss of grip strength.<sup>51</sup> Salvage procedures are required for advanced cases due to the presence of carpal collapse.<sup>52</sup>

Conservative management of prolonged casting with consistent radiological follow-up has been shown not to be sufficient to stop progression of the disease once accurately diagnosed. Reported success of casting is possibly an indication that what was thought to be early-stage Kienböck's was in fact something else.<sup>53</sup> For this reason, it is important to differentiate between a stress reaction of the lunate and Kienböck's disease. Tennis players and other high-use athletes presenting with overuse syndromes in the wrist require exclusion of bony stress reactions including MRI scanning of good quality.

Diagnostic criteria for MRI for stage 1 Kienböck's disease have not been defined in the literature. We do not consider the use of proton density (PD) and T2 MRI images alone as sufficiently reliable for the diagnosis of Kienböck's disease. We recommend that T1 images must be obtained to exclude Kienböck's disease, and stress reactions must be considered in the differential diagnosis of these patients (Fig. 26.15).

Conservative treatment with restriction of high-level impact loading is excellent for the relief of these bony

**Figure 26.15** MRI coronal view of Kienböck's disease of lunate

stress injuries when diagnosed in the first three months of symptoms. Alteration of technique deficits may prevent recurrence, but little is known of the possible cause-and-effect relationship with completed fractures. The evidence base regarding treatment of this condition is controversial.<sup>54</sup>

### Impingement syndromes

A number of impingement syndromes may cause wrist pain. Scaphoid impaction syndrome may occur because of repetitive hyperextension stresses (e.g. in weightlifting or gymnastics). This mechanism is also responsible for avascular necrosis of the capitate in weightlifters. Impaction of the dorsal pole of the lunate on the distal radius is seen in gymnasts. The extensor pollicis longus may impinge on Lister's tubercle and it occasionally ruptures. Triquetrohamate impingement syndrome may result from forced wrist extension and ulnar deviation (e.g. in racquet sports and gymnastics).

Radial styloid impaction syndrome can result from repeated forced radial deviation, especially among golfers (Chapter 9). Patients with these syndromes present with localised tenderness and are treated with rest and a protective brace. Occasionally, corticosteroid injection or surgical exploration may be helpful.

## ULNAR COLUMN PRESENTATIONS

### Ulnar styloid fracture

Ulnar styloid fractures are present in over 50% of distal radius fractures, with 25% of them never uniting. There is no benefit in fixation of an ulnar styloid fracture unless it can be demonstrated that it is associated with distal radio-ulnar joint (DRUJ) instability.<sup>55</sup> Its presence should alert the clinician to assess for triangular fibrocartilage complex injury and monitor for ulnar instability through the rehabilitative period. If the fracture requires addressing, options include small k-wires with a tension band or, when DRUJ instability is present, volar plating of the radius and supination splinting.<sup>56</sup> A recent study did demonstrate that patients with distal radius fractures who had an associated ulnar styloid fracture had decreased function and reported more pain initially; however, by 12 months these differences were no longer significant.<sup>57</sup>

### Fracture of the hook of hamate

Fracture of the hook of hamate may occur while swinging a golf club,<sup>8, 58, 59</sup> tennis racquet or baseball bat. The fracture is especially likely to occur when the golf club strikes the ground instead of the ball, forcing the top of the handle of the club against the hook of the hamate of the top hand (Fig. 26.16a). This mechanism may compress

the superficial and deep terminal branches of the ulnar nerve, producing both sensory and motor changes. Symptoms include reduced grip strength and ulnar wrist pain. Examination reveals volar wrist tenderness over the hook of hamate. Routine radiographs of the wrist do not image the fracture and even the classic 'carpal tunnel view' with the wrist in dorsiflexion is an insensitive test. CT scan (Fig. 26.16b) and MRI are the best imaging tools.

This fracture often fails to heal with immobilisation; most sports medicine cases of the fracture are actually stress fractures that present late. In some athletes (e.g. baseball players), the hook of hamate fracture is likely to be a completed stress fracture not due to acute trauma. If diagnosis is delayed, or the fracture fails to heal clinically within four weeks of immobilisation, current surgical

(a)

**Figure 26.16** Fracture of the hook of hamate (a) Possible mechanism—when the golf club is suddenly decelerated (e.g. hitting the ground), the grip is forced against the hook of hamate

(b)

**Figure 26.16 (cont.)** (b) CT scan of a fracture of the hook of hamate

practice is excision of the fractured hook followed by three weeks wrist immobilisation (in preference to open reduction and internal fixation).<sup>8,60</sup> The pain only dissipates slowly, but the patient can usually resume sport six weeks after surgery. The long-term outcome of this approach is not known.

### Triquetral fracture

Fractures of the triquetrum are the second most common carpal fracture. The two primary injury patterns are a fracture of the triquetral body, or the cortical, dorsal flake fracture which accounts for 93% of all triquetral fractures.

One mechanism of injury for the flake fracture is the ulna chiselling an avulsion fragment following a fall into forced ulnar deviation and dorsiflexion. A less common cause is a high-velocity dorsal blow forcing radial deviation and palmar flexion.<sup>61</sup>

The athlete will present with point tenderness over the dorsum and a painful wrist with flexion. Precise palpation of the fracture is difficult due to its ulnar position. Diagnosis is then dependent upon anteroposterior, lateral and oblique pronated view radiographic scans (Fig. 26.17). CT is a useful tool for occult fractures.

With respect to the flake fractures, the athlete must understand that it is not the bone that is the problem, but rather the soft tissue injury and potential loss of

**Figure 26.17** Lateral radiograph of triquetral flake fracture (arrow)

stability. Cast immobilisation is essential for three to four weeks to ward off instability. Graded range of motion can begin then with a removable splint for protection, with full function usually restored by eight weeks.<sup>62</sup>

The less common triquetral fracture is through the body of the bone following a high-energy collision. Any diagnosis of a fracture must be investigated thoroughly with 12-25% of these associated with perilunate fracture dislocation. Surgery using pins or a compression screw will depend on the degree of displacement and the diagnosed presence of concomitant injury.

### Lunotriquetral dissociation

Lunotriquetral dissociation is an injury that is frequently missed on initial presentation, yet is the second most common form of carpal instability. The injury is often the result of a backwards fall onto an externally rotated, dorsiflexed, supinated and radially deviated hand. Physical examination is unlikely to reveal significant bruising or swelling. There will be pain at end range of pronation and supination and with pronated grip. Ballotement of the joint may be uncomfortable, and relief may be experienced with posterior displacement of the pisiform.<sup>63</sup>

Conservative management can be successful in managing this condition and is preferable to surgery at least in acute settings. The wrist should be splinted or casted for six weeks, at which time a weaning and

ulnar-sided strengthening program can begin. The use of a pisiform boost type of splint may be beneficial in chronic cases. Athletes should be aware that the process of recovery from either conservative or surgical management can take up to six months.<sup>63, 64</sup> Biomechanical studies indicate that training of extensor carpi ulnaris (ECU) may be beneficial; however, this is yet to be demonstrated clinically.<sup>65</sup>

### Triangular fibrocartilage complex tear

The triangular fibrocartilage complex (TFCC) lies between the ulna and the carpus. It is the major stabiliser of the distal radioulnar joint. The 'complex' consists of the triangular fibrocartilage, ulnar meniscus homologue, ulnar collateral ligament, numerous carpal ligaments and the ECU tendon sheath (Fig. 26.18a). Only the periphery of the TFCC is vascular and able to heal if damaged. The central avascular portion cannot heal and usually requires debridement once injured.

The TFCC is commonly injured in racquet or stick sports and those that create repetitive ulnar and compressive loading like gymnastics, weightlifting, boxing and surfing. In water skiers it is considered a traction injury.<sup>1</sup> It should be investigated following distal radius fracture and wherever DRUJ instability exists. The patient complains of ulnar-sided pain that worsens with grip, rotation and weight-bearing.<sup>66</sup>

Examination reveals tenderness and swelling over the dorsal ulnar aspect of the wrist, pain on resisted wrist dorsiflexion and ulnar deviation (Fig. 26.2k), a clicking sensation on wrist movement and reduced grip strength. Sharp pain with deep palpation is known as a positive foveal sign and indicates an ulnatriquetral ligament injury and/or a disruption of the TFCC at the base of the ulna styloid (fovea), which is associated with DRUJ instability (Fig. 26.2l).<sup>13, 66</sup> The 'press test' may also be helpful in diagnosing TFCC tears and differentiating from other conditions like ECU tendinopathy (Fig. 26.2m). The patient creates an axial ulnar load by attempting to lift his or her weight up off a chair using the affected wrist. A positive test replicates the presenting symptom.<sup>14</sup>

High-quality MRI (Fig. 26.18b) can image the TFCC and this is an increasingly popular investigation for ulnar-sided wrist pain.<sup>67</sup> Estimates of sensitivity and specificity are about 60% and 90%, respectively,<sup>68</sup> which suggests that a negative MRI should not be used to rule out the condition if it is clinically suspected. Interestingly, ultrasonography shows promise for matching MRI in the detection of TFCC lesions; however, arthroscopy remains the gold standard and should be considered as early as possible for the athlete wanting a rapid return to play.<sup>69, 70</sup>

(a)

(b)

**Figure 26.18** Triangular fibrocartilage complex (TFCC) (a) TFCC and surrounding ligaments (b) Coronal MRI of foveal tear of TFCC off ulna

Arthroscopy permits accurate diagnosis and excision of any torn cartilage if required. If the ulna is longer than the radius (positive ulnar variance), it impinges on the triangular fibrocartilage and predisposes it to tearing.

It may be necessary to shorten the ulna as well as excising the torn fibrocartilage.<sup>71</sup>

Treatment after surgery will likely involve a period of immobilisation, followed by a carefully graded return to full motion and grip strength.<sup>66</sup> Conservative management involves a short period of splinting followed by specific strapping to offload the TFCC, coupled with stabilisation exercises involving ECU and pronator quadratus, and likely technical adjustment. It is rarely as successful for treatment of central and foveal tears as it is for smaller, peripheral tears.

### Distal radio-ulnar joint instability

The thickened dorsal and volar aspects of the triangular fibrocartilage act as the dorsal and volar ligaments of the distal radio-ulnar joint. Subluxation of the ulnar head occurs because of avulsion of these ligaments. It may be either volar or dorsal. Dorsal subluxation of the ulnar head associated with a tear of the volar radio-ulnar ligament is more common and may be due to repetitive or forceful pronation in contact sports, tennis or gymnastics. Dorsal displacement of the ulnar styloid process during pronation may be detected on true lateral radiograph. Treatment requires repair of the TFCC.<sup>72</sup>

### Extensor carpi ulnaris tendon injuries

The ECU resides in the sixth dorsal wrist compartment and helps stabilise the DRUJ.<sup>65, 73</sup> It has its own subsheath just distal to the ulnar styloid, which prevents subluxation from the distal ulnar groove. Its angular path from its origin on the lateral epicondyle to the tendon insertion at the base of the fifth metacarpal is exaggerated with ulnar deviation and supination (Fig. 26.19a).

The subsheath is designed in such a way that it stretches and deforms in response to forces. It can fail abruptly with hypersupination and flexion, but more usually fails as fibrous tearing occurs over a period of time due to repetitive forearm supination, wrist flexion and ulnar deviation.

The tendon can either sublux (a partial loss of excursion beyond the volar lip of the notch, which occurs in up to 45% of asymptomatic persons) or it can dislocate with a complete loss of continuity. Presentation will be ulnar-sided wrist pain that intensifies with active contraction or stretching of the tendon. Instability will be obvious as the tendon subluxes volarly, often with an audible flick, and ultrasound imaging is useful.<sup>74, 75</sup> Weight-bearing through the palm should not be painful unless other structures like the TFCC are involved.

**Figure 26.19** Extensor carpi ulnaris (ECU) tendon (a) Tendons at the wrist showing supination position where the ECU tendon is most likely to sublux and tear subsheath

(b)

**Figure 26.19 (cont.)** (b) Tennis-specific taping method that unloads and blocks the wrist with TFCC and/or ECU injury. Readers are directed to Stroia et al.<sup>78</sup> for a complete description of the method

Athletes at risk are those who require grip and extremes of wrist motion in supination, for example golfers, cricketers, weightlifters and rodeo riders.<sup>76</sup> Tennis players with double-handed backhands are at particular risk as the hand closest to the racquet head moves rapidly into a supinated, flexed and radially deviated posture.<sup>77</sup>

If there is no tendon rupture, initial treatment can be conservative. The arm is splinted in radial deviation, extension and neutral to pronation. If stability remains a problem, the cast should extend to include the elbow at 90°. <sup>75</sup> The splint is worn for 1–4 weeks, depending on the severity of the symptoms. A strengthening and control program is then initiated with taping to stabilise the ECU within the ulnar groove (Fig. 26.19b).<sup>78</sup> Failure of conservative management is an indication for surgical reconstruction of the sheath with or without recontouring of the sulcus. Anticipated return to play is at three months following surgery.<sup>79</sup>

### Other tendinopathies around the wrist

Any of the flexor and extensor tendons around the wrist may become painful with excessive activity. On examination, there is tenderness and occasionally swelling and crepitus. The principles of treating tendinopathies apply—management should include attention to biomechanics (ergonomics), progressive strengthening and functional rehabilitation.<sup>25</sup>

### CAUSES OF WRIST NUMBNESS AND HAND PAIN

Patients may present with wrist numbness or paraesthesia. This suggests a neurological pathology, most likely carpal tunnel syndrome or ulnar nerve compression.

### Carpal tunnel syndrome

The median nerve may be compressed as it passes through the carpal tunnel along with the flexor digitorum profundus, flexor digitorum superficialis and flexor pollicis longus tendons (Fig. 26.20). This condition is characterised by burning volar wrist pain with numbness or paraesthesia in the distribution of the median nerve (thumb, index finger, middle finger and radial side of the ring finger). Nocturnal paraesthesia is characteristic. The pain can radiate to the forearm, elbow and shoulder. Tinel's sign may be elicited by tapping over the volar aspect of the wrist (Fig. 26.20). A positive Phalen's test will reproduce symptoms in up to 60 seconds when the patient rests both elbows on a table with forearms vertical and their wrists flexed by gravity.

The most important aspects in diagnosis are the history and physical examination, but nerve conduction studies can help confirm the diagnosis and may predict how the patient will respond to surgery.<sup>80</sup> Patients with carpal tunnel syndrome should be checked for diabetes mellitus, as it is a known risk factor.

**Figure 26.20** Median nerve compression in the carpal tunnel

(a)

(b)

**Figure 26.21** Ulnar nerve compression (a) Ulnar nerve (b) Mechanism of nerve compression in cycling

Mild cases may be treated conservatively with non-steroidal anti-inflammatory drugs (NSAIDs) and splinting.<sup>81,82</sup> A single corticosteroid injection may provide temporary relief,<sup>82,83</sup> but persistent cases require surgical treatment.<sup>84</sup> Surgery may be either open or endoscopic, and systematic reviews to date show no difference between the two techniques for symptom relief.<sup>85</sup>

### Ulnar nerve compression

The ulnar nerve may be compressed at the wrist as it passes through Guyon's canal, sometimes with ulnar artery thrombosis. It is called hypothenar hammer syndrome, and it is most commonly seen in cyclists due to supporting body weight over a long duration when cycling,<sup>86</sup> because of poor bike fit or a failure to use several relaxed handlebar grip positions (Fig. 26.21). It also occurs in karate practitioners, and one study highlighted the risk of hand neurovascular changes in baseball players, especially catchers, from repeated trauma associated with catching a ball.<sup>87</sup> Within Guyon's canal, the nerve lies with the ulnar artery between the pisiform bone on the ulnar side and the hamate radially.

Symptoms include pain and paraesthesia to the little finger and ulnar side of the fourth finger. Weakness usually develops later. For cyclists, non-surgical treatment

involves splinting, NSAIDs and changes to bicycle set up. In particular, the grip position should be assessed, and moving the saddle backwards may reduce the amount of weight going through the cyclist's upper limbs. Surgical exploration of Guyon's canal may be required.

### SURGERY FOR WRIST CONDITIONS

Traditional indications for surgery are a failure of conservative treatment together with an applicable surgical procedure that has proven outcome results. In many weekend athletes this holds true. However, in professional athletes with a limited career time span, the career goals impact heavily on both the indication and the timing of surgery.

In the management of intersection syndrome, aggressive use of early surgery with immediate return to elite rowing means less loss of condition and changes to technique that may impact on the sports results and hence the career of the rower. The use of more sturdy fixation than normal for a wrist fracture allows return to sport earlier and with more confidence. The risks of surgery must be discussed with the individual athlete to measure the risk-benefit ratio and to discuss the subsequent rehabilitation. (See Chapter 2—shared decision making). Table 26.4 indicates conditions where an early surgical opinion and liaison with the athlete support team are warranted.

**Table 26.4** Urgent surgical referrals for wrist conditions in sports

Injury	Common sports	Management
Fractured radius	All high-impact sports	Immediate assessment of need for surgery (X-ray/specialist)
Fractured scaphoid	Contact sports/riding sports	Early diagnosis by X-ray or CT scan and early surgery best option
Extensor carpi ulnaris (ECU) dislocation or subluxation	Wrist rotation sports (especially tennis)	Early splinting but often requires surgery
Perilunate dislocation	Contact sports	Emergency joint reduction and pinning (median nerve at great risk)
Kienböck's disease (avascular necrosis of lunate)	All sports but especially golf and tennis	Splint very early but most require specialist reconstruction
Acute carpal tunnel syndrome	Any sports	Numbness must be treated urgently to avoid long-term disability
Forearm compartment syndrome (acute)	Crush injuries (high impact)	Decompression urgently

## WRIST REHABILITATION

The key factor in wrist rehabilitation is the balance between the need to immobilise or restrict movement and the requirement to restore full range of movement.

### Wrist splinting

Correct positioning of a wrist within a cast or splint is crucial to its potential to heal. Commercially available splints rarely fit well enough, and so custom fabrication is recommended for most conditions. If immobilisation of the fingers is not required, then the cast should end at the distal palmar crease to allow full finger flexion. Casting of non-displaced scaphoid fractures does not always require the thumb to be included, but it is preferred to do so.<sup>88</sup>

The material used will depend on the injury, with plaster or fibreglass best for fractures, and thermoplastic more suited to tendinopathies, strains, postoperative splinting and protection during activity. The rules governing the use of splints in sport vary widely between competitions and levels, making it the treating clinician's responsibility to know what is permissible.

### Post-immobilisation wrist rehabilitation

A wrist that has been casted or splinted for an extended period of time will be stiff and weakened when the cast is removed. Management of the expectations of the athlete is paramount. There is no point in restoring full wrist motion at the expense of stability and control. Oedema must be minimised and compression bandages and wraps are useful. Ongoing use of a splint may be required

overnight or in between exercise sessions to minimise pain and inflammatory responses. Its presence can also be a reminder to the patient not to do too much in the initial stages.

Joint mobilisation, stretching, active movement in all planes and graduated strengthening should begin as soon as healing permits, as well as the incorporation of functional activities such as bouncing a ball. The dart thrower's motion (mid-range radial extension to ulnar flexion) is a stable movement that can be used for early mobilisation in situations where ligamentous injury has not been ruled out.<sup>89</sup>

Functional wrist strengthening and neuromuscular training exercises may include:

- bouncing a ball
- ball/towel stretch on a table or wall
- holding a racquet, rolling a ball on strings
- light catching (alter the ball size)
- throwing a ball at a mini-trampoline
- slosh pipe (an unstable weight created by putting water inside a plastic pipe)
- gyro-ball
- tossing ball, underhand/overhand
- TheraBand™
- wrist weights
- weight-bearing progression through putty, ball, wobble board
- putting
- curling a cricket bat
- rotation with a hammer.

# Hand and finger injuries

with HAMISH ANDERSON and GREGORY HOY

*Star midfielder Daniel Kerr says he's willing to risk permanent damage to his injured finger if it means helping the Eagles reach and win another Grand Final. West Coast's bid for a third straight grand final, and back-to-back premierships, was dealt a shattering blow last week when Kerr had to undergo surgery on a ruptured tendon in the ring finger of his left hand.*

Superfooty AFL, 29 August 2007

Sports-related injuries account for up to 15% of all hand injuries seen in accident and emergency departments.<sup>1</sup> Some hand injuries are potentially serious and require immobilisation, precise splinting and/or surgery. Finger injuries are often neglected by athletes in the expectation that they will resolve spontaneously. Athletes often present too late for effective treatment, especially with ligamentous injuries and joint instability.

The importance of early assessment and management must be stressed so that long-term deformity and functional impairment can be avoided. Many hand and finger injuries require specific rehabilitation and appropriate protection upon resumption of sports. Joints in this region do not respond well to immobilisation, which often exacerbates oedema and stiffness. Hence, surgical stabilisation and protected stabilisation with active motion splints are becoming commonplace for sports-related hand injuries.

As in all injury management, return to occupation is important, and if the occupation is sport, then more aggressive management options are often employed.

The sport-specific causes of pain in the hand are shown in Table 27.1. The anatomy of this area is demonstrated in Figure 27.1.

## CLINICAL APPROACH

### History

The mechanism of injury is the most important component of the history of acute hand injuries. A direct, severe blow to the fingers may result in a fracture, whereas a blow to the point of the finger may produce an interphalangeal

dislocation, joint sprain, or long flexor or extensor tendon avulsion.

A punching injury often results in a fracture at the base of the first metacarpal or to the neck of one of the other metacarpals (usually the fifth), or carpo-metacarpal (CMC) joint instability. An avulsion of the flexor digitorum profundus tendon, most commonly to the fourth finger, is suggested by a history of a patient grabbing an opponent's clothing while attempting a tackle.

Lack of active motion is an important warning sign of significant injury. Associated features such as an audible crack, degree of pain, swelling, bruising and loss of function should also be noted.

Patient outcome measures are also useful, particularly in determining levels of function in chronic cases. The Michigan Hand Outcomes Questionnaire and the Disabilities of the Arm, Shoulder and Hand are widely used evaluations<sup>3-5</sup> (Table 27.2).

### Physical examination

At the outset of examination, examine the posture of the hand, the protection of movement and the deformities compared to the other (hopefully) uninjured hand. Ask the athlete to make a fist and open, and to oppose the thumb to each finger on each side.

Carefully palpate the bones and soft tissues of the hand and fingers, looking for tenderness. The examiner should always be conscious of what structure is being palpated at any particular time. The joints should be examined to determine active and passive range of movement

**Table 27.1 Sport-specific hand conditions**

Injury	Common name	Common sports	Management
Flexor digitorum profundus avulsion	Jersey finger	Tackling sports: rugby, all football codes	Early: Surgical repair Late: (>6 weeks) two-stage reconstruction
Flexor tendon pulley rupture (especially A2 and A4)	Climber's finger	Rock climbing and mountaineering	Taping (preventative) Splints (acute) or surgical pulley reconstruction
Sagittal band rupture MCPs 2,3,4	Boxer's knuckle	Boxing	Sagittal band reconstruction
Ulnar digital nerve neuroma	Bowler's thumb	10-pin bowling	Padding to thumb hole Surgical neurolysis
Ulnar collateral ligament rupture MCP thumb	Skier's thumb (gamekeeper's thumb)	Skiing, football ('thumb plant')	Splint if incomplete Surgical reconstruction if Stener lesion
Radial collateral ligament tear MCP thumb	AFL thumb	Australian rules football	Tape +/- splint to finish season Surgical reconstruction
CMC index/middle subluxation and carpal bossing	Boxer's hand	Boxing, martial arts	Splints (for competition without surgery) Resect bossing (short term) CMC fusion
Hook of hamate fracture		Batting and clubbing sports	Early: Protect Late: Excision of hook of hamate
Stress fracture scaphoid		High board diving	Splint or cast for 6 weeks
Stress reaction lunate (differential diagnosis: Stage 0 Kienbocks disease)		Golf, tennis	Splint or cast for 6 weeks Change technique

and stability. Stability should be tested both in an antero-posterior direction and with ulnar and radial deviation to assess the collateral ligaments. Do not forget that a depressed fragment of bone in a joint may produce a false positive test when stretching the redundant collateral ligament. The cause of any loss of active range of movement should be carefully assessed and not presumed to be due to swelling. Normal range of motion for the second to fifth digits is approximately 80° of flexion at the distal interphalangeal, 100° of flexion at the proximal interphalangeal and 90° of flexion at the metacarpophalangeal (MCP) joint. A common injury site that can be overlooked is the volar plate, a thick fibrocartilagenous tissue that reinforces the phalangeal joints on the palmar or volar surface.

The extensor tendons of the hand are often divided into six compartments. At the wrist on the dorsal side of the hand, the tendons are encased in synovial sheaths as they pass under the extensor retinaculum (Fig. 26.1). When palpating in the most radial compartment, also known as compartment one, the examiner identifies abductor pollicis longus and extensor pollicis brevis, the

tissues involved in de Quervain's tenosynovitis. Lister's tubercle is located on the dorsal surface of the distal end of the radius. The extensor pollicis longus angles sharply around this bony prominence and it can damage or even rupture the tendon after a serious wrist fracture.

The anatomical snuffbox is composed of the extensor pollicis longus and brevis and the abductor pollicis longus. The floor of the snuffbox is the scaphoid and scaphotrapezium joint. Clinically this is a significant region for several reasons. Tenderness may suggest scaphoid fracture. The deep branch of the radial arterial passes through, as well as the superficial branch of the radial nerve. Consequently, if a cast or splint is applied too tightly, it can lead to numbness in the thumb.

Examination of the fingers and hand involves:

1. Observation and sensation testing as per the wrist (Chapter 26). Special note should be made of the hand arches and any deformities at the proximal or distal interphalangeal joints.
  - a. hand at rest

## 5. Special test

- ulnar collateral ligament of the first MCP joint (Fig. 27.2f)
- IP joint collateral ligaments

Sensitivity and specificity of testing the stability of the ulna collateral ligament of the first MCP joint has been demonstrated to improve significantly to 100% and 87.5% post injection of local anaesthetic to the joint. The accessory collateral ligament at the proximal interphalangeal (PIP) joint is tested for lateral laxity in extension, whereas the cord collateral ligament is stress tested with the PIP joint flexed to  $45^\circ$ .<sup>2</sup>

### Key outcome measures

Refer to Table 27.2 (Refer also to Chapter 16 Patient reported outcome measures in sports medicine).

### Investigations

Routine radiographs of the hand include the PA, oblique and lateral views. Ideally, 'dislocations' need to be radiographed before reduction to exclude fracture and after reduction to confirm relocation. Even when pre-reduction radiographs are not performed because reduction has occurred on the field, post reduction films should be obtained after the game. Care should be taken with lateral views to isolate the affected finger to avoid bony overlap.

The use of more sophisticated investigation techniques is now more routine. CT scans show subtle avulsions and 3D CT scans are useful for understanding fracture patterns and methods of reduction. Single-photon emission

### PRACTICE PEARL

All traumatic finger injuries should be X-rayed.

computed tomography (SPECT) imaging combined with CT scans can show hot spots and stress reactions in bone as well as excluding bone lesions in some circumstances. MRI scanning is now very common for ligament and tendon injuries to grade and assist surgical decision making. Ultrasound is still widely indicated in dynamic imaging such as with subluxing tendons, the Stener lesion in the thumb, and siting tendon-ends in ruptures and lacerations.

### PRINCIPLES OF TREATMENT

The functional hand requires mobility, stability, sensitivity and freedom from pain. It may be necessary to obtain

**Table 27.2 Patient-reported outcome measures (PROMs) for hand and finger injuries and pain**

Michigan Hand Outcomes questionnaire
1. Hand-specific assessment covering function, ADLs, pain, work performance, aesthetics and satisfaction
2. x items: 37
3. Score range x–y
4. Test–retest reliability: >0.81 <sup>3</sup>
5. Validity: High validity demonstrated

3. Score range x–y: 0 (no impairment)—100 (poor)
4. Test–retest reliability: DASH >0.96; <sup>4</sup> QuickDASH >0.91 <sup>5</sup>
5. Validity: DASH >0.70; <sup>4</sup> QuickDASH >0.70 <sup>5</sup>
6. MDC95%: DASH 12.75%; <sup>4</sup> QuickDASH 11.2% <sup>5</sup>
7. MCID: 10.83%; <sup>4</sup> 8% <sup>5</sup>
8. Available online: DASH and QuickDASH

stability by surgical methods. However, conservative rehabilitation is essential to regain mobility and long-term freedom from pain. Treatment and rehabilitation of hand injuries is complex. As the hand is unforgiving of mismanagement, practitioners who do not see hand injuries regularly should ideally refer patients to an experienced hand therapist, or at least obtain advice while managing the patient.<sup>7</sup>

Inflammation and swelling are obvious in the hand and fingers. During the inflammatory phase, the therapist must aim to reduce oedema and monitor progress by signs of redness, heat and increased pain. During the regenerative phase (characterised by proliferation of scar tissue), the therapist can use supportive splints and active exercises to maintain range of motion. During remodelling, it is appropriate to use dynamic and serial splints, and active and active assisted exercises, in addition to heat, stretching and electrotherapeutic modalities.<sup>8</sup>

### Oedema control

Oedema can be controlled through splinting, compression, ice, elevation and electrotherapeutic modalities (Chapter 17). Splinting needs to be in the intrinsic plus position, with the wrist in 30° of dorsiflexion, the MCP joints flexed

to 70° and the PIP joint extended to 0° with the thumb abducted (Fig. 27.3). Splints are periodically removed to allow exercise. Fist-making exercises are used to maintain joint movement and to help remove oedema. During exercise, the hand should be elevated. Short, frequent exercise periods are optimal.

**Figure 27.3** The 'intrinsic plus' position for splinting of hand injuries: 30° of wrist dorsiflexion, 70° of MCP flexion and minimal PIP flexion

Compression in the hand can be achieved with a compression glove and by using a Coban™ elastic bandage: a 2.5 cm size is appropriate for fingers. If applicable, active tendon gliding and range of motion exercises in combination with elevation can assist in the reduction of swelling. Electrotherapeutic modalities can be useful in the control of oedema.

## Exercises

Exercises may be active, active assisted or resisted. Tendon lacerations or ruptures are generally treated by protocols determined by the surgical technique and preferences of the treating surgeon.

Exercise prescription for other injuries includes:

- blocking exercises, which isolate an injured joint or muscle by immobilising neighbouring joints with the other hand
- composite flexion exercises (e.g. tendon gliding exercises)
- extension exercises
- active assisted exercises in which the patient takes a joint through the available range of motion and then the therapist assists in gaining slightly greater range with overpressure.

## Taping and splinting

The most commonly used method of taping is 'buddy taping' (Fig. 27.4). Its role is to provide a vehicle for active assisted exercise. The uninjured digit provides additional stability and encourages full range of motion.

An injury to the finger can often be managed successfully with a conservative approach using the protection of some form of splint. Thin thermoplastic—1.6 mm or less is ideal—can be remoulded to accommodate changes in swelling or protocol. Finger sleeves (Fig. 27.5a) can be made of neoprene or Lycra® to manage oedema, pain or chronic

**Figure 27.4** Buddy taping of fingers

flexion deformity, and both can be reinforced with thin thermoplastic if extra stability is required.<sup>9</sup>

Splints can have padding added and be taped on for protection during sporting activity. The goal is to provide stability, but not at the expense of limiting movement and impeding performance.<sup>10</sup> The use of splints during a game is entirely dependent upon the athlete, his or her sport and the rules governing the sport at that level.

### PRACTICE PEARL

**1.6 mm thermoplastic can be softened sufficiently in a hot cup of water to make a splint on the sidelines.**

In the acute phase of injury, static splints are used to reduce oedema. Dynamic splints can also be used in the repair phase of injury to provide some force along joints and encourage increased range of motion (Fig. 27.5b and c). With dynamic splinting, the splint should be worn with less tension for a longer period.<sup>9, 10</sup>

## METACARPAL FRACTURES

### Fracture of the base of the first metacarpal

Fractures of the base of the first metacarpal commonly occur as a result of a punch connecting with a hard object, such as an opponent's head, or a fall on the abducted thumb. There are two main types of fracture: (1) the extra-articular transverse fracture of the base of the first metacarpal about 1 cm distal to the joint (Fig. 27.6a) and (2) a Bennett's fracture/dislocation (or Rolando comminuted fracture/dislocation) of the first carpo-metacarpal joint (Fig. 27.6b).

**(a)**

**Figure 27.5** Splints used to treat fixed flexion deformity  
(a) Neoprene finger sleeve provides gentle extension also addresses chronic oedema

(b)

(c)

**Figure 27.5 (cont.)** (b) Static progressive (also known as a 'belly gutter') splint. This simple finger gutter splint has a 'belly' underneath the PIP joint. It is usually put on half an hour before bed with a gentle tension on the central strap. This provides a progressive and controlled end-range stretch into extension overnight (c) A commercial dynamic (spring) finger-based PIP extension splint. This splint is only suitable for contractures of less than 40° and does permit active flexion

The transverse fracture near the base of the first metacarpal results in the thumb lying flexed across the palm. Reduction of this fracture involves extension of the distal segment of the metacarpal. This fracture can be immobilised in a short arm spica cast, but now more commonly internal fixation allows both anatomical reduction and early active movement. This produces prompt return to activity, and less delay in recovery from loss of position. The often-quoted 'surgery only as a last resort' is less relevant today with better surgical training, better imaging and modern surgical implants.

A Bennett's fracture dislocation of the first carpometacarpal joint occurs as a result of axial compression

(a)

(b)

**Figure 27.6** Fractures of the base of the first metacarpal (arrows) (a) Healing transverse fracture (b) Bennett's fracture

when the first metacarpal is driven proximally, shearing off its base. A small medial fragment of the metacarpal remains attached to the strong volar ligament and the main shaft of the metacarpal is pulled proximally by the unopposed pull of the abductor pollicis longus muscle. This injury should be referred to a hand surgeon.

Treatment in recreational athletes requires closed reduction and percutaneous Kirschner wire fixation together with cast immobilisation for 4–6 weeks. Upon removal of the cast, mobilisation of the surrounding joints is required and, if early return to sport is required, a protective device should be worn.

Professional athletes will have anatomical reduction, plate fixation and early active movement. Patients not engaging in contact sport find soft neoprene braces (Fig. 27.7) supportive and comfortable after a Bennett's fracture and other common hand injuries. These are not replacements for firmer splints and braces that might be needed when trauma can be anticipated.

### Fractures of the other metacarpals

Fractures of the second to fifth metacarpals may also occur as the result of a punch, contact with ball and ground, and direct hits at hockey, cricket, baseball, etc. When seen in the fourth and fifth metacarpals, it is referred to as a 'boxer's fracture'. The fracture is usually accompanied by considerable flexion deformity of the distal fragment which is countered by the extra dorsiflexion available at the MCP joint to make up for this deformity. This results in surprisingly little functional disability (Figs 27.8 and 27.9).

The acceptable angulation for fractures of the neck of the fourth and fifth metacarpals is up to 30°, as long as there is little rotational deformity. Up to 10° angulation is acceptable in the second and third metacarpals. However,

**Figure 27.7** Soft neoprene splints can provide support during rehabilitation after a hand injury

prominence of the metacarpal head in the palm of the hand may be a problem for tennis players and athletes who require a firm grip.

Treatment involves splinting or casting in a position of 70° of flexion of the MCP joints to prevent shortening of the collateral ligament and subsequent stiffness (Fig. 27.10a). Check that this position does not displace the fracture. The splint may be removed after 2–3 weeks and non-contact sport resumed immediately with

**Figure 27.8** In metacarpal fractures, the more proximal the fracture, the more the knuckle will drop

**Figure 27.9** Spiral fractures of the second and fifth metacarpals (border digits) are more unstable than those of the third and fourth metacarpals as only one side of the border metacarpals is supported by the strong, deep transverse intercarpal ligaments

protection (Fig. 27.10b). Unprotected return to contact sport is more controversial, and recently suggestions of aggressive return to play 1–2 weeks after strong plating in professional sports have been put forward.

Shortened, rotated and intra-articular fractures of the metacarpals require anatomical reduction and fixation. In

displaced fractures, this usually involves plating from the dorsal or lateral aspect to correct angulation and rotation. Check for rotation of finger fractures clinically (as subtle rotation causes 'crossing' of metacarpals and affects grip) and not by using radiographs. Undisplaced fractures can be immobilised in a gutter splint with flexion of the MCP joint.<sup>11</sup>

(a)

(b)

**Figure 27.10** Splints used in the management of fracture of the fifth metacarpal (a) The treatment splint should position the MCP joints of the 4th and 5th fingers in 70° of flexion, leaving the IP joints free to move (b) Protective splint used for early return to sport when appropriate. Note the bubble over the fracture site to accommodate swelling

## FRACTURES OF PHALANXES

### Proximal phalanx fractures

Fractures of the proximal phalanx may lead to functional impairment due to the extensor and flexor tendons coming into contact with callus and exposed bone, and due to imbalance of the extensor expansion with flexors creating 'Z' deformities through the PIP and distal interphalangeal (DIP) joints in hypermobile individuals.

Undisplaced fractures require weekly radiographs to ensure movement has not occurred. If further stability is needed, the adjacent finger can be buddy taped, but it is more common now to pin, wire or plate these fractures to regain stability and allow hand therapy to achieve better early results. Splints are removed after a maximum 3–4 weeks but ideally earlier to improve function. Unstable fractures require urgent surgical referral.

Rotational deformity of phalangeal fractures may not be obvious in extension so the fingers should be examined end on with PIP and DIP flexion to reveal any deformity present. All rotated fractures need open reduction and possibly internal fixation.

### Middle phalanx fractures

Fractures of the middle phalanx involve hard cortical bone. Generally oblique or transverse, these fractures heal slowly. The central slip of the extensor tendon attaches dorsally to the base of the bone and the flexor digitorum inserts on the volar surface more distally. Thus, fractures distal to the flexor tendon attachment show flexion of the proximal fragment and extension of the distal fragment.

Stable fractures are immobilised in a splint for 3 weeks (70° of MCP joint flexion and 0° of PIP joint flexion). When the splint is removed, range of motion exercises are begun.

Unstable fractures, or intra-articular fractures involving more than 25% of the PIP joint surface, require open reduction and internal fixation. Small-calibre Kirschner wires or screws are used and range of motion exercises are begun as soon as fixation is considered to be stable in order to avoid stiffness.

Volar plate avulsion fractures can occur at the PIP joint following a hyperextension injury (and often a joint subluxation or dislocation). This injury is very common,

**Figure 27.11** Radiograph confirms the subtle nature of a volar plate avulsion

and usually ignored owing to an unawareness of the potential consequences. The typical anatomy is shown above in Figure 27.1b and the radiographic appearance is shown in Figure 27.11.

Non-randomised controlled trials have compared early mobilisation with splinting and found that mobilisation has led to good functional outcomes,<sup>12</sup> although extension blocking helps prevent hyperextension and recurrent dislocations. Often flexion deficits occur when the volar fragment and scarred volar plate are too thick and interfere with tight grip. Excision of the fragment and volar plate arthroplasty (VPA) helps eliminate this problem.

### Distal phalanx fractures

Fractures of the distal phalanx are usually caused by crushing injuries, such as fingers being jammed between a fast-moving ball and a stick or bat. They are usually non-displaced.

Often a splint and compression dressing will provide adequate treatment for non-displaced fractures. Much of the pain associated with these fractures can be due to subungual haematoma. Significant subungual haematoma requires nail bed exploration and excision as the nail bed is often disrupted. In this case surgical repair may be required to prevent future nail deformity. This represents a compound fracture and should be treated as such.

Perforation of the nail to drain a subungual haematoma is a relative contraindication in this instance as it

converts a closed fracture to a compound fracture and requires careful prevention or prophylaxis of infection. A percutaneous K-wire from the tip down across fracture and DIP joint allows early function but not contact sport.

### PRACTICE PEARL

Most distal phalangeal fractures heal in 4–6 weeks.

### DISLOCATIONS OF THE CARPO-METACARPAL JOINTS

Most carpo-metacarpal (CMC) subluxations (with or without fractures of the carpal bones) occur with hitting, such as martial arts, or impact with the ground. Plain radiograph demonstrates the incongruence and the subluxation (Fig. 27.12). While splints can protect temporarily, the best treatment of this injury is reduction and pinning (acutely) or fusion of the CMC joints involved (usually index and middle finger metacarpals to trapezoid and capitate) if chronic.<sup>13</sup>

Dorsal dislocation of the MCP joints of the fingers is uncommon and usually occurs in the index finger or thumb. It has been called the 'irreducible dislocation' because the metacarpal head is pushed through the volar plate of the MCP joint and caught between the lumbrical and long flexor tendons with a buttonholing effect. Suspect this injury when examination reveals hyperextension of the involved MCP joint with ulnar deviation of the finger overlapping the adjacent finger.

An attempt to reduce the dislocation may be made by increasing the deformity and pushing the proximal phalanx through the tear in the volar plate. However, open reduction is sometimes required. The MCP joint is

**Figure 27.12** Radiograph of CMC. Sagittal view showing dorsal subluxation of metacarpal (arrow)

usually stable after reduction in 30° of MCP flexion and early movement can be commenced in a dorsal splint allowing full flexion but preventing the last 30° of MCP joint extension. The immobilisation is maintained for 5–6 weeks. Associated osteochondral fractures require open reduction and internal fixation, and the collateral ligaments should be checked (even by MRI if required) to ensure accurate reduction.

## DISLOCATIONS OF THE FINGER JOINTS

### Dislocations of the PIP joint

Dorsal PIP joint dislocations are the most common hand dislocation. They usually result from a hyperextension stress with some degree of longitudinal compression such as may occur in ball sports. This may produce disruption of both the volar plate and at least one collateral ligament. Ideally, radiographs should precede reduction to confirm the diagnosis and exclude an associated fracture. In practice, reduction often occurs on or beside the playing area so it is vital that radiography be performed afterwards. If a fracture is present, the stability of the joint must be tested.

If the joint is stable post-reduction, a splint is not necessary and buddy taping to prevent hyperextension with active movement is recommended. If the joint is unstable, then the joint should be splinted in flexion beyond the point of instability and gradually extended to neutral over a period of 3–4 weeks<sup>14</sup> (Fig. 27.13).

Fixed flexion deformities are common following this injury in spite of treatment; however, if left untreated, a hyperextension deformity and instability may develop. Swelling around the joint can last for several months and should be managed using an elastic pressure bandage or neoprene sleeve, soft tissue treatment and electrotherapeutic modalities.

Volar dislocations of the PIP joint are uncommon and are often resistant to closed reduction. There is almost always an associated rupture of one or more collateral ligaments along with disruption of the extensor central

**Figure 27.13** Splinting following a PIP joint dislocation. This dorsal block splint allows flexion but stops full extension at the PIP joint

prevention of flexion for 6 weeks and so significant loss of game time occurs in mid-season injuries. Waiting until the end of the season risks a fixed boutonnière deformity which often heals poorly with or without surgery.

### Dislocations of the DIP joint

Dislocations of the DIP joint are most often due to a ball hitting the tip of the finger forcing hyperextension. They are commonly associated with a volar skin laceration. Reduction is achieved by traction and flexion. The joint is usually stable post reduction, but should still be splinted for 3 weeks in 10° of flexion.<sup>15</sup> Controlled active flexion is permitted during this time if the joint is stable, and can be progressed gradually from that point. Collateral ligament injuries are rare. Failure to achieve reduction of the joint should be investigated, and flexor tendon function must be assessed as avulsion can occur with this injury.<sup>16</sup>

The less common volar dislocation occurs in association with a fracture and usually involves damage to the extensor tendon. This presents with the mallet finger deformity. Thus, all mallet fingers must be radiographed to exclude fracture. If volar dislocation has occurred, open repair may be indicated depending on the size and position of the fracture fragment.<sup>17</sup>

#### PRACTICE PEARL

If radiographs reveal an associated fracture of the volar lip of the middle phalanx involving more than one-third of the joint surface, open reduction and internal fixation are usually required to restore stability.

slip insertion. This injury predisposes to the development of a boutonnière (buttonhole) deformity and should be treated aggressively with either surgery or a splint, holding the PIP joint of the affected finger in extension for 6 weeks while encouraging DIP movement. Surgery requires

## LIGAMENT AND TENDON INJURIES

### Sprain of the ulnar collateral ligament of the first MCP joint

Initially known as 'gamekeeper's thumb', and more recently 'skier's thumb', this injury is one of the most common injuries to the hand and is found in all sports, especially those requiring stick holding or ball handling. Damage to the collateral ligaments of the thumb has an adverse effect

on the hand's strength and precision.<sup>18</sup> This is particularly appreciated in pinching tasks such as holding a key (Fig. 27.14a).

Diagnosis is typically made clinically, with stress testing of the metacarpal joint of the thumb done in neutral and at 30° of flexion (Fig. 27.2f). Laxity in a radial direction of greater than 15° with soft end feel compared to the contralateral thumb is an indication of a complete rupture. Less than 15° indicates an incomplete tear. Radiographs are required to rule out an avulsion fracture.<sup>18, 19</sup>

Surgical repair is required for complete tears because the anatomy of the ulnar aspect of the metacarpal joint can preclude opposition of the ends of the ruptured ligament. This is known as a Stener lesion for which surgical repair

is mandatory (Fig. 27.15). In general, surgical management using suture anchors with pinning of the MCP joint is preferred for full tears, with inconsistent results reported for conservative treatment.<sup>18, 20</sup> However although results are better if repaired acutely, delayed repair is still successful, making the timing of surgery dependent upon factors specific to the athlete such as the sport and the time of season.<sup>21</sup>

Incomplete tears are splinted in a hand-based thumb spica with the thumb MCP joint placed in slight radial deviation and return to play dependent upon the athlete. The splint is worn full-time for 6 weeks, at which time a weaning and active motion protocol is initiated with strengthening at 8-10 weeks, and return to play with taping and/or a protective dorsal gutter splint for another 2-3 months (Fig. 27.14b). Postoperative rehabilitation is similar, with return to protected play as early as 2 weeks after surgery.<sup>19, 22</sup>

### Sprain of the radial collateral ligament of the first MCP joint

Tears of the radio-collateral ligament at the MCP joint of the thumb are not as common as ulnar-sided injury and the management is mostly conservative. The major difference is that Stener-type lesions are extremely rare due to differences in anatomy. The injury occurs as a result of an ulnar directed force, be it from a punch or from a ball. Stability is usually not the chief presenting problem, with pain on grip and stiffness being the chief complaints, making delayed surgery more acceptable. Stress testing is positive with greater than 15° of laxity compared to the contralateral side and confirmation made radiologically.<sup>18</sup>

Management is usually conservative, with hand-based spica splinting in a position that minimises the pull of the adductor pollicis for 6 weeks, followed by an extended period of protected taping and splinting in play. Surgery is required for large tears with volar subluxation and chronic cases, with presentation often more delayed than for UCL injuries.<sup>21, 23</sup> Immobilisation is required for 4-6 weeks afterwards, and protection in play for 2-3 months, with good long-term results reported.<sup>24</sup> Surgery is often indicated between seasons for contact sport athletes due to chronic instability.

### Capsular sprain of the first MCP joint

Capsular sprains of the first MCP joint are an extremely common injury in ball-handling sports. They result from a hyperextension injury and are prone to recurrence. Treatment involves active rehabilitation and protection of the joint from hyperextension. This is achieved with the use of a thermoplastic brace over the dorsal aspect of the MCP joint.

(a)

(b)

**Figure 27.14** Complete ligament tear of the first MCP joint (a) Pinching is affected (b) Protective splint worn under tape during return to sport. A hole can be created over the MCP joint to permit some flexion but still restrict deviation

**Figure 27.15** Mechanism of formation of a Stener lesion of the thumb (a) Anatomy (b) Valgus stress opens up the joint and the adductor aponeurosis slips past the distal end of the proximal portion of the ruptured ulnar collateral ligament (c) As alignment returns to normal, the adductor aponeurosis catches the proximal portion of the ulnar collateral ligament and flips it back proximally to form the Stener lesion

### PIP joint sprains

The collateral ligaments of the PIP joints are commonly injured as a result of a sideways force. Partial tears of the collateral ligament are painful, but remain stable on lateral stress. Complete tears show marked instability with lateral stress. This injury also includes hyperextension stress to the volar plate, which may avulse its insertion from the base of the metacarpal.

Stable tears should be treated by 10 days of finger-based splinting with the PIP in neutral, followed by buddy taping (Fig. 27.4), swelling management and active exercises. If the joint is unstable the splint should be fashioned in 10° of flexion greater than the point of instability (Fig. 27.13). This splint should then be gradually extended towards neutral, adjusting weekly over a period of 3 weeks. Active flexion within this controlled arc is permitted and encouraged.<sup>25</sup> Complete tears of the collateral ligament should ideally be treated with surgical repair, although in most cases conservative management provides an adequate result.<sup>26</sup>

Volar plate injuries without dislocation may heal normally, but also may produce a painful PIP joint or

a lax volar plate with repeated sprains and arthritis. Cortisone injected into the joint helps with chronic pain, but sometimes a volar plate arthroplasty is indicated to prevent further complications.

Combined tears of the volar plate and either collateral ligament may lead to a 'windscreen wiper' effect on the condyles of the proximal phalanx and eventual deformity. Repair is a better option.

### Mallet finger

Mallet finger is a flexion deformity resulting from either avulsion of the extensor tendon from the distal phalanx or following rupture of the tendon proximal to its insertion into the distal phalanx (Fig 27.16a). As a result, it can be classified as bony or soft (Table 27.3). It affects the ulnar three digits 90% of the time and commonly results from a ball striking the extended fingertip, forcing the DIP joint into flexion while the extensor mechanism is actively contracting. This produces disruption or stretching of the extensor mechanism over the DIP joint and is often seen in baseball catchers, fielders, football receivers, cricketers and basketball players.<sup>27</sup>

**Figure 27.16** Mallet finger (a) Mechanism of deformity—rupture or avulsion (b) Stack splint. A dorsal splint is preferred for early return to sport because it will permit some tip protection and allow palmar sensation

Examination reveals tenderness over the dorsal aspect of the distal phalanx and an inability to actively extend the DIP joint from its resting flexed position. If left untreated, a chronic mallet finger type deformity develops. This flexion deformity is caused by the unopposed action of the flexor digitorum profundus tendon.

Radiography must be performed to exclude an avulsion fracture of the distal phalanx or injury and subluxation to the DIP joint. The avulsion fracture is only considered significant if greater than one-third of the joint surface is involved. Any volar subluxation requires open reduction and internal fixation to correct the joint position (the subluxation).<sup>27</sup> A fracture dislocation of the epiphyseal

plate may occur in children. Most of these injuries are type II epiphyseal injuries and closed management is preferred.

Treatment of uncomplicated mallet finger involves splinting the DIP joint in slight hyperextension for a period of 6 weeks for a bony mallet and up to 8 weeks for a soft mallet injury, with regular monitoring. The splint is then worn for an additional 4 weeks while engaging in sporting activity and at night (Table 27.3). Treatment is reinstituted at any sign of recurrence of a lag. The splint may be made of metal or plastic and applied to either the volar (Fig. 27.16b) or the dorsal surface. Patients with dorsal splints maintain pulp sensation, which may

**Table 27.3** Mallet finger treatment protocol

	Type of injury	
	Bony mallet	Soft mallet
Continuous splinting	Thermoplastic palmar splint for 6 weeks (2/52 more if lag)	Thermoplastic palmar splint for 8 weeks (2/52 more if lag)
<b>Weaning protocol</b>		
Week 1 after continuous splinting period over	Off for 1 hour am, 1 hour pm On all other times	As for bony
Week 2	Off for 2 hours am, 2 hours pm On all other times	As for bony
Week 3	Off for 4 hours am, 4 hours pm On all other times	As for bony
Week 4	Off during day, on during sleep and sport	As for bony
Weeks 5 and 6	Tape for sport. Initiate exercises to increase DIP flexion if required	Tape for sport

be more suitable should the athlete insist on returning to sports before the injury has healed. The finger should be kept dry and examined regularly for skin slough and maceration.<sup>28</sup>

When treating mallet finger, emphasise to the patient that the joint must be kept in hyperextension at all times during the first 6–8 weeks, even when the splint is removed for cleaning. If a patient is not prepared to do this, then surgery should be considered. The consequences of not splinting are a chronic mallet finger type flexion deformity with osteophyte formation and degeneration of the DIP surface, and hyperextension at the PIP joint.

### Chronic swan neck deformity

There is commonly confusion between the presentation of swan neck and boutonnière deformities (Fig. 27.17). Hyperextension of the PIP with DIP joint flexion is characterised as a swan neck deformity. It can be a sequela to mallet finger injury or volar plate disruption.<sup>28</sup> Chronic cases will demonstrate instability of the PIP joint with visible snapping and discomfort. Fine motor activities become difficult and the finger can lock. Given that palliative treatment can be provided with dorsal blocking, game-day taping or functional figure-eight

**Figure 27.17** There is commonly confusion between the presentation of (a) swan neck and (b) boutonnière deformities

**Figure 27.18** Functional figure-eight splint for swan neck deformity preventing hyperextension but permitting PIP flexion

splints (Fig. 27.18),<sup>29</sup> many athletes opt to delay surgical reconstruction to the end of their season or career.

### Boutonnière deformity

Injury to the extensor tendon of the finger just proximal to its insertion on the middle phalanx can result in a boutonnière deformity, characterised by PIP joint flexion and DIP joint hyperextension. It is a common injury in ball handling sports like basketball, football and volleyball.<sup>30, 31</sup> With the central slip damaged, the lateral bands of the extensor mechanism migrate volarly and proximally, flexing the PIP joint and extending the DIP joint. This is then exacerbated by the now unopposed flexor digitorum superficialis. Without correction, ligaments will contract and the position become entrenched (Fig. 27.19).<sup>32</sup>

**Figure 27.19** Boutonnière deformity

**Figure 27.20** Barrel splint holding the PIP in extension but permitting DIP flexion

The deformity may not be immediately obvious and can take several weeks to develop, making an early accurate assessment important, but also highlighting the need for ongoing evaluation where injury is suspected.<sup>32, 33</sup> Typically there will have been blunt trauma to the dorsum of the PIP or an instance of PIP joint hyperflexion. Open laceration requires immediate surgical consult and intervention. There will usually be significant swelling, and radiographs may show an avulsion fracture. The central slip can be tested by hyperextending the MCP joint and then asking the athlete to actively extend the PIP joint. If this can be done fully, the central slip is intact.<sup>32</sup>

Management of the closed injury involves extension splinting of the PIP joint continuously for 6–8 weeks, encouraging regular active DIP joint flexion (Fig. 27.20). Ongoing night splinting may be required. Controlled active PIP joint flexion protocols introduced after 3 weeks of PIP joint extension have been shown to have fewer complications but require consistent monitoring, and are best instituted by a skilled hand therapist.<sup>33, 34</sup>

Surgical repair of open or chronic injuries often requires reconstruction and/or pinning of the PIP joint, which can preclude a return to sport for 6 weeks until the pin is removed. Reconstruction of a chronic injury is more successful if a flexion contracture has been reduced to a more neutral position with a splint.<sup>32</sup> For the athlete with a closed boutonnière, if they can play with a splint that maintains PIP extension, then immediate return is possible.<sup>30, 31</sup>

### Avulsion of the flexor digitorum profundus tendon ('jersey finger')

This injury is most commonly seen in the ring finger and may be caused by the player grabbing an opponent's clothing, resulting in the distal phalanx being forcibly extended while the athlete is actively flexing. The patient

often feels a 'snap'. The condition is often referred to as 'jersey finger'.

Examination may reveal the finger assuming a position of extension relative to the other fingers. There is an inability to actively flex the DIP joint of the affected finger. Radiography should be performed to exclude an associated avulsion fracture of the distal phalanx. A bone fragment may be seen volar to the middle phalanx or PIP joint. A lump may be palpated more proximally in the finger corresponding to the avulsed tendon.

#### PRACTICE PEARL

**Treatment is urgent surgical repair with reattachment of the profundus tendon to the distal phalanx. This must take place within 10 days of the injury.**

Late treatment requires the use of a two-stage operation, with a silicon rod being placed for some months in the finger to create the tendon sheath gap for the tendon graft to slide in. This is sometimes considered too big an operative insult, and fusing the DIP joint without grafting the tendon gives a nearly acceptable result.

### Lacerations and infections of the hand

Lacerations to the fingers and hand occur frequently in sport as a result of contact with equipment such as the undersurface of a football boot. All lacerations have the potential to become infected and should, therefore, be thoroughly cleaned with an antiseptic solution and observed closely for signs of infection. Tetanus toxoid should also be administered where appropriate.

A particular concern is a laceration of the hand, often over the MCP/PIP joint, caused by teeth, usually from a punch to the mouth. These injuries should always be assumed to be contaminated and an immediate course of a broad-spectrum antibiotic should be commenced. The wound should not be closed.

Lacerations over volar DIP or PIP joints may represent compound dislocations. If this has occurred, the joint has been contaminated and the patient requires hospital admission for surgical debridement and repair. Otherwise septic arthritis may follow.

### OVERUSE CONDITIONS OF THE HAND AND FINGERS

Important but sometimes overlooked are the overuse problems associated with the hand. These include trigger finger, flexor pulley injuries and other small joint injuries that are commonly seen in rock climbers.<sup>35–37</sup> Trigger finger is caused by a tenosynovitis in the flexor tendon

that is large enough to be impeded by the proximal A1 (annular) pulley located at the base of the finger. Diagnosis is made clinically, with the patient presenting with often painful clicking and locking of the finger as it actively flexes. Ultrasound is used for confirmation. Conservative treatment involves splinting to prevent metacarpal flexion only, and local treatment to reduce the enlarged tendon. Corticosteroid injection is often advocated first, and then surgical release of the impeded A1 pulley.<sup>38, 39</sup>

Rock climbers put chronic severe stresses on the flexor tendons and can damage or tear the important A2 and/or A4 pulleys, producing bowstringing. This often appears to be simple swelling initially, but can become quite severe. Most serious climbers wear tape or circular splints to control the tension, but surgical reconstruction may be required.

### SURGICAL REFERRALS FOLLOWING HAND AND FINGER INJURY

There are a number of conditions that require urgent referral to a hand surgeon. These are shown in Table 27.4.

#### Exercises for the hand

Exercises following hand injury should be prescribed so as to include both intrinsic and extrinsic hand musculature.

The tendon gliding sequence of exercises does this well, and passive stretches that push into these positions should also be encouraged when appropriate in the case of hand and finger stiffness (Fig. 27.21). Strengthening exercises utilising Theraputty®, grippers and stress balls are useful once the injured finger is stable but should not be introduced before joint or fracture stability is achieved. Building up the handles on a barbell or chin-up bar will increase grip strength demands, weight plate pinches will isolate intrinsic muscles, and finger extensors and the interossei can be worked using rubber bands.

**Figure 27.21** Tendon gliding sequence of exercises

**Table 27.4** Urgent surgical referrals for sports hand conditions

Injury	Common sports	Management notes
Flexor digitorum profundus avulsion	Tackling sports, including rugby and all football codes	Early: acute surgical repair Late (>6 weeks): two-stage reconstruction
All compound lacerations	Contact sports and/or motor sports and/or cycling i.e. high velocity sports	Surgical washout (local or general) Explore to exclude foreign bodies (especially teeth, soil) and debride
Sagittal band rupture MCPs 2,3,4	Boxing	Sagittal band reconstruction (not as urgent)
Mallet fracture/dislocation	Ball sports	Joint reduction and pinning
Ulnar collateral ligament rupture, MCP thumb	Skiing, football ('thumb plant')	Splint if incomplete Surgical reconstruction if Stener lesion
Bennett's/Rolando fracture base of 1st MC	Contact sports	Must reduce joint surface for good result
Rotated fracture, middle phalanx	Contact sports	Does not tolerate shortening or rotation
Rotated fracture, proximal phalanx	Contact sports	Often leaves stiff PIP if left unreduced
Rotated metacarpal fracture	Contact sports	Causes crossover of fingers; quicker return in professional sports
CMC subluxation and dislocation	Boxing, martial arts	Must be reduced to maintain strength and power; if late needs CMC fusion

# Thoracic and chest pain

with KEVIN SINGER and JEFF BOYLE

*I want to apologise to my fans. I broke my rib and again I am out of the fight.  
I really wanted to come back, I'm not sure if I will ever come back.*

Khabib Nurmagomedov, UFC, October 2015

## THORACIC PAIN

As with neck pain (Chapter 23) and low back pain (Chapter 29), it is frequently difficult for the clinician to make a precise diagnosis in patients with pain in the region of the thoracic spine given the interplay between the thorax, upper limb, neck, low back, and the cardiorespiratory and visceral systems. The most common musculoskeletal problems are disorders of the thoracic intervertebral joints and the numerous rib articulations as this region of the spine contributes stability to the axial skeleton. The thorax never sleeps as, even at rest, this complex interplay of joints, ligaments and muscles moves with respiration.

Injury to the intervertebral disc, the facet joints (also named zygapophyseal joints) or other nociceptive structures (Chapters 5 and 6) of the thoracic spine may lead to local or referred pain. Clinical presentation of these often articular problems is varied. Pain and altered motion are the dominant

features when one or more intervertebral segments or rib joints are involved. There may be associated abnormalities of the paraspinal and periscapular muscles as well as increased neural mechanosensitivity (Chapter 6). Thoracic intervertebral joint problems frequently refer pain to the lateral or anterior chest wall. Prolapse of a thoracic intervertebral disc is rare in athletes; however, it may be under-reported given the often diffuse symptoms that arise.<sup>1, 2</sup> Appropriate imaging studies are often necessary to rule out this diagnosis. The astute clinician keeps all diagnostic options open when considering the thoracic region.

In adolescents, the most common cause of thoracic region pain is Scheuermann's disease (Chapter 44), a disorder of the growth plates of the thoracic vertebral endplates associated with an accentuated lower thoracic kyphosis. A list of the causes of pain in the region of the thoracic spine is shown in Table 28.1. The surface,

**Table 28.1 Causes of thoracic pain**

Common	Less common	Not to be missed
Intervertebral joint sprain	Rib stress reaction/fracture	Cardiac causes
• Disc	Fracture of the rib posteriorly	Peptic ulcer
• Zygapophyseal joints	Thoracic disc prolapse	Tumour (e.g. carcinoma of the breast with bony metastasis)

Scheuermann's disease (adolescents)		
Postural imbalance of neck and shoulder and upper thoracic spine		

muscle and cross-sectional anatomy of this area are shown in Figure 28.1.

Vague symptoms must alert the astute clinician to consider the possibility of visceral origins as convergence of pain pathways may mimic somatic disorders (Chapters 5 and 6). The literature reporting occult pain presentations of thoracic-like pain encourages caution when assessing an individual with unresolved, at times over-investigated, symptoms.<sup>3, 4</sup> Consider 'red flags' (see Chapter 7).

## Assessment

### History

The patient often complains of pain between or around the scapulae. The pain may be central, unilateral or bilateral, and have commenced suddenly as a result of a specific movement or have been of gradual onset without discernible precipitating incident. Symptoms may be elicited by any active movement—particularly rotation (Fig. 28.2) or lateral flexion.<sup>5</sup> The T4–8 segments show greater ranges of axial motion compared with the stiffer upper and lower segments. Note any associated sensory symptoms such as paraesthesia or numbness. Although dermatomal patterns are more predictable in the thoracic region, symptoms may depart from such conventions. Vague pain noted in the region of the shoulder may relate to disturbance of the cervicothoracic junction<sup>6</sup> and, similarly, buttock, hip or inguinal region symptoms may have a low thoracic origin.<sup>5</sup> The behaviour of symptoms relative to activity or diurnal variation will assist in classification of the condition (Fig. 28.3).

If you have established a musculoskeletal cause of symptoms, consider aspects of the clinical presentation relative to SINS (Severity, Irritability, Nature and Stage) to inform clinical reasoning and management. The Severity of the condition helps to determine the vigour of any prescribed activity or physical treatment; Irritability, or ease of aggravation, relates to the volume of prescribed activity or physical treatment; Nature refers to the type of condition (e.g. fracture, instability, neurological (radicular?, somatic?; see Chapter 6); and Stage means being relative to an acute, subacute or chronic classification.

**Figure 28.1** Anatomy of the thoracic spine region

(a) Surface anatomy (b) Muscles of the thoracic spine region (c) Axial computed tomography (CT) image of the typical motion segment from the lower thoracic region. The most accessible rib articulation for palpation and mobilisation is the costotransverse joint (CTJ), with the costovertebral joint (CVJ) attached firmly to the lateral margin of the vertebral body, intervertebral disc and base of the pedicles

(a)

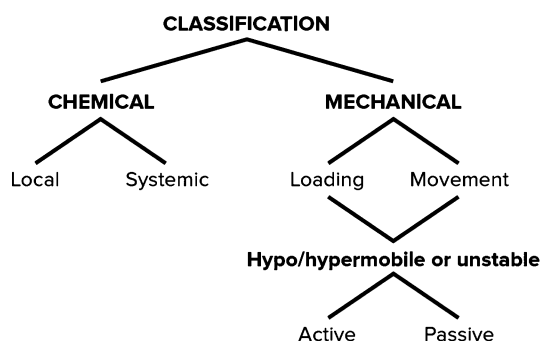

(b)

(c)

**Figure 28.2** Axial CT depicting the nature of thoracic zygapophyseal joint translation in response to induced segmental rotation

**Figure 28.3** Flowchart of thoracic region disorders. Classification facilitates the differential diagnosis and better outcomes through prescription of condition-specific treatment.

In the thoracic region, carefully consider the potential for non-musculoskeletal causes. Red flags may include systemic illness, malignancy, unexplained weight loss, fever or night pain. As Professor Gwen Jull was fond of saying, 'If the voice in the back of your head tells you something is not right, listen to that voice' (and refer/investigate appropriately).

**Figure 28.4** Examination of the patient with thoracic pain begins with observation and testing active movements

### Physical examination

In the thoracic spine region, assess range of motion and mobility of each intervertebral segment and carefully palpate the paraspinal and periscapular soft tissue. Examine the lower cervical and upper lumbar spine and perform a neurological examination for altered mechanosensitivity.

1. Observation (Fig. 28.4)
  - a. any asymmetry, scoliosis or kyphosis should be noted
  - b. muscle spasm
  - c. skin changes (sweating or erythema may suggest an autonomic response)
2. Active movements
  - a. flexion
  - b. extension
  - c. rotation.

Active movements are assessed in the cardinal planes for range of motion, symptom reproduction, and aberrant patterns of movement that may be antalgic or indicate dysfunction. Combinations of these movements in two planes may help guide treatment (Fig. 28.5).<sup>7</sup> A consistent pattern in which a movement that stretches the symptomatic area produces symptoms which are increased by the addition of movement in another plane that also has a stretch effect may suggest an extra-articular source of symptoms (myofascial, nerve, joint capsule), while a pattern consistent with symptoms primarily on compressive movements may indicate an intra-articular source. Mixed patterns may suggest multiple tissue involvement.

**Figure 28.5** Combined movement assessment is performed by determining the most symptomatic primary movement; this movement is then repeated in the two extremes of another plane. For example, the primary symptomatic movement of axial plane left rotation (a) is subsequently performed in two positions in the sagittal plane—flexion (b) and extension (c)

### 3. Palpation

- a. soft tissue
- b. assess segmental unilateral mobility by posterior to anterior directional pressure over the transverse process (Fig. 28.6a)
- c. assess rib mobility by posterior to anterior directional pressure over the angle of the rib with the scapular protracted (Fig. 28.6b)
- d. zygapophyseal
- e. costovertebral joints and, indirectly, the costovertebral joints
- f. paraspinal muscles
- g. anterior palpation of sternal, chondral and clavicular joints.

Soft tissue is palpated for tenderness, swelling, spasm, and trigger points while bony and chondral structures are assessed for tenderness and deformity and for motion anomalies.

### 4. Special tests

- a. springing of the ribs and costochondral junctions
- b. maximal inspiration
- c. cough/sneeze
- d. neural tissue sensitivity tests (slump test—Chapter 15)
- e. cervical spine examination (Chapter 23)
- f. lumbar spine examination (Chapter 29)
- g. muscle strength testing.

(a)

(b)

**Figure 28.6** (a) Assess segmental unilateral mobility by posterior to anterior directional pressure over the transverse process (b) Assess rib mobility by posterior to anterior directional pressure over the angle of the rib with the scapular protracted

## Investigations

Plain radiograph of the thoracic spine region is not routinely indicated as it usually adds little to the clinical picture. It may, however, demonstrate the presence of intervertebral growth plate abnormalities, indicate Scheuermann's disease, or show the presence of a secondary neoplastic disorder affecting the thoracic spine or ribs. Computed tomography (CT) and magnetic resonance imaging (MRI) scans may be indicated to exclude serious pathology in the presence of red flags such as unexplained weight loss or nocturnal pain. These imaging modalities may confirm a thoracic intervertebral disc prolapse or help stage neoplastic disease. Atypical pain patterns unresponsive to routine management should also signal the need for investigation, even in the young athlete (see also Chapters 5 and 6).

## Thoracic intervertebral joint disorders

Intervertebral joint injuries involving the intervertebral discs, rib articulations and zygapophyseal joints are the most common cause of pain in this region. They may be of sudden or gradual onset. Examination may reveal hypomobility of one or more intervertebral segments associated with local tenderness over the spinous processes, the zygapophyseal joints, the costotransverse joints or the surrounding paravertebral muscles. However on occasion, pain rather than stiffness may be the main presenting feature.

Treatment aims to restore full mobility by mobilisation or manipulation techniques. Passive overpressure (Fig 28.7) can be used to assess treatment response (feel for resistance and assess pain response). Soft tissue therapy and graded specific exercise may be required to restore normal function in the paravertebral and periscapular muscles. Passive techniques include digital ischaemic pressure and sustained myofascial tension. Trigger points in the paraspinal muscles are common and may be treated with appropriate soft tissue techniques. Use of dry needling techniques for trigger points may be used with caution; avoid complications such as pneumothorax.

Note that there is considerable variation in joint anatomy at the transitional junctions of the spine, particularly at the thoracolumbar junction.<sup>8</sup> These variations may contribute to subtle differences in segmental mechanics and injury patterns. While some zygapophyseal joints are remarkably asymmetrical, others may show a morphology that acts to constrain motion which should not be perceived as unusual hypomobility (Fig. 28.8). However, the transitional segments between the thoracic and lumbar regions are disposed to severe strain or injury during overload and these segments account for the highest incidence of spine-related trauma, particularly from high-energy sports (e.g. skiing, equestrian events, jet ski, motorcross).<sup>9</sup>

**Figure 28.7** Thoracic rotation overpressure applied passively at the end of active range to assess for resistance and pain response

## Costovertebral and costotransverse joint disorders

Disorders of the rib articulations include inflammatory spondyloarthropathies (such as ankylosing spondylitis), degenerative change (such as osteoarthritis) and mechanical joint sprains. Costotransverse joint problems are associated with localised tenderness and restricted mobility of the joints. This is often evident on deep inspiration and active movement as the ribs rotate in a predictable pattern relative to thoracic motion. Treatment may include mobilisation of the costotransverse joints, which will also have a modest influence on the deeper costovertebral articulations. There is no quality evidence to support image-guided corticosteroid injection as treatment when the condition remains unresponsive to standard management. A common problem of these small synovial joints may be derangement of intra-articular synovial fold inclusions which occupy the periphery of the internal joint cavity (Fig. 28.9). These conditions are usually amenable to mobilisations or manipulation.<sup>10</sup>

(a)

(b)

**Figure 28.8** Zygapophyseal joint abnormalities (a) Axial CT scan highlighting marked zygapophyseal joint tropism (rotation in response to load) (circled); a central Schmorl's node is noted within the endplate (arrow) (b) Horizontal histological section (100  $\mu$ m) through the zygapophyseal joints of the thoracolumbar junction to demonstrate variations in articular morphology from asymmetric (top image) to an enclosing morphology which constrains motion (lower image)

**Figure 28.9** Painful costovertebral joint synovial inclusions (black arrows). Horizontal histological section through the dorsal region of a costovertebral joint demonstrates a long fibro-fatty synovial inclusion within the joint cavity. Entrapped innervated inclusions may contribute to localised thoracic pain which can often be relieved through manipulation

### Scheuermann's disease

Scheuermann's disease is the most common cause of pain in the thoracic spine region in adolescents and is characterised by an accentuated low thoracic kyphosis arising from multiple vertebral endplate irregularities involving four or more vertebral bodies (Fig. 28.10). This condition is described in Chapter 44. Accentuated kyphosis may also arise from habitual training postures which involve loading into flexion.<sup>11, 3</sup> Extended training periods in one posture (e.g. cycling) tend to be associated with adaptive changes, and modification to training postures may need to be considered when recommending long-term management.

### Thoracic intervertebral disc prolapse

Prolapse of a thoracic intervertebral disc is a relatively rare condition that may be under-reported in the athletic

**Figure 28.10** Multiple endplate lesions (Schmorl's nodes) evident within the lower thoracic vertebral bodies (circles) typical of Scheuermann's disease

(a)

(b)

(c)

**Figure 28.11** MRI of T12–L1 disc prolapse in a 26-year-old Australian rules footballer (a) T1-weighted axial MRI demonstrating left para-central displaced disc fragment (arrow) (b) T2-weighted axial MRI highlighting internal disc derangement (arrowheads) and disc herniation (arrow) (c) T2-weighted sagittal image showing disc fragment (circled) at T12–L1. It impinges on the spinal cord

community.<sup>1, 12</sup> The segments that tend to be most commonly involved are the larger discs of the lower thoracic segments. MR images are shown for a T12–L1 disc prolapse (Fig. 28.11). The pathology of thoracic disc prolapse is shown in Figure 28.12. The clinical

B

(a)

(b)

**Figure 28.12** Thoracic disc prolapse (a) Haematoxylin and eosin (H&E) stained horizontal section at T10–11 depicting a posterolateral prolapse of the intervertebral disc (arrows). Such prolapses are most common in the lower thoracic segments given the greater volume and height of these discs and loading patterns involving flexion and rotation (b) Macroscopic horizontal section of a T11–12 disc to demonstrate a midline annular fissure and small central prolapse (arrow), which is a common presentation for thoracic disc lesions

presentation involves local back pain with radicular pain radiating in the distribution of the affected thoracic spinal nerve/s. However, pain from a thoracic disc prolapse often does not follow a characteristic radicular pattern so this may confuse the diagnosis (see also Chapters 5 and 6).<sup>2, 13</sup> Consider this potential diagnosis and refer for axial imaging and relevant pain intervention if you suspect the diagnosis.

### T4 syndrome

Occasionally, patients present with diffuse arm pain and sensory symptoms such as bilateral paraesthesias in the hands, generalised headache and interscapular tightness which is attributed to intervertebral joint problems around the upper thoracic region. This vague constellation of symptoms has been labelled the T4 syndrome.<sup>14</sup> Although not verified clinically, it speculates that the sympathetic nervous system contributes to symptoms. Examination often reveals hypomobility of the upper to middle thoracic segments together with a forward head position and shoulder protraction. Restoration of sagittal postural alignment of the head in relation to the thorax, shoulder retraction, improved neck and scapular muscle endurance, and mobilisation or manipulation of affected joints may relieve symptoms.

### Postural imbalance of the neck, shoulder and upper thoracic spine

Common muscle imbalances relative to shoulder dysfunction include weakness of the scapula retractors, particularly inferior and middle trapezius, and serratus anterior. Stronger muscles will often exhibit increased tone and decreased length, and commonly include scalenus posterior, pectoralis minor and both rhomboid major and minor.<sup>15</sup> These muscle imbalances may adversely influence segmental thoracic and rib articulation accessory motion.<sup>16</sup>

### CHEST PAIN

Chest pain occurs not infrequently in athletes, usually due to musculoskeletal causes. In mature athletes, the possibility that pain is of cardiac origin must be considered. This possibility is increased in the presence of associated symptoms, such as palpitations or shortness of breath, or when there is a family history of cardiac disease. Male endurance athletes who perform high-intensity training are susceptible to atrial fibrillation, either as paroxysmal episodes or as a persistent form.<sup>17</sup> Other causes of chest pain include peptic ulceration, gastroesophageal reflux, chest infection and malignancy.

The most common cause of chest pain in the athlete under 35 years is referred pain from the cervical or

**Table 28.2 Causes of chest pain in the athlete**

Common	Less common	Not to be missed
Rib trauma <ul style="list-style-type: none"> <li>• Fracture</li> <li>• Contusion</li> </ul>	Costochondritis	Cardiac causes
	Sternocostal joint sprain	Peptic ulceration
	Intercostal muscle strain	Gastroesophageal reflux
Referred pain from the thoracic spine	Rib stress fracture	Pneumothorax
Sternoclavicular joint disorders	Fractured sternum	Herpes zoster
Side strain		Pulmonary embolism

thoracic spine. Thus, patients presenting with anterior or lateral chest wall pain require a thorough examination of the cervicothoracic spine and thorax.

A list of possible causes of chest pain in athletes is presented in Table 28.2. The surface anatomy of this region is shown in Figure 28.13.

It may be difficult to distinguish between chest pain of cardiac origin and pain referred from the thoracic spine. They may both be unilateral and related to exercise. The clinical features of these two causes of chest pain in the athlete are considered in Table 28.3.

Major trauma to the chest wall is a medical emergency. Injuries sustained in contact sport commonly affect the ribs, resulting in either bruised or fractured ribs. These may lead to secondary dysfunction of the thoracic zygapophyseal joints, which can cause persistence of pain. Sternoclavicular and costochondral joint injuries

**Figure 28.13** Surface anatomy of the anterior chest to assess for symmetry

**Table 28.3 Comparison of clinical features of chest pain of cardiac origin and chest pain referred from the thoracic spine**

Feature	Referred pain from thoracic spine	Myocardial ischaemia
Age	Any age, especially 20–40 years	Older (>35 years), greater likelihood with greater age
History of injury	Sometimes	No
Site and radiation	Spinal and paraspinal, arms, lateral chest, anterior chest, substernal, iliac crest	Retrosternal, parasternal, jaw, neck, inner arms, epigastrium, interscapular
Type of pain	Dull, aching, occasionally sharp, sudden onset and offset, severity related to activity, site and posture	Constricting, vice-like ('clenched-fist' sign), may be burning, gradual onset and offset
Aggravation	Deep inspiration, postural movement of thorax, certain activities (e.g. slumping or bending, walking upstairs, lifting, sleeping or sitting for long periods)	Exercise, activity, heavy meals, cold, stress, emotion
Relief	Maintaining erect spine, lying down, firm pressure on back (e.g. leaning against wall)	Rest Glyceryl trinitrate (GTN)
Associations	Chronic poor posture, employment requiring constant posture such as at a keyboard or computer	Cardiac risk factors such as family history, obesity, smoking, dyspnea, nausea, tiredness, pallor, sweating, vomiting

are not uncommon. Intercostal muscle strains have been considered a cause of chest wall pain but, on close clinical examination, many patients with this presentation are actually suffering referred pain from the thoracic spine. Stress fractures of the ribs occur in sports such as rowing, tennis, golf, gymnastics and baseball pitching where rapid torsion loads are common. The aetiology of chest wall muscle injury from violent overload is exemplified by cricket fast bowlers who induce a rapid alternation between muscle lengthening followed by rapid eccentric contraction during delivery. This action can result in a strain injury at the rib or costal cartilage insertion of the internal oblique muscle over the lower four ribs.

## Clinical assessment

### History

A history of trauma to the chest wall will lead the clinician to suspect a rib injury. In the absence of trauma, the history should distinguish between musculoskeletal conditions and other cardiac, gastrointestinal and respiratory causes. It is important to elicit the type of pain and the location of the pain. Associated symptoms such as palpitations, shortness of breath and sweating may indicate that the pain is cardiac in nature. A history of productive cough may suggest pain is of respiratory origin, while symptoms of food-related pain or a burning, boring pain behind the sternum should alert the clinician to include gastroesophageal reflux or peptic ulceration in the differential diagnosis.

Pain aggravated by deep inspiration or coughing may be musculoskeletal in nature or indicative of a respiratory problem. Associated thoracic and, to a lesser extent, cervical or lumbar pain may suggest the thoracic spine or rib joints as possible sources of the patient's chest pain. An increase in pain with trunk rotation might add to this suspicion.

### Examination

Examination of the patient with chest wall pain should include palpation of the painful area and of possible sites of referral, especially the thoracic spine. Examination of the thoracic spine has been described earlier in this chapter. The cardiovascular and respiratory systems must always be examined. The abdomen should be examined for sources of referred pain.

### Investigations

If there has been significant rib trauma, a chest radiograph should be performed to exclude the presence of a pneumothorax. Specific rib views may be necessary to detect rib fractures. Chest radiography will indicate cardiac size and may reveal evidence of respiratory infection.

MRI (nuclear imaging/CT where MRI not available) may be required to detect stress fractures or other reactive bony conditions.

Electrocardiography and other cardiac investigations, including a stress ECG and an echocardiograph, may be performed if there is clinical suspicion of cardiac dysfunction. A Holter monitor may be indicated to help detect occult cardiac pacing irregularities. Gastroscopy may be indicated if peptic ulceration or reflux is suspected.

## Rib trauma

A direct blow to the chest may result in trauma to the ribs. This may range from bruising to an undisplaced or displaced rib fracture or to costal cartilage displacement (Fig. 28.14). Typically, the patient complains of pain aggravated by deep inspiration or coughing. Examination reveals local tenderness over one or more ribs.

A pneumothorax or rarely, a haemopneumothorax, may occur as a result of a rib fracture. Any athlete with rib trauma must undergo a respiratory examination to exclude these conditions. It is also important to consider trauma to underlying structures such as the liver, spleen and kidneys.

Radiographs may confirm the presence of a rib fracture, although it is not essential as treatment is symptomatic. Injury to the upper four ribs is unusual as they are somewhat protected. The lower two ribs are likewise rarely fractured as they are not attached to the sternum.

Treatment consists of analgesia and encouragement of deep breathing to prevent localised lung collapse. A fractured rib can be extremely painful. It will continue to be painful and tender to palpation for at least 3 weeks. Bruised ribs may also be painful and tender for up to 3 weeks.

Return to sport for athletes with an undisplaced rib fracture is appropriate when pain settles. Protective padding or splints may be used in contact sports after a rib

**Figure 28.14** Fracture of the costal cartilage in a 30-year-old footballer

injury. Local anaesthesia may be used for short-term pain management where indicated and with due care to avoid causing a pneumothorax. Contusion of the costochondral joints can be painful. Local treatment consists of cold therapy and strapping to splint the region.

### Referred pain from the thoracic spine

Referred pain to the chest may or may not be associated with a history of thoracic spine pain. On examination, there will usually be marked tenderness and stiffness, either centrally over the spinous processes of the thoracic vertebrae or, more commonly, on the same side as the chest pain over the thoracic zygapophyseal or costovertebral joints. There is also often associated tenderness in the soft tissues surrounding the thoracic spine, especially the paravertebral muscles. Active trigger points may develop and contribute to the referred pain. Referred pain, however, may not follow predictable patterns, which requires the clinician to explore symptoms and to rule out visceral disorders.<sup>5, 13</sup>

Local treatment aims to restore full range of motion of the involved thoracic intervertebral segments by mobilisation or manipulation. Soft tissue therapy to surrounding areas may be helpful. This includes digital ischaemic pressure to painful sites, and sustained myofascial tension and other massage techniques where chronic muscle and soft tissue tightness is established. Dry needling of involved trigger points may also be considered.

### PRACTICE PEARL

Referred pain from the thoracic spine is probably the most common cause of chest wall pain in the young athlete.

### Sternoclavicular joint problems

The sternoclavicular (SC) joint is the sole articulation between the upper extremity and the axial skeleton. The joint itself is diarthrodial, with an articular disc interposed between the two bones (Fig. 28.15). The articular surface of the medial clavicle is much greater than the sternal articulation. Only about 25% of the medial clavicle's surface articulates with the sternum at any one time, making the SC joint the joint with the least bony stability in the body.

The integrity of the joint comes from the strong surrounding ligaments, including the anterior, posterior, superior and inferior SC ligaments and the interclavicular, costoclavicular and intra-articular disc ligaments. The epiphysis of the medial clavicle is the last to ossify and fuse, at around 18 and 25 years of age, respectively. Another feature of this joint is the number of vital structures located directly posterior to the joint. These include the subclavian veins and artery, the trachea, the oesophagus and the mediastinum.

The SC joint can be injured by a direct blow or, more commonly, indirectly from a blow to the shoulder and is

**Figure 28.15** Anatomy of the sternoclavicular joint

**Figure 28.16** CT scan of anterior sternoclavicular joint dislocation showing clear asymmetry between the dislocated side (arrow) and the normal articulation

seen in upper limb weight-bearing sports (e.g. gymnastics). Simultaneous injuries of the acromioclavicular (AC) and SC joints are reasonably common.<sup>18–20</sup>

Traumatic injuries of the SC joint can be divided into first and second-degree sprains involving the joint capsule, subluxations, and dislocations involving rupture of the SC and/or costoclavicular ligaments and fractures of the medial clavicle. Subluxations and dislocations are further divided into anterior (more common; Fig. 28.16) and posterior (more dangerous given the adjacent neurovascular structures).<sup>21–23</sup>

Patients present with local pain and swelling depending on the severity of the injury. Anterior subluxations can be treated symptomatically by a figure-of-eight bandage for 1–2 weeks. Anterior dislocations can be reduced with lateral traction on the abducted arm and direct pressure over the medial clavicle. Dislocations are immobilised for 3–4 weeks in a clavicular strap. If the joint redislocates after closed reduction, a period of observation is appropriate. Many patients remain asymptomatic.

Posterior dislocations should be reduced closed under general anaesthesia as soon as possible after the injury. Traction is applied to the patient's abducted arm and the medial clavicle is brought forward manually or with a towel clip. Reductions are generally stable and are held with a figure-of-eight strap for 4 weeks.

### Costochondritis

Costochondritis occurs at the plane joints between the sternum and ribs. It is characterised by activity-related

pain and tenderness localised to the costochondral junction, usually over the T2–5 segments. Tietze's syndrome describes a painful inflammation of usually a single costochondral joint, although the sternoclavicular joint may be involved.<sup>24</sup>

Treatment consists of nonsteroidal anti-inflammatory drugs (NSAIDs), local physiotherapy and gentle mobilisation of the costochondral joints. This can prove an extremely difficult condition to treat. Corticosteroid injection to the costochondral junction may be of some assistance in refractory cases.

### Stress fracture of the ribs

Stress fracture of the ribs has been reported with a number of sports and is due to excessive muscle traction at the attachments to the ribs.<sup>25–28</sup> Stress fracture of the first rib is seen in baseball pitchers and appears to occur at the site of maximal distraction between the upward and downward muscular forces on the rib. This stress fracture tends to heal poorly. The injury has also been reported in golfers, generally on the leading side (i.e. left ribs in a right-handed player).

Anterolateral stress fractures of the ribs (Fig. 28.17), mainly the fourth and fifth ribs, are commonly seen in rowers. This stress fracture is thought to be due to excessive action of the serratus anterior muscle. The biomechanics of the rowing action (Chapter 9) should be assessed and discussed with the coach and athlete to determine the possible cause/s and changes to technique where indicated. The concept of excess rib cage

**Figure 28.17** Isotopic bone scan of a stress fracture of the ribs

compression coupled with excessive isometric thoracic muscle contraction in the beginning of the drive phase in rowing has been proposed as the mechanism.<sup>28-30</sup>

## Side strain

with ANDREW NEALON

'Side strain' is an injury sustained by athletes that is characterised by pain and focal tenderness of the lateral trunk over the inferior rib cage.<sup>31, 32</sup> It has most commonly been reported in cricket fast bowlers<sup>31, 33-35</sup> and baseball players,<sup>32, 36, 37</sup> and has also been reported in case studies in a golfer, javelin thrower, rower,<sup>31</sup> rugby player<sup>35</sup> and professional tennis player.<sup>38</sup> The injury typically occurs on the side contralateral to the bowling arm in fast bowlers.<sup>31</sup> In major league baseball the majority of injuries occur to the side contralateral to the throwing arm in pitchers, and the side facing the pitcher in batters.<sup>32</sup> It is evident that side strain is most commonly reported in sports that require highly repetitive, unilateral, asymmetrical and explosive actions that place great demand on the trunk.<sup>39</sup>

## Clinical features

The athlete typically presents with sudden pain and focal tenderness over the lateral aspect of the lower costal margins,<sup>31-32, 35-38</sup> and may initially have considerable pain to breathe deeply,<sup>31, 36, 38</sup> cough and roll over in bed.<sup>39</sup> Palpation is typically reported to reproduce pain. Diagnosis is primarily clinical, although imaging with MRI or ultrasound is common practice in elite sport.<sup>39</sup>

Pain is commonly reproduced by movements associated with the initial mechanism of injury.<sup>31</sup> Trunk lateral flexion range of motion is a common clinical test and is typically reduced and limited by pain when moving both towards and away from the injury side.<sup>39</sup> Isometric resisted shoulder adduction on the injury side may also reproduce symptoms.<sup>39</sup>

## Pathology and epidemiology

The pathology of side strain has been described in MRI<sup>31</sup> and ultrasound<sup>35</sup> studies as a tear of the internal oblique muscle from its rib or costal cartilage attachment with acute oedema and haemorrhage (Fig 28.18). Rib oedema and stripping of the rib periosteum have also been reported in a significant proportion of cases.<sup>31</sup> This suggests that some side strain injuries involve both soft tissue and bony pathology though the effect of this on recovery time is yet to be determined.<sup>39</sup> Injury from the undersurface of the eleventh rib is most common, followed by the tenth and then ninth ribs.<sup>31</sup> The relationship between imaging findings and recovery time is yet to be determined and is the subject of current research.

## PRACTICE PEARL

Cricket fast bowlers are particularly vulnerable to side strain injury, with over half of the fast bowlers playing regularly at first class level in Australia and England reporting at least one episode during their career.

The injury tends to occur most commonly in the early twenties and often during the early stages of a player's career at first class level. Side and abdominal strain contributed the second highest incidence of all body areas over the past two decades in the most recent Australian first class cricket injury report, causing the third highest total player unavailability behind only lumbar stress fractures and thigh and hamstring strains.<sup>40</sup> It also comprised 5% of all injuries in major league baseball.<sup>32</sup> Injury surveillance studies in both cricket and baseball suggest that the incidence of side strain injury has increased in recent years.<sup>32, 40</sup>

The mechanism of side strain injury is difficult to establish, although it is typically incurred in a single specific activity, such as bowling or throwing, and prevents further play.<sup>39</sup> It has been postulated to occur due to sudden eccentric contraction of the internal oblique muscle after the lengthening that occurs during the wind-up phase of bowling or throwing.<sup>31</sup> However, trunk lateral flexion range of motion during the fast bowling action exceeds the range demonstrated in standing by a mean of 29%<sup>41</sup>

**Figure 28.18** MRI (axial proton density image with fat saturation) of a side strain injury of the right internal oblique muscle. Focal grade II tearing of the internal oblique muscle is shown (solid arrows) just below the muscle attachment to the periosteum of the undersurface of the tenth rib. Intermuscular haemorrhage (open arrows) tracks between the internal and external oblique muscles

and compression of the lower ribcage versus the iliac crest may also be a factor. Side strain is most commonly sustained during the early stages of the competitive playing season.<sup>32, 42</sup> This suggests that adjusting to the demands of competition intensity may be a risk factor for this injury.<sup>39</sup>

### Management

Treatment includes resting until pain has resolved during respiration followed by the restoration of strength and lateral flexion mobility of the trunk with graduated return to sports-specific activity. The repetitive nature of the sports commonly associated with side strain mean that high volumes of strengthening exercise need to be performed in the rehabilitation phase so that the athlete can cope with the demands of sport upon returning to play.<sup>39</sup>

Recovery time can be prolonged. Case series of cricket and baseball players report times of 4–10 weeks to return to play.<sup>39</sup> Currently ongoing research in first class cricket in Australia and England indicates that while about 20% of first class cricket fast bowlers return to pre-injury level of competition within 3 weeks, almost 50% require more than 5 weeks. In excess of 7 weeks was required for over 20% of fast bowlers. Major league baseball surveillance reports that baseball players spent a mean time of 4–5 weeks on the disability list over the 20 years to 2010.<sup>32</sup>

#### PRACTICE PEARL

**Recurrence is common—30% of cricket first class bowlers suffered a further injury.**

This is most common in the first 12 months, with 20% of all cases recurring in this time. In the only published

case series of first class cricket fast bowlers to date, six out of ten cases were recurrences.<sup>33</sup> Baseball data reports a lower recurrence rate of 12%.<sup>32</sup>

Costoiliac impingement symptoms following side strain injury are also common, experienced by over a third of fast bowlers upon their return to bowling during rehabilitation and persistent in 20% of cases at time of return to competition. Currently it is unknown if such symptoms are associated with risk of recurrence. Non-remitting pain has led to surgery in cricket fast bowlers, with excision of the involved rib resolving symptoms.<sup>34</sup>

Despite its high prevalence in sports such as cricket and baseball, knowledge on side strain remains limited. The relationship between clinical assessment measures, MRI findings and time to return to play in first class cricket fast bowlers is the subject of current research.

### Conclusion

Disorders of the thoracic region in athletes can be complex given the interactions between musculoskeletal, cardiorespiratory and visceral systems, and their convergence in innervation patterns. Athletic training and competition impose unique strains on the thorax and thoracic spine, particularly during the important skeletal development years, which may give rise to a variety of stress or overuse responses.

In considering a differential diagnosis, the clinician needs to consider the biomechanics of the activity and common soft tissue and joint disorders of the thoracic region, and to be alert to the potential for occult symptoms masquerading as musculoskeletal problems. Similarly, symptoms suggestive of a musculoskeletal presentation may indeed arise from cardiac or visceral systems which can require timely referral and intervention.

# Low back pain

by PETER O'SULLIVAN and ALEX KOUNTOURIS, with JOEL PRESS and MARIA REESE

*My MRI shows I have a damaged disc at L5/S1. I am disappointed that I can never play basketball, golf and go for a run ever again. A neurosurgeon says he can perform a fusion. Is there anything else I can do?*

24-year-old athlete with disabling low back pain

Low back pain (LBP) is the leading cause of disability in the world affecting both the general population and athletes alike. In this chapter we outline a contemporary, multidimensional understanding of LBP and detail a clinical perspective of assessing and managing the disorder.

The anatomy of the low back is shown in Figure 29.1.

### EPIDEMIOLOGY

Back pain affects up to 85% of the population at some time in their lives. LBP is rarely reported before the age of 10; however, during adolescence there is a rapid increase in the reporting of LBP reaching near-adult rates (lifetime prevalence of 70%) at the age of 17 years. While the majority (70–80%) improve from an *acute* episode over a 3-month period irrespective of treatment, between 50–80% will have at least one *recurrent* episode. However, for up to 20–30%, LBP can become *persistent* and disabling, limiting sporting activity, physical functioning and impacting on a person's quality of life.<sup>1</sup>

LBP is the most common cause of disability in those under the age of 45, and the most expensive healthcare problem in those between the ages of 20 and 50. Back problems account for a significant percentage (25% in the United States) of workers' compensation claims. LBP is also a common cause of lost time from sport. Of great concern is that in spite of enormous financial resources being spent on radiological imaging, treatments and medicating for LBP, the chronicity and disability rates are increasing.<sup>2</sup> The estimated annual cost of LBP in the United States, for example, is over US\$40 billion.

## The multidimensional nature of low back pain

Once serious and specific pathology has been excluded, LBP in an athlete is frequently considered to be caused by an injury to the spine's structures. This is in spite of the fact that a clear mechanism of injury or even biomechanical strain often cannot be identified. Consequently, clinicians often reinforce the belief to the athlete that LBP is due to tissue damage, with treatments being directed at treating spinal structures.

In contrast, contemporary evidence supports the concept that LBP disorders in both sporting and non-sporting populations are associated with a complex combination of factors which may include pathoanatomical, physical, lifestyle, psychological, social, neurophysiological and genetic, all of which can predispose to LBP as well as maintain a vicious cycle of pain, distress and disability.<sup>1, 3</sup> This may present as LBP associated with an acute injury, repeated strain or in the absence of any tissue strain. The combination of contextual risk factors for the individual will determine levels of pain experienced, disability behaviours and coping strategies, as well as the risk for pain recurrence and chronicity. A detailed understanding of the various risk factors for LBP is required in order to provide a clear framework for clinicians to both examine and direct effective treatment and management.

## TRIAGE

When a person presents with LBP, the clinician must first triage him or her to rule out serious and specific pathology (Fig. 29.2, right column and left column).

## Serious pathology

For 1-2% of patients, LBP may be associated with serious pathology such as malignancy, infection or inflammatory disorder. The strongest factor suggestive of malignancy is a previous history of malignancy; for infection, a previous history of intravenous drug use coupled with fever; and for inflammatory disorder, an insidious onset of non-mechanical pain linked to night pain and morning stiffness.<sup>4</sup>

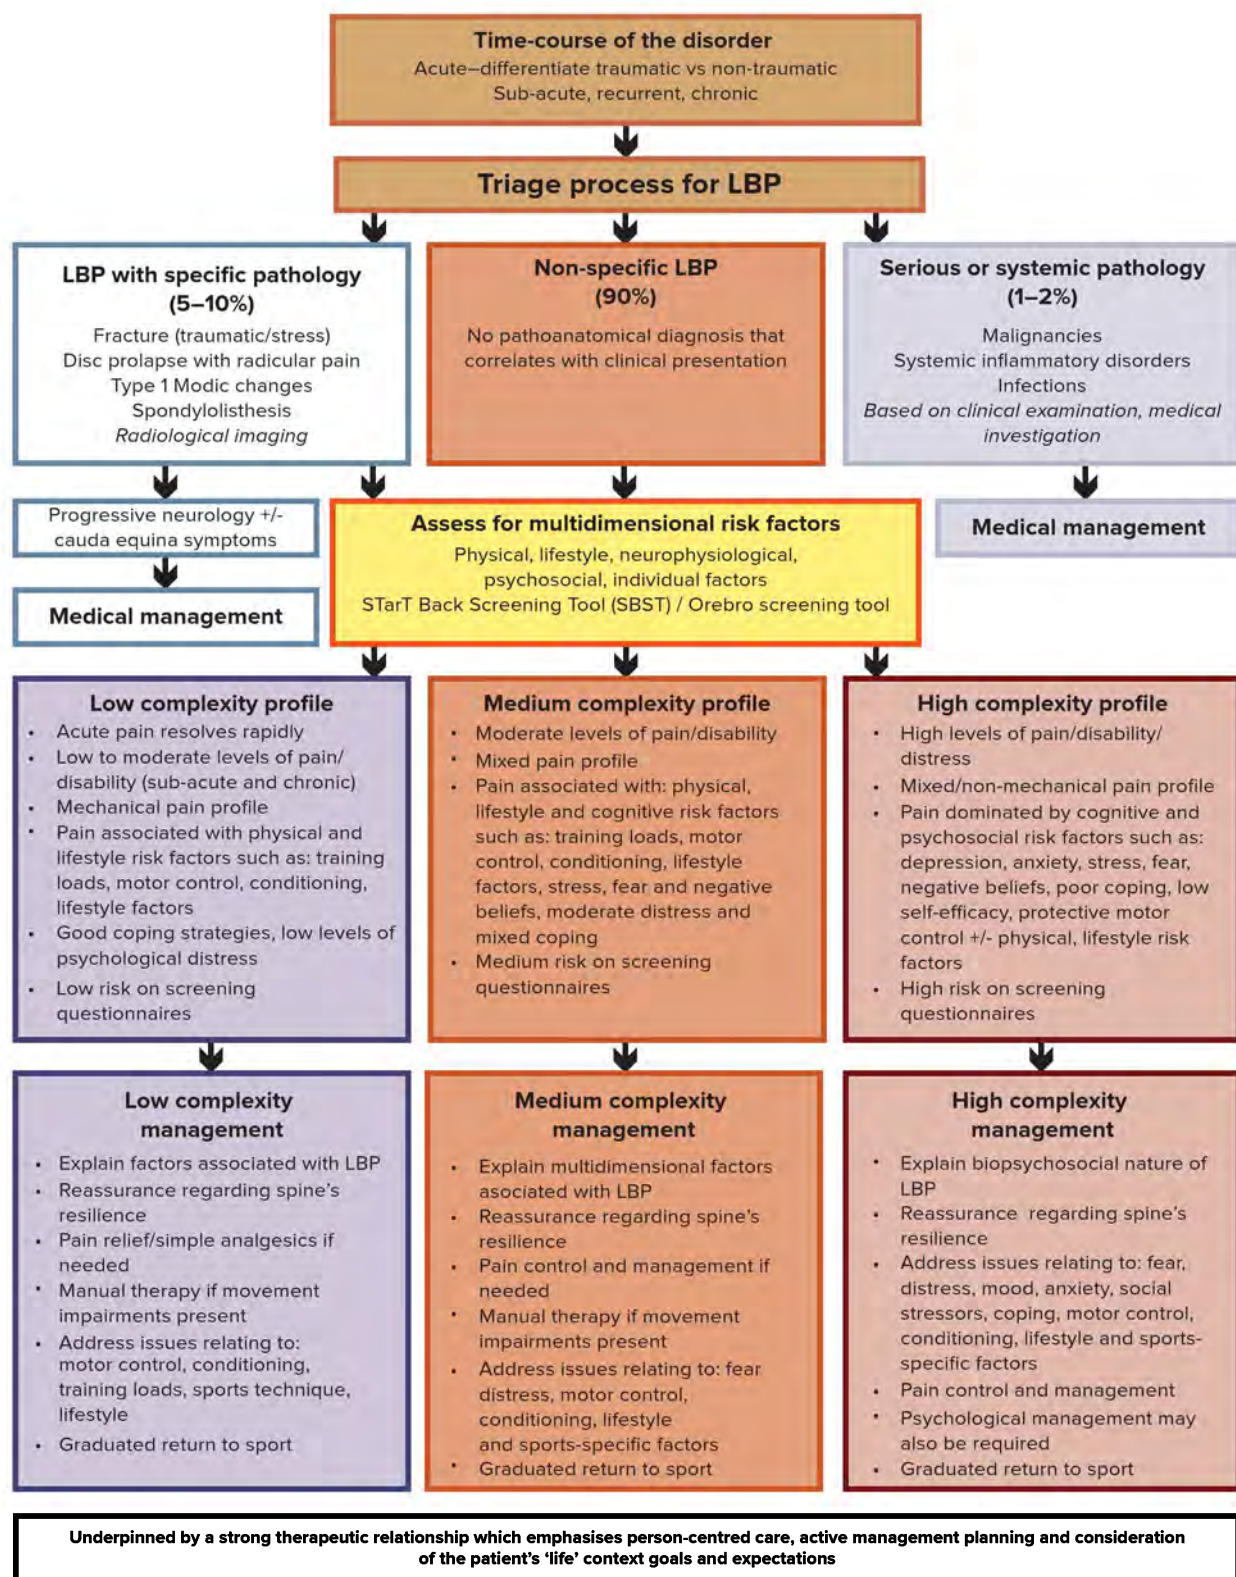

## Specific pathoanatomical diagnoses

For another 5-10% of patients with LBP, a definitive diagnosis can be made based on spinal imaging linked to careful clinical examination.

- In sporting populations, fractures related to direct trauma, such as a transverse process fracture (e.g. from a knee in the back) or compression fracture of the vertebra

**Figure 29.1 (cont.)** (e) Segmental motion: (i) flexion/extension (sagittal plane motion); (ii) torsion (transverse plane motion); (iii) side bending (frontal plane motion) showing compressive and torsional forces

**Figure 29.2** Clinical framework for the profiling and targeted management of LBP

(loading injury), can occur in the lumbar spine. Stress fractures of the pars interarticularis may also present, usually during the adolescent growth phase, in association with increased training exposures to sports that involve cyclical spinal loading such as cricket fast bowling, tennis, weightlifting, throwing sports and gymnastics. The natural history for these injuries is favourable, with conservative management involving a period of relative rest from pain-aggravating activities with a graduated return to full function.

- Spondylolysis or spondylolisthesis are present in 5% of the pain-free population and have genetic predisposition. They correlate poorly with pain and disability, but may become symptomatic in sporting populations that involve repeated spinal bending and loading. Their natural history is positive with good conservative care, unless the listhesis is high grade (>3) and/or when it is associated with neural compromise.
- While disc protrusions are present in pain-free populations, LBP associated with acute radicular pain +/- neurological deficits that correlates with imaging findings of disc prolapse, is considered a specific cause of LBP and associated leg pain. This may be linked to a history of a sudden increase in exposures to repeated spinal loading with flexion and rotation, and is considered to result in radial fissuring in people genetically vulnerable to disc prolapse. Although very painful in the acute phase, the natural history for disc prolapse is favourable and, for the majority, the prolapse resolves over time. Only in the case of progressive neurological deficit and/or cauda equina symptoms is imaging and surgical review required.
- Vertebral endplate oedema (Modic type 1 changes) is also associated with LBP and can be observed on magnetic resonance imaging (MRI) scan (T1-weighted view). It

reflects an active inflammatory process of the subchondral bone of the vertebral endplate. This may be linked to repeated biomechanical loading of an underlying degenerate disc and tends to be more prevalent in middle-aged populations. When symptomatic, this may present as disabling pain associated with loading, movement and night pain. However, the natural history for these presentations is good with appropriate conservative management.

- Spinal canal stenosis is rare in young and middle-aged athletes as the condition is related to advanced degenerative changes, but may occasionally be seen in older athletes. It is typically characterised by diffuse pain in the buttocks or legs, aggravated by standing and walking, and relieved by sitting, lying and lumbar flexion. This may be managed conservatively with exercises that reduce the lumbar lordosis and enhance hip extension mobility to reduce extension loading. Where this approach fails, surgical review may be indicated.

It must be understood that in pain-free populations, there is a high prevalence of abnormal findings on MRI scans (Table 29.1).<sup>5</sup> These findings are poor predictors of future back pain and do not correlate well with levels of pain and disability.<sup>6</sup> This makes a true pathoanatomical diagnosis difficult to achieve, reinforcing the need for careful clinical examination. Early MRI imaging for minor back strains results in poorer prognosis, increased instances of sick leave and a higher possibility of surgery.<sup>7</sup>

This highlights the potential iatrogenic influence that imaging plays in LBP and confirms that clinicians need to take great care in communicating radiology findings in a manner that is evidence based and does not create fear and anxiety, causing the patient to catastrophise their

**Table 29.1 Age-specific prevalence estimates of degenerative spine imaging findings in asymptomatic patients**

Imaging finding	Age						
	20	30	40	50	60	70	80
Disc degeneration	37%	52%	68%	80%	88%	93%	96%
Disc signal loss	17%	33%	54%	73%	86%	94%	97%
Disc height loss	24%	34%	45%	56%	67%	76%	84%
Disc bulge	30%	40%	50%	60%	69%	77%	84%
Disc protrusion	29%	31%	33%	36%	38%	40%	43%
Annular fissure	19%	20%	22%	23%	25%	27%	29%
Facet degeneration	4%	9%	18%	32%	50%	69%	83%

condition. Even when a specific diagnosis can be made, consideration of the multidimensional factors that can influence pain and disability (listed in the next section) is important and may need to be addressed for optimal management of the disorder.

## Low back pain without a pathoanatomical diagnosis

### PRACTICE PEARL

For the majority of patients who present with LBP (85–90% of patients), no definitive structural diagnosis can be made, leaving a management vacuum and a diagnosis of 'non-specific low back pain'. However, the experienced clinician can usually identify a clear pattern of tissue sensitisation linked to specific spinal structures.

## FACTORS CONTRIBUTING TO LOW BACK PAIN

A major recent paradigm shift has been the recognition that non-specific back pain can be strongly associated with a variety of different modifiable physical, lifestyle, psychosocial and neurophysiological risk factors that provide the clinician with the opportunity to target management.<sup>1,5</sup> We explore those in turn.

### Physical factors

#### Extrinsic factors

Each sport carries a different risk for LBP. An increased risk of LBP is linked to specific sports associated with high volumes of sustained and cyclical loading of the spine especially when coupled with rotation and side bending. For example, sports such as cycling, field hockey and rowing are associated with increased flexion loading +/- rotation strain, whereas sports such as dance, gymnastics, tennis and fast bowling in cricket are associated with increased extension strain coupled with side bending and rotation. These sport-specific factors interplay closely with training loads, volumes and technical aspects of the sport, which are closely related to the reporting of LBP.<sup>8</sup> Considering these extrinsic factors in conjunction with the coach and sport demands, and in line with the intrinsic factors of the individual, is important for targeted management.

#### Intrinsic factors

There is evidence that non-neutral spinal postures in standing (sway, hyperlordotic and flat back) are associated with an increased risk of LBP.<sup>9</sup> These postures are linked to changes in spinal loading as well as altered motor control patterns of the trunk and the hip region.<sup>10</sup> There

is also evidence that these habitual postures influence movement patterns and may represent a 'signature' upon which more complex motor patterns develop.<sup>11</sup> These postural patterns, when interacting with sport-specific related extrinsic factors, may result in end-range tissue strain sensitising the spinal structures. This can result in directional patterns of pain sensitisation (flexion/extension/lateral [side bending] or multidimensional) in the presence or absence of tissue injury.<sup>12</sup>

In the acute phase of an LBP disorder following a traumatic injury and/or when associated with pathology, muscle guarding and movement impairments may be protective and adaptive. However, in the absence of tissue injury or when pain persists past tissue healing time, 'protective muscle guarding' may become unhelpful, provocative and maladaptive. This may reflect a response to a person's perception of underlying sense of threat, fear or vulnerability in the absence of ongoing pathology or tissue injury.<sup>12,13</sup>

In this case, increased protective trunk muscle co-contraction may increase spinal stiffness and compressive loading, which may provoke pain-sensitive structures. This is similar to the 'limp' that occurs when a person sprains their ankle and that then persists beyond the natural tissue healing time, predisposing the person to recurrent and/or persistent pain.

Persistent motor control deficits (as described below) can also potentially leave a person vulnerable to increased tissue loading. These patterns are not stereotypical and are commonly associated with directional patterns of sensitisation with spinal movement and loading.<sup>12,13</sup>

There is also evidence that people with LBP present with proprioceptive deficits specific to these patterns,<sup>14</sup> as well as changes in the cortical mapping of the motor cortex,<sup>13</sup> which may act to reinforce the maintenance of provocative patterns of movement. This highlights the need for an individualised mind-body approach to rehabilitation.

Deconditioning and muscle weakness in one body region, secondary to habitual postures and movement patterns, avoidance or sedentary behaviours, can also alter patterns of motor control in a proximal region. For example, weakness of the gluteal or lower limb muscles has been shown to increase lateral trunk shift and increased levels of trunk muscle co-contraction with single-leg loading resulting in increased spinal loading.<sup>15</sup> This may be linked to pain associated with sports involving limb loading. On the other hand, deficits in back muscle strength and endurance may render a person vulnerable to flexion loading strain in a sport such as rowing or hockey.<sup>14,16</sup>

### Lifestyle factors

Sedentary behaviour, sudden increases in activity levels, abdominal obesity, sleep deficits and disruption, excessive alcohol and smoking are all known to be risk factors

that can act both peripherally and centrally to sensitise spinal structures.<sup>17-19</sup> These may be important targets for management.

## Psychosocial factors

### Cognitive factors

Negative beliefs, as well as fear of pain, movement and activity, are strong predictors of disability levels.<sup>20</sup> Healthcare professionals provide a critical role in transferring beliefs with regard to back pain to their patients. Language such as 'your back is unstable' may be interpreted as 'my back is damaged and it's dangerous to move'. A comment that states a 'lack of core stability' may lead the patient to believe that 'my back is weak and vulnerable and I need to be vigilant to protect when I move'. Words such as 'disc degeneration' and 'wear and tear' may also have long-lasting negative effects.<sup>21, 22</sup>

These may contribute to: fear of pain, movement and sporting activity; pain hypervigilance; and catastrophising linked to the belief that pain equals harm. Low levels of confidence and self-efficacy are also related to higher disability levels and this is often related to poorer coping strategies.<sup>23</sup> In some athletes, this may manifest as 'avoidance' of movement and/or sporting activity and dependence on passive treatments, while for other athletes 'endurance' coping strategies may present where they overexert themselves with pain-provoking activities in spite of significant pain exacerbation.<sup>24</sup> This can lead to an activity 'boom' (i.e. overactivity), followed by 'bust' (i.e. inactivity) pattern.

The responsibility of the clinician is to use language and management strategies that build confidence and empower the patient to develop effective self-management strategies while reducing reliance on passive therapies.<sup>21</sup> It is known that negative back pain beliefs and fear are also associated with avoidance behaviours and protective muscle guarding highlighting the close body-mind relationship with LBP.<sup>25</sup> Inquiring and screening for an athlete's pain beliefs, levels of fear and thoughts about pain are essential for effective management.<sup>21, 26</sup>

### Emotional factors

Emotional factors such as stress, anxiety, depression, anger and frustration can act to reinforce maladaptive behaviours, further enhancing the pain experience and disability levels.<sup>3</sup> They can also influence pain processing, both centrally and peripherally, through dysregulation of the hypothalamic-pituitary-adrenal axis, altered immune and neuro-endocrine function, and cortical changes. They are commonly associated with LBP in sporting populations<sup>27</sup> and require screening and enquiry.<sup>26</sup> Screening for comorbid mental health disorders (anxiety disorder, obsessive compulsive disorder, panic disorder and depression) is important, especially when an athlete is disabled and distressed.

## Social stressors

Work- and sports-related stress, expectations of the coach, media, family stress and cultural factors can all have an influence on pain beliefs, coping and vulnerability and need to be considered in the context of the athlete.<sup>3</sup> Significant life stress events are predictive of LBP disorders and should be screened for when the pain experience is disproportionate to the pain history (i.e. disproportionate pain responses to mechanical loading) and when pain develops in the absence of a clear history of tissue loading.

## Neurophysiological factors

LBP is associated with complex changes in both the peripheral and central nervous system. There is growing evidence that persistent LBP is also associated with changes in the neuro-immune and neuro-endocrine systems, sensorimotor cortex, and associated with a loss of endogenous pain inhibition related to genetic/environmental interactions.<sup>3</sup> These factors are thought to contribute to the various sensorimotor changes observed by clinicians in a clinical setting, ranging from anatomically specific to more widespread pain disorders.<sup>28</sup>

## Proportionate pain responses to mechanical loading

In sporting populations, LBP disorders are often localised to an anatomical region and present with proportionate pain responses relative to specific patterns of biomechanical loading (i.e. pain is clearly linked to directional patterns of spinal loading and movement).<sup>28</sup> There is growing evidence that cyclical spinal loading that involves either end-range or combined spinal movements (sagittal with side bending and/or rotation) with compressive loading can result in pain sensitisation of spinal structures without demonstrable 'tissue damage'.

In these cases, any of the nociceptive structures of the lumbopelvic region may be associated with LBP. These structures may include the vertebral endplate, annulus fibrosis of the intervertebral disc which are the main load-bearing structures, the laminae, zygapophyseal joints and surrounding ligamentous structures which provide resistance to end-range loading and torsion, the dura mater and nerve structures, as well as muscles and their fascia. All of these structures are richly innervated and may become sensitised by different combinations of the multidimensional risk factors reported earlier.

In the case of referred or 'neurogenic' pain where leg pain presents with signs of neural tissue sensitivity (positive single-leg raise [SLR] and slump tests), this may be associated with sensitisation of the nerve root epineurium in the absence of nerve root compression.<sup>29</sup> The potential lumbar spine nociception generators are listed in Table 29.2. By using skillful palpation, the clinician may be able to localise pain to discrete spinal levels associated

**Table 29.2 Lumbar spine pain generators**

- Nucleus pulposus
- Annulus fibrosus
- Facet joints
- Ligaments
- Muscles
- Nerve
- Synovium

with localised muscle tension and tenderness (trigger points); however, the ability to identify the sensitised structure/s with confidence (i.e. disc versus facet joint) based on clinical examination is limited.

### Disproportionate pain responses to mechanical loading

Inflammatory pain is usually a sequel to tissue injury or trauma. It is characterised by constant pain at rest that may be provoked with movement or loading. This pain should settle with expected healing time and may respond to non-steroidal anti-inflammatory drugs (NSAIDs). Inflammatory pain may also be associated with a repetitive tissue strain mechanism (i.e. after an hour on a rowing ergometer or bowling 10 overs in cricket).

For others with LBP, their symptoms may be more widespread, variable and demonstrate disproportionate pain responses relative to biomechanical loading (i.e. pain that is provoked with minimal biomechanical stress or aggravated by levels of stress, anxiety, low mood, disrupted sleep and/or fatigue rather than biomechanical factors). In these cases, pain is often more bothersome, distressing and disabling; and the underlying pain mechanisms are commonly linked to central pain processes (central sensitisation) and widespread tissue hypersensitivity rather than clear nociceptive processes.

This may present clinically as pain provoked by minor mechanical provocation in all directions of spinal movement and/or loading, and associated with widespread tissue hyperalgesia and multiple trigger points in surrounding muscles. On the other hand, it may present as a person who is distressed, anxious and hypervigilant, but with an absence of clear clinical signs.

The identification of widespread tissue sensitivity to palpation, cold and/or movement may be clinical indicators of central sensitisation. Localisation of pain to discrete spinal levels is usually difficult in these cases. These presentations are also more likely to present with comorbid anxiety, depression, heightened levels of distress as well as non-specific health complaints (i.e. fatigue, nausea, headaches, stomach pain, sleep disturbance and so on).

Treating the sensitised tissue structures (with injections or manual techniques) may result in short-term relief, be

unsuccessful or indeed exacerbate the pain disorder, resulting in more distress. In contrast, care that targets the underlying mechanisms of the disorder (i.e. sleep, mood and stress-related factors) is required and likely to be more effective.

Many with LBP may present with a mixed pain picture where consideration of all multidimensional factors is required.

### Individual considerations

There is growing evidence to support the idea that genetic variations have a powerful influence on pain processing as well as tissue structure (i.e. what you see on an MRI scan).<sup>3</sup> These factors interact with biopsychosocial factors in the presentation of LBP. This can explain how two people with similar MRI findings can have very different pain experience and disability levels.

The presence of health (irritable bowel, fatigue, restlessness) and pain (headaches, migraines) comorbidities are important as they may reflect the level of the allostatic load on the athlete (physiologic consequences of adapting to repeated or chronic stress).<sup>30</sup> It has been identified that these factors are predictive of episodes of LBP which may be mediated via neuro-immune processes.

The athlete's goals, expectations and readiness for change are also known to be important considerations in the assessment, management and prognosis of people with LBP and need to be considered.<sup>31, 32</sup>

### CLINICAL APPROACH

A clinical reasoning process, based on the patient's 'story', screening questionnaires<sup>26</sup> and clinical examination, determines the relative weighting, dominance and relevance of the variety of factors with regard to the individual's disorder (Fig. 29.2). This allows the clinician to prioritise and target treatment and management.

### History

The aim of the interview is to hear the story of LBP from the patient's own perspective. This involves the pain history, gaining a clear understanding of the mechanism of injury or biomechanical aggravation if present. Where LBP is of insidious onset, it is essential to understand changes in training load, contextual stressors and lifestyle factors.

Determination of the location of the pain, any radiation to the buttocks or legs, the aggravating and relieving factors (postures, movements and activities), and the presence of any associated features including sensory and motor symptoms is important. Any previous history of back pain and response to treatment in the past is noted. Understanding directional patterns of pain provocation and relief (such as flexion, extension or combinations of movement and/or loading) and how easily the pain is aggravated is important in gaining an insight into patterns

of tissue sensitivity, and for directing the physical examination as well as the type and intensity of treatment.

Where LBP is distressing and/or disabling, screening for psychosocial factors including levels of stress, anxiety, fear, focus on pain and mood are critical as well as levels and patterns of sleep. Understanding the person's beliefs about their pain, fear of pain and/or movement, coping strategies, as well as any patterns of avoidance or persistence provides insight into their levels of self-efficacy.

Understanding personally relevant goals and expectations for treatment as well as their current levels of training, activities of daily living and future sporting commitments is also important. Screening for general health, levels of energy/fatigue, comorbid pain and health complaints is necessary.

Review of radiology, where present, allows for consideration of imaging relative to the clinical presentation, as well as an opportunity to reassure the patient

regarding their spine's structural integrity if no specific pathology is present.

Screening for potentially serious symptoms include:

- cauda equina symptoms (e.g. bladder or bowel dysfunction)
- spinal cord symptoms (e.g. difficulty walking, tripping over objects)
- sensory symptoms (e.g. pins and needles, paraesthesia)
- motor symptoms (e.g. muscle weakness)
- systemic symptoms (e.g. weight loss, malaise)
- severe night pain.

The use of standardised self-reporting measures for pain (Numeric Pain Rating Scale (NPRS), body chart), disability (patient-specific functional scale, Oswestry Disability Index or Roland Morris Disability Questionnaire), psychosocial distress (STarT Back Screening Tool, Orebro multidimensional screening tool) are also recommended as screening tools to identify the complexity profile of the athlete and as a way of quantifying the effects of treatment (Table 29.3). Having the

patient fill in at least the body chart, as well as a disability and a psychosocial screening questionnaire prior to examination is considered best practice.

## Physical examination

Examination of the patient with LBP may include the following test elements.

- Assessment of functional postures, movements and sports-specific activities nominated during the interview as pain provoking and relieving. This is first carried out to observe for patterns of pain provocation, motor control strategies, guarded movement, protective behaviours, patterns of avoidance and levels of confidence.
- Assessment of the pattern, timing and range of spinal movement in relation to the whole kinetic chain. This is important in order to identify the adopted movement strategies.
- Repeated and/or sustained movements can be tested to determine patterns of pain provocation and easing (in the case of central back pain), as well as pain centralisation (where symptoms move peripheral to central, seen as a positive clinical finding) and peripheralisation (where symptoms move peripherally, seen as a negative clinical finding) in the case of leg pain. Finding a patient's directional preference or centralising the patient's pain during the physical examination can help guide management.<sup>50</sup>
- Combined movement testing can be useful to establish patterns of pain provocation related to combined spinal movement and loading. For example, in a tennis player with LBP related to the serve, combined movement testing of backward bending combined with side bending and rotation may reproduce symptoms.
- Palpation of the back and trunk muscles is to determine levels of muscle tension during spinal movements. For example, where the back muscles are activated during

backward bending or the abdominal wall activates during forward bending, this is seen as an abnormal muscle bracing motor control strategy.

- Functional tests can be applied during these provocative functional tasks to determine whether altering the spinal posture, the movement pattern or level of muscle tension increases or reduces the pain experience during functional tasks. For example, where pain is related to lumbar spine flexion during lifting/loading tasks, enhancing the anterior pelvic tilt with relaxation of the thoracic spine can be tested during lifting to determine whether this reduces the pain experience. In contrast, where pain is related to lumbar spine extension during lifting/loading/backward bending tasks, then enhancing posterior pelvic tilt to reduce lordosis can be tested. Where pain is related to loading in neutral spine positions, relaxation of the abdominal wall with diaphragm breathing in conjunction with a relaxed thoracic posture can be used. Where pain is provoked by frontal or rotation plane activities then modify these activities by addressing control within these planes. These functional tests can provide an insight as to whether the identified motor control strategies (i.e. protective muscle guarding) protective (adaptive) or provocative (maladaptive).
- Assessment of spine 'stiffness' and patterns of tissue sensitivity in muscles and joints with palpation examination.
- Screening for lower limb (squat and lunge) strength and endurance is conducted where pain is associated with sustained and/or repeated spinal loading (i.e. running, jumping, limb loading).
- Screening for back muscle strength and endurance (squat hold or Sorensen test) is conducted where there is a pain associated with a clear loss of control into lumbar flexion.
- Testing for neurological deficits in the presence of radicular pain and signs of nerve compression.

These examination goals can be met by following this clinical routine.

1. Observation movement patterns in sitting, lying, standing, bending
2. Active movements
  - a. flexion (Fig. 29.3a)
  - b. extension (Fig. 29.3b)
  - c. lateral flexion (Fig. 29.3c)
  - d. combined movements—quadrant position (Fig. 29.3d)
  - e. single-leg extension (Fig. 29.3e)
3. Passive movements
  - a. overpressure may be applied at the end of range of active movements

b. muscle length (e.g. psoas, hamstring, gluteals)

c. hip quadrant

#### 4. Palpation

- a. spinous processes (Fig. 29.3f)
- b. over the zygapophyseal joints
- c. inferior sulcus sacroiliac joint (Fig. 29.3g)
- d. over the iliolumbar ligament
- e. paraspinal muscles (Fig. 29.3h)
- f. quadratus lumborum (Fig. 29.3i)
- g. gluteal muscles

#### 5. Assessment of strength

- a. lower limb (e.g. double leg squat, single-leg squat; Fig. 29.3j, lunge)
- b. Sorensen (or Biering-Sorensen) test (Fig. 29.3k)

#### 6. Special tests

- a. straight leg raise/slump test (Chapter 15)
- b. prone knee bend/femoral slump
- c. sacroiliac joint stress tests and active straight leg raise (Chapter 30)
- d. neurological examination

The clinical utility of various clinical assessment findings are outlined in Table 29.4.

## Investigations

In the management of most cases of LBP, investigations are not required. However, there are certain clinical indications for further investigation. Radiography should be performed if traumatic fracture or spondylolisthesis is suspected. Radioisotopic bone scan may be helpful in cases of suspected stress fracture of the pars interarticularis.

When specific pathology is suspected or LBP is distressing, disabling and progressive, and further diagnostic imaging is needed, MRI is often the imaging modality of choice. MRI can evaluate for a variety of possible sources of nociception including lumbar disc herniation, nerve root compression, spinal stenosis and bony stress reactions. MRI can also be used to image the internal structure of the discs. Degenerated discs that have lost fluid have a characteristic appearance on MRI (Fig. 29.4). MRI may confirm the presence of bone oedema of the vertebral endplate. The clinician must be wary, however, of placing too much emphasis on this investigation, as abnormalities shown on MRI may not necessarily be responsible for all or any of the patient's pain—they commonly reflect normal age-related changes.<sup>57</sup> MRI studies with and without contrast can be beneficial in patients with prior history of lumbar spine surgery and to help identify malignancy or metastatic disease.<sup>58, 59</sup>

Unlike MRI, computed tomography (CT) scanning is unable to provide further information on the internal structure of the intervertebral disc, yet it can be used in cases of suspected nerve root compression where MRI is either contraindicated or unavailable. The presence and

acuity of a pars interarticularis defect can be determined with reverse gantry CT scanning.

## MANAGEMENT OF SPECIFIC LBP DISORDERS

### Stress fracture of the pars interarticularis/lumbar spondylolysis

Lumbar spondylolysis is a term used to describe radiologically confirmed lesions in the posterior vertebral arch, in the region of the pars interarticularis.<sup>60–64</sup> The term includes a spectrum of bone stress injuries (stress reactions and stress fractures) and defects (non-united fractures). Traditionally spondylolysis was considered

**Figure 29.4** Sagittal T2-weighted image of the lumbar spine showing decreased fluid (dark signal) in the L4/5 and L5/S1 intervertebral discs. Also noted are small disc herniations (arrows) at both levels. The clinical significance of these findings is debated (see below)

an injury of the pars interarticularis, but with the advancement of imaging techniques it is apparent that it commonly involves the adjoining pedicle and lamina.<sup>65, 66</sup>

The incidence of spondylolysis in the general population is 4-9% and varies with race and sex.<sup>60, 67-70</sup> In the athletic population, the incidence of spondylolysis is much higher, affecting predominantly adolescents involved in sporting activities that require repetitive spinal loading.<sup>71, 72</sup> It is particularly common in tennis players, platform or springboard divers, gymnasts, soccer players, volleyball players, track and field athletes and ballet dancers.<sup>73-79</sup> Cricket fast bowling, which involves a combination of repetitive trunk rotation, extension and lateral flexion during the delivery stride, has one of the highest incidence of spondylolysis of any sport.<sup>80-84</sup> The biomechanics of cricket fast bowling are described in Chapter 9.

The reports of spondylolysis in the athletic populations can sometimes be misleading because they often include symptomatic and asymptomatic spondylolysis together, and there is typically no differentiation between active bone stress injuries (stress reactions and stress fractures) and symptomatic chronic non-united fractures or defects.

#### PRACTICE PEARL

When considering spondylolysis it is important to have a clear understanding of the terminology, pathology, clinical presentation and radiology because the management of spondylolysis will vary depending on the morphology of the spinal abnormality.<sup>62</sup>

### Terminology

The terminology used to subcategorise spondylolysis is not universal, but there are basically two main types of lesions that are distinctly different in regards to pathology, clinical presentation and radiological features.<sup>60, 62</sup>

1. Active bone stress lesions. These can be subcategorised to reflect the progression along the bone stress continuum:
  - a. pre-spondylolytic bone stress
  - b. stress reaction
  - c. stress fracture.
2. Non-united stress fractures. These are often referred to as chronic defects.

The broad spectrum of spondylolytic pathology is reflected in vastly different clinical features ranging from asymptomatic to debilitating pain.<sup>85, 86</sup> The clinical presentation is also typically varied and complex; and best appreciated by the radiological characteristics that traverse the bone stress continuum (Table 29.5).

The earliest stage in the bone stress continuum is *pre-spondylolytic bone stress* that is characterised by the absence of symptoms, but a radiological appearance of bone stress on imaging such as MRI or nuclear medicine but with no fracture line (Table 29.5). The absence of symptoms means that it is a condition typically identified in radiology-based screening programs or incidentally when imaging for another injury.<sup>87</sup>

*Stress reactions* have similar radiological characteristics to pre-bone stress lesions but are symptomatic, highlighting a progression of bone stress continuum, such as more advanced microfractures (Table 29.6). It is possible that the intensity and extent of the signal on MRI may be greater in stress reactions than in pre-bone stress conditions; however, this has not been scientifically validated. At the final stage of the bone stress continuum are *stress fractures*, which are the most advanced bone stress injuries and identified radiologically by the presence of active bone stress (similar to stress reactions) but with a visible fracture line (partial or complete).

Spondylolytic stress fractures are prone to non-union and should therefore be considered as high-risk stress fractures like the navicular and fifth metatarsal stress fractures (Chapter 4). This explains the high rate of non-united spondylolytic fractures (also known as defects) reported in the published literature. A clear distinction between active stress fractures and non-united defects is essential as the management strategies need to be vastly different.

It is therefore important to understand the difference in pathology, clinical presentation and radiological features between active spondylolytic bone pathology and chronic defects.

### Clinical presentation

There is no scientific research that outlines the clinical features of spondylolysis. The few papers published highlight a clinical picture that is similar to many other lumbar spine conditions.<sup>61</sup> Kobayashi et al. reported

**Table 29.5 Radiological and clinical definition of athletic spondylolytic lesions**

Diagnosis	Bone stress (MRI and scintigraphy)	Cortical breach (X-ray, CT, MRI)	Symptoms
Pre-symptomatic bone stress	Yes	No	No
Stress reaction	Yes	No	Yes
Stress fracture	Yes	Yes	Yes
Chronic non-united defect	No	Yes	Yes or no

that key clinical tests were unable to differentiate pain from spondylolytic injury or other back pain.<sup>61</sup> There are also no scientifically validated tests that differentiate spondylolysis between active bone stress injury (stress reaction or fracture) and chronic non-united defects. It is understandable that some clinical features would be similar because the source pain is from the same anatomical location of the posterior vertebral arch.

In active spondylolytic bone stress injuries, pain is typically of gradual onset and often related to changes in training volume and/or repeated cyclical loading of the spine. Pain is localised to the lumbar region, with occasional radiating pain to the buttock and posterior thigh.<sup>61, 62, 88, 89</sup> Pain often begins as low grade or 'stiffness', but typically progresses (in severity) quickly with continued activity (loading). The pain is typically mechanical in nature, particularly reproduced by spinal side flexion, rotation and hyperextension.<sup>68, 88-90</sup> Clinical tests that load the ipsilateral posterior vertebral arch and facet joints, such as active and passive lumbar extension and ipsilateral side flexion (or a combination of these movements), reproduce symptoms.<sup>61, 91, 92</sup> The single-leg extension test or stork test (Fig. 29.3e) had been advocated as a possible clinical test that can specifically differentiate spondylolytic pain from other sources of pain; however, studies have demonstrated that this is not a valid test for spondylolysis.<sup>93, 94</sup> Localised palpation tenderness and muscle spasm are also common features of spondylolytic injury and may be useful in identifying the specific vertebral level involved.<sup>94</sup>

### Imaging

The lack of scientifically validated clinical tests means that radiological imaging has an important role in establishing

the diagnosis when spondylolysis is suspected. It is important to use imaging tests that:

1. differentiate spondylolysis from other sources of back pain
2. confirm the presence of active bone stress pathology
3. establish the stage of the bone stress continuum (Table 29.6 and Fig. 29.5).

What the various imaging modalities provide

Traditionally, spondylolysis was identified on the oblique radiograph with the classic 'Scotty dog' appearance confirming the presence of a spondylolytic lesion (Fig. 29.5a and b).<sup>64</sup> However, with advancements in other imaging modalities, plain radiography has a very limited role in detecting spondylolytic lesions because it does not allow differentiation of early active bone stress and does not provide the same level of detail of spondylolytic lesions as other imaging techniques.<sup>61, 68, 99</sup>

CT (Fig. 29.5c and d), MRI (Fig. 29.5e and f) and scintigraphy (Fig. 29.5g) are therefore the most commonly used imaging modalities when spondylolysis is suspected, with each modality having its advantages and disadvantages in evaluating spondylolytic injury. Sometimes a combination of modalities is required for accurate diagnosis and to differentiate clinically suspected spondylolysis from other sources of back pain.

Bone oedema (high signal on T2 fat saturated sequence) on MRI or increased tracer uptake on scintigraphy (particularly single-photon emission computed tomography [SPECT]) indicates active bone stress injury.<sup>99, 100</sup> Early comparisons between SPECT and MRI in detecting clinically relevant bone stress had favoured SPECT at detecting early stage bone stress spondylolysis.<sup>93</sup> However, with advances

**Table 29.6 Imaging appearances along bone stress continuum**

	Pre-spondylolytic bone stress	Stress reaction	Stress fracture	Non-united defect
Plain radiograph <sup>61, 68</sup>	Unreliable	Unreliable	Unreliable	Scotty dog appearance (oblique view), particularly larger defects (Fig. 29.5a and b)

WITH PERMISSION OF SPRINGER

(f)

(g)

in MRI imaging technology (higher powered magnets and image sequences) and the associated improvements in radiologists' ability to interpret abnormal signal, MRI is the first choice of imaging modality for detecting bone stress particularly as it does not involve ionising radiation.

Apart from detecting bone stress, MRI can be used to identify the presence of spondylolytic stress fractures,

(h)

**Figure 29.5 (cont.)** (f) T2-weighted fat-suppressed axial MRI of L5 vertebral body, showing left-sided pars inter-articularis defect (arrow). There is mild bone marrow oedema (bright signal) surrounding the defect, most noteworthy in the left transverse process (g) Scintigraphy (SPECT) demonstrating increased uptake at the posterior vertebral arch (arrow) (h) MRI 3D T1 fat-suppressed image that allows better visualisation of the fracture (arrow)

although thin-slice reverse gantry CT imaging remains the gold standard for imaging these fractures.<sup>68</sup>

CT provides the most detail of a fracture and allows for the grading of spondylolytic lesions as early stage (hairline fractures), progressive stage (wider fractures) or terminal (chronic sclerotic pseudoarthrosis).<sup>95, 101</sup> The staging of stress fractures is important because early stage lesions have a much better chance of bone healing, compared to progressive lesions, while terminal defects have no ability to heal.<sup>100-102</sup> With advances in MRI, reconstructed fat suppressed T1 MRI images (Fig. 29.5h) can image fractures and non-united defects that would usually require CT imaging.<sup>95, 96, 98</sup>

The usefulness of MRI extends beyond making the initial diagnosis, with the presence or absence of MRI bone oedema an important determinant of whether bone healing is possible in spondylolytic stress fractures.<sup>102</sup> Sequential MRI imaging following spondylolytic stress fractures has also been used in the management of spondylolysis, with the gradual resolution of bone oedema on monthly scans correlating with bone healing and the resolution of pain.<sup>100</sup>

As discussed earlier, non-union is a common outcome following spondylolytic stress fractures in athletic populations.<sup>85, 103</sup> Unlike some other stress fractures such as the navicular and fifth metatarsal, athletes with non-united spondylolytic stress fractures can remain asymptomatic and return to playing, even at the elite level.<sup>85, 103</sup> MRI, plain radiograph and CT imaging can detect chronic defects as sclerotic scar-filled clefts. These fibrous defects are prone to becoming symptomatic with mechanical loading, but the pain is similar to that from other nociceptive structures such as the intervertebral discs or facet joints. To determine if the defect is the source of pain, the gold standard is radiologically guided local anaesthetic injection into the defect and re-assessing key clinical tests.<sup>90</sup>

### Pathogenesis

As with other bone stress injuries, the pathogenesis for athletic spondylolysis involves localised repetitive bone loading that consistently exceeds the normal bone strain threshold.<sup>60, 104, 105</sup> The posterior vertebral arch is loaded during trunk extension, rotation and side flexion movements.<sup>106</sup> It is possible that these movements either lead to shear forces or bony impingement that result in microfractures (early bone stress) and eventually lead to symptomatic stress (macro) fractures.<sup>106-108</sup>

High ground reaction forces contribute to athletes exceeding the bone strain threshold. For example, cricket fast bowlers can have weekly bowling loads of 150 to 300 deliveries or 5000 to 7000 deliveries per year, with ground reaction forces of 7-10 times body weight per delivery.<sup>109</sup>

The magnitude and frequency of load required to fracture the posterior vertebral arch is unknown, but individual variations (intrinsic factors) may predispose some athletes to lower fracture thresholds than others. Age influences the fracture threshold for spondylolytic bone stress, with younger and skeletally immature athletes at greatest risk.<sup>72</sup> Bone geometry is also important as a lower proportion of cortical to trabecular bone at the pars region increases risk of fracture.<sup>110</sup> Other intrinsic factors such as shorter interfacet distances,<sup>105, 111</sup> increased coronal facet joint orientation,<sup>112</sup> excessive lumbar lordosis<sup>105, 111, 113</sup> and increased pedicle length<sup>114</sup> are associated with spondylolytic injury.

As discussed previously, spondylolytic stress fractures are prone to non-union, which results in a scar-filled defect and eventually a pseudoarthrosis.<sup>60, 95, 100-102, 115</sup> The reason for the high rates of non-union are unknown, but likely to be related to either an inadequate period of unloading to allow healing, or because of a delay in confirming the diagnosis (continue playing sport) that may disrupt the bone's attempt at healing. The non-united defect eventually fills with scar tissue to form a pseudoarthrosis.

The histological appearance of the scar tissue is that of a fibrocartilaginous mass that has similar properties to ligamentous tissue combined with a small amount of osseous particles, and has been described as enthesis-like, resembling a ligament-bone junction.<sup>115</sup> The enthesis-like nature of the spondylolytic mass allows it to stabilise the vertebral arch and absorb tensile forces.<sup>115</sup> This enthesis-like material suggests that pain from spondylolytic defects can be analogous to a joint or tendon pathology and should be managed in the same manner once symptomatic.

When non-union occurs and enough time is allowed for the fibrocartilaginous mass to mature and stabilise, some athletes can return to an elite level of athletic participation.<sup>85</sup> It is not clear why some athletes with chronic defects cope and others do not, and why some defects remain asymptomatic and others painful. It is likely that repetitive mechanical loading or single high-force trauma (e.g. landing in a lumbar hyperextension) causes disruption of the fibrocartilaginous tissue, leading to pain.

### PRACTICE PEARL

The pseudoarthrosis and nature of the enthesis-like mass suggest that symptomatic defects should be managed as chronic (or acute on chronic) joint or tendon injuries.

In rare cases, herniation of the fibrocartilaginous mass can cause nerve root impingement and radicular symptoms.<sup>115</sup>

### Management of lumbar spondylolysis

The difference in the pathogenesis of spondylolysis between symptomatic bone stress injuries (stress reactions and fractures) and non-united defects highlights the importance of accurate diagnosis and that management strategies need to be appropriate for the pathology.

### PRACTICE PEARL

Management of spondylolysis needs to be considered as two separate entities: active bone stress injury and symptomatic non-united defects.

### Active spondylolytic bone stress injury

The key management goals for active spondylolytic bone stress injury (stress reactions and stress fractures) are the resolution of symptoms, bone healing, return to pre-injury function and avoidance of recurrence. All four goals are interrelated and bone healing is key to the process.<sup>86, 89, 116, 117</sup>

Conservative management can produce excellent clinical and radiological outcomes, particularly in young athletic populations.<sup>86, 88, 118-123</sup> However, return-to-sport times range from 3-6 months and complex cases take up to 12 months.<sup>86, 89, 101, 102, 121, 123, 124</sup> This reflects the physiology of bone healing and correlates with imaging resolution of bone oedema on MRI and bone union on CT.<sup>100</sup> It reflects the need to invest time in a well-planned rehabilitation program that addresses musculoskeletal and biomechanical deficiencies.

The type of exercise and loading activities should be guided by clinical symptoms, bone healing times, imaging and clinical assessment. To simplify this, the rehabilitation program can be divided into three distinct periods that have specific focus.

#### ***Weeks 0-8: fracture healing phase***

The aim is to protect the stress fracture and create an environment to enhance bone healing. For stress reactions, the aim is to prevent the progression to a stress fracture, and for stress fractures it is to attain bone healing and avoid non-union.

The most important aspect of the early management is to cease sporting activities that load and stress the posterior vertebral arch, such as running, jumping and landing. It also includes ceasing other training activities such as resistance-based strength training that involves axial loading<sup>125</sup> and avoiding repeated or end-range trunk positions, particularly extension, rotation and side flexion that may load the posterior elements of the vertebrae.<sup>101</sup>

It is not clear whether any specific exercises can improve fracture healing, reduce recurrence rates or enhance return-to-sport times, but when planning rehabilitation, prescribe exercises that can minimise muscle atrophy, address lumbopelvic deficiencies and improve the lower limb kinetic chain deficiencies that are often present in the young athletes with spondylolysis.<sup>71</sup> In particular, prescribe exercises that focus on strength, control and flexibility of the lumbopelvic region, such as abdominal strengthening and 'core stabilising'.<sup>123</sup> Lumbar extensor muscle endurance has been linked with the development of lumbar bone stress injury in cricket fast bowlers and should be considered in those identified to have insufficient strength and endurance.<sup>126</sup>

#### **PRACTICE PEARL**

**A good starting point with the rehabilitation program is lower limb body weight exercises such as squatting, bridging and lunging to address strength and control deficits, while minimising excessive lordosis and developing a base for strength training later in the rehabilitation program.**

Exercises to improve lumbopelvic control are also appropriate to minimise the effects of deconditioning of the trunk postural muscles, particularly in athletes with ongoing pain. It is important to closely monitor clinical signs during this part of the rehabilitation program, as any reproduction of symptoms during or after the exercise could be a sign of disruption of the fracture site. General exercise such as walking and cycling is safe and can be used to maintain cardiovascular fitness.

The use of thoracolumbar bracing can be considered during this stage to restrict spinal movements during daily activities and protect the fracture. There are some published reports that demonstrate good clinical and radiological (bone healing) outcomes with the use of strict protocols for bracing following lumbar bone stress injuries.<sup>71, 100, 123</sup> The brace needs to be worn almost all day and for months to enhance the potential for healing. A practical approach to brace treatment might be to use it in athletes who have pain at rest or with daily activities during the early period post-injury, in those with excessive lumbar lordosis, if there is radiological evidence of delayed bone healing, or with bilateral stress fractures.<sup>71, 123</sup>

#### ***Weeks 9-16: protected reloading phase***

During this stage, there should be total resolution of key clinical signs, while daily activities and rehabilitation exercises should also remain pain-free. The introduction of low-impact activities that specifically load the lumbar spine can commence and theoretically stimulate bone healing through the process of mechano-transduction.<sup>127</sup>

Typically, the bone oedema will be less apparent on MRI during this stage, indicating resolution of bone stress, and in most cases should have totally resolved by 12 weeks post injury.<sup>100</sup> It is unknown how MRI bone oedema correlates with physiological bone healing, but Sakai et al. demonstrated that the resolution of bone oedema in active spondylolytic injury occurred between 3-4 months post injury and correlated well with bone healing observed on CT imaging and resolution of symptoms.<sup>100</sup>

The progression from body weight to loaded strength exercises such as dumbbell leg squats and lunges is

an appropriate transition, while lumbopelvic control exercises can also be progressed to more functional trunk positions. Body weight exercises involving trunk rotation and extension can commence to gradually load the spine and stimulate healing.

Jogging can commence during this period with a gradual transition to higher intensity running by (approximately) week 12 onwards if symptoms and imaging suggest that healing is progressing without complication. In the latter part of this stage, functional submaximal dynamic exercises (e.g. plyometric) or sports-specific drills can commence at lower intensity and volume. For example, hopping or jumping activities for athletes involved in sports such as basketball and volleyball, kicking drills for sports such as football (soccer) and Australian football, or drills that mimic specific activities such as cricket fast bowling can commence.

The commencement and progression of exercises and activities should be guided by consistent absence of localised LBP and no change in clinical symptoms on key tests. If there is any deterioration in clinical presentation, the progression of exercises should be reviewed until symptoms resolve. Additionally, if imaging demonstrates that bone healing is delayed, these milestones should be held back until satisfactory progress is evident.

#### ***Week 17 onwards: transition to return to full function and sport***

This is an important and often neglected part of the rehabilitation process that should involve careful monitoring of symptoms, reassessment of key physical competencies, addressing biomechanical changes and gradually introducing unrestricted load until there is a full return to pre-injury function. All daily activities, training exercises and key clinical tests should remain pain-free during this stage.

Radiologically, evidence of advanced bone healing would be expected during this stage. In particular, resolution of MRI bone oedema has been demonstrated by 16 weeks post injury and coincides with bone healing on CT imaging.<sup>100</sup> Repeating an MRI (fracture views shown in Fig. 29.6) and/or limited (only the appropriate vertebral segment) CT scan at approximately 16 weeks post injury is useful to determine the bone healing response.

#### **PRACTICE PEARL**

Although radiological healing is an encouraging sign in the recovery process, it is unknown how this correlates with physiological bone healing.

The key rehabilitation principle for this stage is the gradual increase in rehabilitation and training loads to allow a safe transition to return to play. As part of the process, unrestricted strength training can be progressed to ballistic exercise. Running and other conditioning methods can become sports specific, but it is important to monitor both workload intensity and volume during this stage, so the transition from the training ground to playing arena is graduated appropriately avoiding 'spikes' in workloads, that have been shown to be linked with athletic injuries.<sup>128, 129</sup> Sport-specific exercise and training is gradually progressed so that intensity and workload are at a level required to return to competition. Once again, an exacerbation of LBP in the region of the previous injury and reproduction of pain with key clinical tests should be seen as a sign to slow down or to cease the activity.

Symptomatic non-united fractures or chronic defects When spondylolytic stress fractures fail to heal, the remaining defect fills with scar tissue that offers enough

**Figure 29.6** Different imaging modalities. The image on the left is an MRI T1 fat-suppressed three-dimensional image. The second is the same MRI image inverted (black becomes white) to make it look similar to CT. The third is the CT image of the same patient on the same day. Note the similarity between the CT and MRI images

stability to the segment to allow some athletes to return to unrestricted pre-injury function, even at the elite level. It is unknown how many athletes with non-united spondylolytic stress fractures fail to return to pre-injury level of activity, but there are numerous reports of athletes competing at the elite level with (often asymptomatic) chronic lumbar defects.<sup>80</sup> If an athlete does return to sporting activities with a non-united defect, episodic or ongoing pain is common if the fibrous scar tissue is disrupted and irritated with mechanical loading.

An exacerbation of pain from a non-united spondylolytic defect needs to be managed as an acute or chronic injury. The acute component is likely to be inflammatory in nature due to mechanical disruption of the fibrous scar and can respond to appropriate anti-inflammatory management strategies. The chronic nature of the defect does mean that there is virtually no possibility of bone healing, so this should not be considered as a viable management goal.<sup>101, 102, 121</sup>

### Symptom management

With little prospect of bone healing, the main aim of treatment is to reduce pain and restore function. While the exact source of pain is unknown, disruption and inflammation of the fibrous scar is a likely mechanism so the use of these anti-inflammatory methods should be considered as well as analgesic medication and possibly oral corticosteroids.

Radiologically guided corticosteroid and local anaesthetic injection within the defect (Figure 29.7) has considerable merit. The short-acting local anaesthetic is useful in determining if the defect is the source of pain, while the corticosteroid can provide the localised anti-inflammatory response thereby reducing pain and allowing a faster transition through the rehabilitation program and return to function.<sup>90</sup>

### Unloading phase

The nature of the fibrous tissue within the bony defect, particularly that it is histologically similar to ligament

and tendon, suggests that the management of non-union should be similar to the management of those tissues. Importantly, a brief period of unloading to allow irritability of the fibrocartilaginous scar to resolve may be required, with rest from aggravating (sporting) activities required if pain does not settle. The length of the unloading period needs to be guided by the nature of the pain and typically involves initially reducing exposure to provocative activities that involve repetitive trunk extension, rotation and side flexion or any other aggravating activity.

The length of the unloading phase and the transition to reloading should depend on the reduction of symptoms and improvement in painful clinical tests.

### PRACTICE PEARL

Unlike acute bone stress injuries, total resolution of pain of non-union is not necessary, but careful monitoring of response to reloading is important.

It may be possible that athletes can return to sport with some low-grade pain as long as the pain characteristics remain manageable with increase in load and during the transition to sporting function. In this sense, the unloading phase for chronic symptomatic pars defects is similar to tendinopathy, where the unloading phase serves to reduce but not always eliminate pain.<sup>130</sup>

### Summary

Lumbar spondylolysis is a complex condition with little scientific evidence underpinning the clinical tests to differentiate it from other causes of lower back pain. Even more complex is understanding the stage in the bone stress continuum as this is important in the management of spondylolysis. Advances in imaging have improved the understanding of this condition, particularly the stage in the bone stress continuum and differentiating active bone stress injury from symptomatic non-united defects. The management of spondylolysis needs to consider the clinical features and the imaging. The management of active spondylolysis needs to focus on bone healing that takes months, while symptomatic non-united fractures can be treated symptomatically, reducing the recovery period.

### Spondylolisthesis

Spondylolisthesis (Fig. 29.8a) refers to the anterior displacement of part or all of one vertebra forwards on another. It is often associated with bilateral pars defects that usually develop in early childhood and have a definite family predisposition. Pars defects that develop due to athletic activity (stress fractures) rarely result in spondylolisthesis.

**Figure 29.7** Guided injection into the chronic pars defect

(a)

Spondylolisthesis is most commonly seen in children between the ages of 9 and 14. In the vast majority of cases, it is the L5 vertebra that slips forwards on the S1. The spondylolisthesis is graded according to the degree of slip of the vertebra. A grade I slip denotes that a vertebra has slipped up to 25% over the body of the vertebra underlying it; in a grade II slip the displacement is greater than 25%; in a grade III slip, greater than 50%; and in a grade IV slip, greater than 75%. It is rare for a slip to progress once the athlete has reached maturation. Lateral X-rays best demonstrate the extent and possible progression of vertebral slippage (Fig. 29.8b). A recent systematic review suggests that spondylolisthesis is not predictive of LBP in the general population.<sup>131</sup> However, in an athletic population it may become symptomatic.

### Clinical features

Spondylolisthesis is often asymptomatic and the patients may be unaware of the defect. However, LBP, with or without leg pain associated with the spondylolisthesis, may develop in response to various biopsychosocial factors and is frequently aggravated by extension activities and postures. On examination, there may be a palpable step off corresponding to the slip.

(b)

**Figure 29.8** Grade I spondylolisthesis and pars defect (a) Anterior slip (arrow) (b) Plain radiograph (single arrow shows the defect; dotted lines show the method of measuring slippage)

### Treatment

In considering the treatment of this condition, it is important to remember that the patient's LBP is not necessarily being caused by the spondylolisthesis. First, it is important to reassure the athlete that spondylolisthesis is common in the pain-free population and the natural history for these disorders is usually very good. Addressing the various biopsychosocial features of the disorder described above is central to management.

Treatment of athletes with grade I or grade II symptomatic spondylolisthesis is usually non-surgical, and rehabilitation exercise approaches are shown to be effective.<sup>132</sup> Athletes with grade I or grade II spondylolisthesis may return to sport after their rehabilitation program, when they have minimal pain on extension and have good spinal control during functional and sports-specific activity. If the symptoms recur and are distressing, activity should be modified.

Athletes with grade III or grade IV spondylolisthesis should avoid high-speed or contact sports. Treatment is initially conservative, yet if a patient continues to experience symptoms after a 6-month non-surgical treatment period, he/she may be considered for surgical fixation. Other indications for surgery include growing children with a

slip >50%, progressively worsening neurological signs and radiological evidence of further displacement.<sup>133</sup>

### Acute radiculopathy +/- nerve root compression

Acute radiculopathy is usually the result of an acute disc prolapse when the contents of the nucleus pulposus of the intervertebral disc are extruded through the annulus fibrosis into the spinal canal, irritating the nerve root (Fig. 29.9). The irritation of the nerve root may be due to direct mechanical compression by the nuclear material and/or as a result of the chemical irritation caused by the prolapse, and is usually very painful and distressing.

Prolapse usually occurs in discs that have been previously weakened by one of the processes mentioned already. Disc prolapse usually occurs between the ages of 20 and 50 years and is more common in males than

females. The L5-S1 disc is the most commonly prolapsed disc and L4-5 the next most common.

### Clinical features

Typically, a patient with a disc prolapse presents with acute LBP and radicular leg pain following a relatively trivial movement, usually involving forward bending. This is frequently preceded by a period of rapid increase in repeated flexion loading (such as a sudden increase in rowing training volumes). On occasion, the presentation may be painless, with weakness or sensory symptoms only (in the case of nerve compression).

(a)

**Figure 29.9** Disc extrusion compressing nerve root (a) Spinal cord compression from severe disc prolapse (b) Axial CT scan. Arrowheads point to the border between the bulging disc (anterior) and the compressed cord (posterior) (c) Sagittal MRI showing prominent posterior L3-4 disc bulging (arrow) and cauda equina compression. The L4-5 disc (arrowhead) is also abnormal (compressed) but not protruding

(b)

(c)

**Figure 29.9 (cont.)** (d) Common areas of pain radiation with disc prolapse at the L3–4, L4–5 and L5–S1 levels

The symptoms depend on the direction of the prolapse. Posterior herniations are more likely to cause LBP with later development of leg pain, whereas posterolateral herniations may cause radicular symptoms without LBP. Sharp, lancinating pain in a narrow band down the leg is common with radicular pain and is associated with nerve root irritation and positive SLR, accompanied by pins and needles, numbness and weakness. Pain is often aggravated by sitting, bending, lifting, coughing or sneezing. Pain is usually eased by lying down, particularly on the asymptomatic side, and is often less after a night's rest.

On examination, the patient often demonstrates a list to one side that is usually, although not always, away from the side of pain (Fig. 29.10). This is a protective scoliosis and reflects an adaptive motor response. Examination may be difficult if there is severe pain and irritability. Straight leg raise is usually limited (less than 30° in severe cases) and all active movements of the lumbar spine, particularly flexion, are usually restricted by muscle guarding. Palpation usually reveals muscle spasm with marked tenderness but occasionally it may be unremarkable. A neurological examination should always be performed when pain extends past the buttock fold or there are subjective sensory and/or motor changes.

### Treatment

It is important to educate the patient that the natural history for disc prolapse is excellent for the majority, with resolution of symptoms and reabsorption of the prolapse occurring

**Figure 29.10** List to the left, commonly associated with pain on the right

over a 3–6 month period of time. The 2-year outcomes for surgical compared to non-surgical interventions are the same.<sup>134</sup> However, any deterioration in bladder function or neurological deficits must be monitored and reported immediately for investigation and surgical review.

In the acute phase (1–5 days), if pain is severe, adopting positions of maximum comfort with administration of analgesics and NSAIDs is indicated. The patient should minimise sitting and keep active with gentle walking. In the absence of nerve compression (neurological signs), gentle spine mobility exercises such as extension and/or rotation exercises (Fig 29.11) may provide pain relief and if so should be commenced as soon as possible. However, if exercises cause an increase in peripheral (i.e. lower extremity) symptoms and/or neurological signs, they should be ceased immediately.

Mobilisation techniques should be performed with care. Rotational positioning (Fig. 29.11) may be effective in providing pain relief. Manipulation is contraindicated in conditions with severe pain, muscle guarding and acute neurological signs and symptoms.

**Figure 29.11** Rotation exercise for acute LBP

A transforaminal epidural injection of corticosteroid may help if there is no significant improvement in symptoms and signs with rest, and pain levels are distressing. Selective nerve root blocks using only local anaesthetic can be helpful to confirm a particular nerve root as a source for radicular leg pain. A transforaminal epidural steroid injection can be performed to provide pain relief from the implicated irritated nerve root. These injections are more specific and concentrate the medication around the nerve root as compared to interlaminar or caudal epidural steroid injections that cover a larger area yet place a more dilute injectate at each level.<sup>135</sup>

Epidural injections with a long-acting local anaesthetic +/- a corticosteroid are a treatment for radicular leg pain and not a treatment for LBP.<sup>136</sup> However, there is little research evidence for the efficacy of these procedures in chronic radicular pain.

As the acute episode settles, restoration of normal pain-free movement to the area can be assisted with localised mobilisation and gentle stretching. Following restoration of range of movement, optimising patterns of spinal control, conditioning and adjustment of sporting technique is important in order to optimise stress on spinal structures and prevent recurrence. This is discussed later in this chapter.

Spinal surgery should only be considered when nerve root compression results in persistent: bladder or bowel symptoms, progressive sensory or motor abnormalities, or where radicular pain is intractable despite adequate conservative management. Various surgical options exist including microsurgical decompression, open laminectomy or percutaneous discectomy using a needle aspiration technique.

While complications are rare, it is important for the clinician to advise the patient of the potential risks for each of the interventions just discussed, which include infection, bleeding, worsening pain, allergic reaction, vascular and neural injury, as well as intravascular injection.<sup>135</sup>

### Vertebral endplate oedema (Modic type 1 changes)

A patient with vertebral endplate oedema typically presents with persistent, severe and disabling localised LBP. Pain is usually constant (at rest and at night) and exacerbated with loading and movement. Diagnosis is based on MRI with finding of oedema of the vertebral endplate proximal to a degenerate disc (Fig. 29.12).

**Figure 29.12** MRI demonstrating disc degeneration and moderate intensity signal Modic type 1 changes (arrows)

## Treatment

Management is consistent with other LBP disorders (outlined in the next section) and involves addressing the relevant extrinsic and intrinsic risk physical factors, as well as lifestyle and psychosocial factors in conjunction with medical management (anti-inflammatory medication). A period of relative unloading from sport, combined with regular unloaded cardiovascular exercise (water-based/exercise bike), is usually required to allow the inflammatory process to settle, followed by a gradual return to sport. The natural history is good.

There is some preliminary evidence to suggest that these MRI findings, when presenting secondary to a disc prolapse, may represent an underlying low-grade infection. One randomised controlled trial (RCT) reported benefit with treating this using broad-spectrum antibiotics, although replication trials are required to confirm this.<sup>137</sup>

## MANAGEMENT OF NON-SPECIFIC LBP DISORDERS

Once the patient has been triaged to exclude serious and specific pathology (Fig. 29.2), treating the symptom of pain when it is acute, severe and distressing is very important. However, there is growing evidence to support that targeting the modifiable beliefs and behaviours that drive pain and disability may be more effective than simply treating the symptom of pain in order to achieve long-term changes and especially where LBP is persistent and/or recurrent.<sup>16, 138</sup>

An integrated person-centred, goal-orientated management approach for LBP is adapted to the time course and complexity of the patient's profile. The focus of this process is directed by the findings taken from the examination with regard to the primary contributing factors, across the different domains, linked to the patient's disorder.

### PRACTICE PEARL

Developing a strong clinical alliance underpins the therapeutic process. Effective communication encompassing therapist empathy, active listening, responsiveness, validation of the patient, confidence, warmth and friendliness are central to clinical outcomes.

Any management approach in the athlete must be applied in discussion with the coach and in consideration of managing training loads.

## Clinical approach

### Effective patient education

As LBP can often be distressing and associated with increased fear, catastrophising, vigilance, anxiety and worry, providing the athlete with a clear understanding

of the underlying mechanisms linked to the disorder and directions for treatment and management is central to any intervention. This may involve:

- providing effective patient-centred education regarding the multidimensional mechanisms that drive their pain and disability, as well as clear expectations for prognosis and management
- education regarding the influence of beliefs, fear, vigilance, levels of mood, anxiety, stress, worry, sleep deficits and levels of fatigue on pain physiology
- addressing negative beliefs and fear regarding pain with positive information regarding the spine's resilience and providing epidemiological advice regarding MRI findings if relevant<sup>21</sup>
- education regarding the importance of optimal motor control, body relaxation and conditioning, and the interplay this has with sports-specific biomechanical demands and training loads to influence tissue strain and sensitivity
- promoting active coping strategies for pain and installing confidence
- facilitating goal-orientated behavioural change regarding stress management, sleep, physical activity, pacing and diet
- feedback, which is critical and involves:
  - mindfulness of the body's responses to pain and
  - visual feedback with the use of mirrors, video and written instruction.

### PRACTICE PEARL

Effective, evidence-based patient education and targeted reassurance is a treatment in its own right. (See also Chapter 5 which underscores that explaining pain is a treatment in its own right.)

## Pain relief

There is strong evidence that symptomatic treatments for LBP (such as manual therapy, soft tissue therapy, needling, spinal injections and pharmacology), while providing a window of short-term pain relief, have little impact on the long-term trajectories of LBP. Therefore, these treatments need to be closely integrated with active management strategies that address the relevant biopsychosocial factors identified in the examination. They should be seen as creating a window of opportunity to enhance functional capacity, but should not be relied on as a treatment in itself. Furthermore, creating a reliance on passive therapies may be unhelpful in the long term as it likely reduces the patient's levels of self-efficacy and internal locus of control.

## Functional restoration

Restoration of full range of relaxed spinal movement is the first priority. Once this has been achieved, then

pain-provocative postural and movement patterns and protective behaviours are identified (specific to the individual), broken down into component parts and retrained in a mindful and relaxed manner in order to provide strategies that enable the athlete to actively control their pain during functional tasks (see later section).

These 'new' postural and movement patterns are gradually targeted towards the activities and movements that provoke pain and/or are avoided by the patient in order to reduce the threat value of the task and normalise it. These 'new' patterns are then integrated into the patient's daily life and sporting activities in a graduated manner. Targeted strengthening and conditioning is incorporated as required by the functional goals of the patient and the specific demands of the sport.

### Addressing lifestyle aspects

Addressing lifestyle factors such as sleep hygiene, body-mind relaxation (using meditation techniques), activity pacing, healthy diet, reducing sedentary behaviours, alcohol consumption and drug taking where relevant is also important.<sup>17</sup>

### Multidisciplinary care

In situations where pain is severe and a barrier to rehabilitation, integrating care with medical management may be indicated. Where psychological comorbidities dominate, combined psychological management may be required.

### Acute severe low back pain

Acute severe LBP associated with a clear history of a significant sudden or repeated high-level biomechanical loading of the lumbar spine, where there is no sign of disc prolapse and radiculopathy or risk of fracture, should be considered an acute tissue strain. The pain response may involve local sensitisation and an inflammatory sequel related to affected spinal structures, which may involve the vertebral endplate, intervertebral disc, zygapophyseal joints and/or associated ligamentous structures.

#### PRACTICE PEARL

As clinical examination cannot accurately determine the specific source of pain, a 'structure specific' diagnosis cannot be made with any confidence. Reassuring the athlete that these 'tissue strains', while very painful, have an excellent natural history if managed well, is important.

However, it must also be noted that severity of symptoms and levels of distress for acute LBP are often a poor indicator of levels of tissue damage, and acute pain may also reflect the level of underlying tissue sensitisation

and contextual distress of the individual. This may be characterised by an athlete who presents with acute pain and distress linked to a minor mechanical loading event or an insidious onset of pain. Careful questioning commonly identifies high levels of contextual stress, anxiety or mood fluctuations coupled with lifestyle factors (such as sleep deficits and fatigue) as precipitating factors in these presentations.

These disorders should not be treated as an 'injury', with care being directed to reassure the person that they aren't 'damaged', but that their spinal structures are sensitised by contextual factors in their life. These disorders usually settle quickly with confident management that targets reassurance, body relaxation and functional restoration while addressing contextual stress and lifestyle-related factors. Careful correlation between the history of pain (i.e. injury mechanism/s), lifestyle factors, contextual stresses, psychosocial screening and disability levels can help differentiate these groups.

### Clinical features

The patient presents with high ratings of pain and disability of sudden onset. The pain is usually in the lower lumbar area, but it may radiate to the buttocks, hamstrings or lower leg, and is somatic in nature, with the patient complaining of a deep-seated ache. The patient with acute, sudden onset of LBP often adopts a fixed, guarded position and movements are severely restricted. Palpation of the lumbar spine reveals areas of marked tenderness with associated muscle spasm.

### Management

Successful management of acute severe low back pain requires education, pain control and progressive rehabilitation to permit the patient to regain function.

#### Education

Once triage has been completed to rule out serious and specific pathology, educate the patient that pain is associated with acute sensitisation of spinal structures. Reinforce that levels of pain do not equate well to degree of damage and that a severe pain experience can be related to sensitisation of spinal structures, amplified by sleep deficits, contextual stress, lower mood, heightened anxiety, fear and muscle guarding, and so on. Keeping the athlete calm, relaxed and positive is central to effective management. Reassure the patient that these disorders are very painful, but self-limiting and with an excellent natural history.<sup>21</sup>

#### Pain control and functional restoration

Initially, encourage the patient to adopt the position of most comfort and relax using diaphragm breathing. This position is often supine crook lying depending on the

**Figure 29.13** Taping

patient's pattern of sensitisation. Following this, these management strategies may be helpful:

- Movements that aggravate pain should initially be limited, whereas movements that reduce or minimise pain should be encouraged.
- Relative rest in the position of most comfort may be continued for up to 48 hours if pain is severe

and disabling and related to biomechanical loading. Bed rest longer than 48 hours has been shown to be detrimental.<sup>139</sup>

- Taping of the low back (Fig. 29.13) for the first 48 hours can reduce acute back pain, provide reassurance, allow trunk muscle relaxation and allow quicker functional restoration.
- Analgesics may control the pain and reflex muscle spasm. NSAIDs may help reduce inflammation if a clear pattern of tissue injury is present.
- Exercise in a direction away from the movement that initially provoked the patient's symptoms should be commenced as early as possible.

For example, for those patients in whom lumbar flexion aggravates their symptoms (linked to flexion strain), extension exercises can be performed. The degree of extension should be determined by the level of pain sensitivity and pattern of pain provocation. Initially, lying prone may be sufficient. Later, extension of the lumbar spine by pushing up onto the elbows may be possible. Eventually, further extension with straight arms can be achieved.

In patients for whom extension movements aggravate their pain (usually linked to an extension pattern of strain), flexion exercises can be performed (Fig. 29.14). For these patients, prolonged posture involving extension, such as standing with excessive lumbar lordosis, should be minimised in the acute phase (48 hours).

If a side bending or rotational strain has occurred, then rotation and side bending away from the direction of tissue strain and pain provocation can be performed.

#### PRACTICE PEARL

Exercises should be discontinued if peripheralisation or exacerbation of symptoms occurs (i.e. increasing pain in the lower extremity).

**Figure 29.14** Flexion exercise

Manual therapy has a limited role in treating severe LBP where there has been a clear history of tissue trauma. Gentle mobilisation techniques, such as non-provocative physiological movements of the spine, may assist the patient to relax and move; however, the patient's response must be monitored. If there is deterioration of symptoms, mobilisation should be ceased. The mobilisation should be performed in the position of comfort adopted by the patient and in the direction of pain 'easing'.

Similarly, gentle soft tissue therapy may be helpful in relieving pain and muscle spasm. Traction has not been found to be helpful in patients with acute LBP. Manipulation should not be attempted in the presence of marked muscle spasm.

In the absence of a clear history of tissue strain, manual therapy can be very helpful to relax the person and facilitate functional restoration in a graded manner and with respect to pain.

### Subacute low back pain

Once the acute phase (up to 48 hours) of severe LBP has passed with reduction in pain and muscle spasm,

graduated exercise therapy can be commenced. The aim of this stage of therapy is to first restore normal relaxed spinal movement. This can be facilitated with the use of pain-relieving manual and soft tissue treatments (outlined below) in conjunction with exercise therapy.

Once normal spinal movement has been restored, this is gradually integrated into functional postures and movements of daily living with attention to confident relaxed body control and other multidimensional factors associated with the onset of the pain disorder based on their complexity profile (see below). Once the person's symptoms settle and spinal movement is normalised (usually within 1-3 weeks), then a graduated return-to-sport program is developed.

The over-arching aims are to provide a clear understanding to the patient of their disorder, enhance pain controllability and return the athlete to their desired level of activity with confidence. An exacerbation prevention and management plan is also important where recurrent back pain is a feature of the disorder. To monitor the effectiveness of the treatment, regular screening questionnaires are helpful in order to monitor levels of pain, disability and distress.

### Passive treatments for low back pain

Passive treatments for LBP (where the patient is the recipient of the treatment rather than being actively involved) may be helpful where pain acts as a barrier to functional activation. These treatments can be used as a window of opportunity in the acute or subacute phase to provide pain relief, to activate the athlete. It is important for the clinician to recognise that passive therapies only provide short-term pain relief and they do not change the natural history of the disorder on their own.

Where active pain control strategies can be integrated with these treatments, such as mindfulness and relaxation techniques as well as exercise, functional activation and lifestyle modifications, they should be actively encouraged. Passive treatments should not be used in isolation and they have a limited role in recurrent and persistent LBP disorders (see below). Passive therapies include the following.

#### Pharmacological treatment

There is some evidence that NSAIDs are effective for short-term symptomatic relief in patients with LBP.<sup>140</sup> There is no evidence that one type of NSAID is more effective than another. There is no evidence to support the long-term use of NSAIDs, both in relation to their lack of effectiveness

and their significant incidence of side effects. Other medications with good evidence of short-term effectiveness for pain control include skeletal muscle relaxants for acute LBP and tricyclic antidepressants for chronic LBP.<sup>141</sup> Gabapentin has fair evidence for effective pain relief for radicular type pain.<sup>141</sup>

#### Mobilisation and manipulation

Mobilisation and manipulation techniques may be helpful for short-term pain relief (Chapter 17) and to restore spinal movement impairments detected on examination. These techniques affect multiple structures and can be adapted to the pattern of movement impairment that presents. Mobilisation techniques used in the treatment of LBP include:

- posteroanterior (PA) central pressure (Fig. 29.15a)
- posteroanterior unilateral pressure (Fig. 29.15b)
- rotational mobilisation (Fig. 29.15c).

Posteroanterior central mobilisation and rotations are used in patients with central or bilateral pain with movement impairments into extension. Posteroanterior unilateral mobilisation and rotation mobilisation techniques may be

*continued*

used for unilateral pain with sagittal and/or frontal plane movement impairments. The strength of the mobilisation technique used will depend on the level of tissue sensitivity and response to treatment. Mobilisation techniques can also be used to reassure the patient that movement is beneficial and not to be feared.

#### Soft tissue treatments

Tension and hypersensitivity of the myofascial structures is common with LBP and are related to pain-related muscle guarding and associated tissue hyperalgesia. This commonly involves the back muscles (lumbar multifidus and erector spinae), quadratus lumborum, abdominal wall and hip muscles (flexors, abductors and extensors). Tender focal areas of tension/'thickening' in the myofascial structures may be palpated.

Treatment of these areas with the use of soft tissue techniques and dry needling can result in short-term pain reduction and relaxation of guarded muscles. Soft tissue techniques may consist of transverse gliding, sustained longitudinal pressure on the tense bands emanating away from the most sensitive point and sustained firm pressure on the painful point (Fig. 29.16). Treatment is aimed at reducing tissue tension and sensitivity.

(b)

(c)

**Figure 29.15** Mobilisation techniques (a) Posteroanterior central—The therapist performs an oscillating movement over the spinous processes using thumbs or heels of the hands. Elbows are extended and pressure is exerted through the shoulders and arms (b) Posteroanterior unilateral—Thumbs are placed over the apophyseal joints (c) Manipulation—rotation. With the patient positioned as shown, the therapist exerts a short sudden forward thrust on the ilium while maintaining strong counterpressure on the shoulder. This position can be used for manipulation or mobilisation

(a)

Dry needling to sensitised myofascial structures (Fig. 29.17) may also reduce pain and muscle tension in the short term, thus providing a window to facilitate the restoration of movement and function.

After treatment directed to either the articular and/or myofascial structures, the patient should be provided mobility exercises to maintain and restore the functional capacity.

#### Neurodynamic treatments

Neural tissue sensitisation may be linked to an LBP disorder when it is associated with peripheral referral of pain into the leg. If neural provocation tests such as the slump test and straight leg raise are limited (reflecting protective motor responses to a sensitised nerve), aggravate the patient's peripheral symptoms, and nerve palpation is associated with hyperalgesic responses, this may indicate peripheral sensitisation of the epineurial structures. Management of these pain states may respond to mobilisation of the articular and myofascial structures proximal to the nerve tissue (see above). Gentle mobilisation of the neural tissue (Fig. 29.18), if the structures are not highly sensitised, may also be

(b)

**Figure 29.16** Soft tissue techniques (a) Sustained ischaemic pressure at each segmental level (b) Sustained ischaemic pressure using the knuckles to the quadratus lumborum in the position of sustained stretch

beneficial. However, 'stretching' of the nerve is **not** advisable as it may result in provocation of the disorder

#### Spinal injections: What is the evidence?

Where localised mechanically provoked pain persists, acting as a barrier for functional restoration, spinal injections may create a window of relief to enhance functional capacity. It must be noted that these techniques are usually short acting and so must be integrated with cognitive functional restoration programs. Some clinicians argue that this should occur once the pain has become chronic (i.e. 3-month duration) while others argue that interventional techniques may aid in the identification of the pain generator and may help expedite the athlete's recovery.<sup>135</sup>

When compared to target-specific diagnoses achieved through accurate local anaesthetic injections done under image intensifier, our ability to make a specific diagnosis using clinical skill or imaging is very limited.

Structures that may become sensitised with LBP are:

- zygapophyseal joints
- intervertebral discs

*continued*

**Figure 29.17** Dry needling of trigger points in the paraspinal and gluteal muscles

- sacroiliac joints
- nerve root sensitisation (i.e. pain radiating into the lower extremity without neurological signs).

These areas may be diagnosed and at times treated by the use of specific interventions outlined below.

*Zygapophyseal joint pain* can be diagnosed with medial branch blocks as the medial branches of the dorsal rami of the spinal nerves above and below the joint innervate each lumbar zygapophyseal joint. These procedures involve using an image intensifier to place a needle onto the appropriate medial branches that supply a zygapophyseal joint and injecting local anaesthetic onto the nerve. To block one joint, two nerves must be blocked; to block two adjacent joints, three nerves must be blocked. The patient then completes a pain chart and if the pain goes away for the duration of the anaesthetic, the clinician can be approximately 60% sure of the diagnosis. A second block with a different local anaesthetic is then done. If there is concordant pain relief, then the diagnostic confidence is approaching 90%.<sup>142</sup>

**Figure 29.18** Gentle mobilisation of the neural tissue

If the two medial branch blocks confirm the pain generator is the zygapophyseal joint, a radiofrequency neurotomy procedure can be performed. Radiofrequency neurotomy utilises an electrical current to ablate the medial branches to provide long-term symptom relief from zygapophyseal joint mediated pain.<sup>135</sup> This technique has a 90% chance of 60% pain relief and a 60% chance of 90% pain relief for lumbar zygapophyseal pain.<sup>143</sup> Note that zygapophyseal joint injections lack diagnostic and therapeutic validity.

Diagnostic criteria for *discogenic pain* are not clearly defined.<sup>135</sup> While discography is available and often used to aid in the diagnosis of discogenic pain, it lacks diagnostic validity and reliability.<sup>144</sup> Additionally, clinicians should be aware that discography can lead to accelerated progression of degenerative changes and carries a significant risk of infection.<sup>145, 146</sup> Several interventional options have been proposed to treat discogenic pain including nucleoplasty, corticosteroid injection, anaesthetic injection and intradiscal electrothermal therapy (IDET). However, there is little quality evidence to support these interventions.<sup>135</sup>

*Sacroiliac joint pain* can be diagnosed with a sacroiliac joint injection of anaesthetic performed with image guidance. With a control block, diagnostic confidence can approach 90%. An injection of anaesthetic and corticosteroid into the sacroiliac joint can provide symptomatic relief. Additionally, radiofrequency neurotomy can be performed for sacroiliac joint mediated pain with evidence for a 60% chance of more than 50% pain relief and with a 30% chance of 90% pain relief.<sup>147</sup> While some people advocate prolotherapy for sacroiliac joint problems, evidence for this is currently inconclusive.

Selective *nerve root blocks* using only local anaesthetic can be helpful to confirm a particular nerve root as a source for radicular leg pain as well as provide pain relief as stated earlier (radicular pain with nerve compression section).

### Recurrent/persistent low back pain: a clinical sub-grouping approach

For a significant group of people (10–15%), LBP may persist beyond natural healing time following a tissue injury. For others, LBP develops insidiously and becomes persistent. This group of people together consume the majority of the healthcare resources.

#### PRACTICE PEARL

Genetic, physical (maladaptive movement patterns), neurophysiological (tissue sensitisation), psychosocial (fear, catastrophising, low self-efficacy, poor coping responses, stress, anxiety and depression) and lifestyle (sleep deficits and disruption, fatigue) are all risk factors for LBP persistence.

A combination of a person's negative thoughts and emotional and behavioural responses to pain (such as protective muscle guarding and/or avoidance) can set up a vicious cycle of pain sensitivity and disability.

Screening and identification of these factors early in the presentation of an LBP disorder is important to target treatment and prevent chronicity. Passive therapies for symptom palliation in this group should be avoided.

#### PRACTICE PEARL

Persistent LBP disorders can be broadly sub-grouped into low-, medium- and high-complexity categories (Fig. 29.2).<sup>21, 148</sup>

In the rest of this chapter we outline the approach to this common group of patients according to the clinical subgroupings shown in Figure 29.2.

### Low-complexity profile

A large group of athletes will present with low-complexity profiles. This profile is characterised by low to moderate levels of pain and disability, and with minimum distress. They predominantly have localised LBP with proportionate pain responses linked to specific movements, postures and activities (i.e. pain is provoked with spinal movements and loading but relieved when movements are ceased). They are commonly able to continue to participate with sport and have high levels of self-efficacy and active pain coping strategies. They present as low risk on psychosocial screening questionnaires.

Factors underlying this disorder may be ongoing sensitisation of spinal structures due to sport demands and training loads coupled with intrinsic physical factors (provocative motor control patterns +/- deconditioning). This may also be coupled with other sensitising factors

such as sleep disturbance or deficits and fatigue. Identification of the underlying modifiable drivers of the disorder is important for management.

### Clinical presentation

Athletes with LBP complain of pain that is usually intermittent (provoked and relieved with specific postures, movements and activities), or constant only when following sustained provocative activities. Pain is relieved quickly when the provocative movement or activity ceases. The pain may be central or unilateral and is often described by the patient as a 'band across the lower back' +/- somatic pain in the buttock and/or hamstring.

On examination, impairments in spinal movement are uncommon; however, motor control impairments (patterns of movement linked to end-range strain of the lumbar spine) are usually observed. These clinical presentations are characterised by clear directional patterns of pain provocation.<sup>12, 149</sup> They can be identified by trained therapists and present an opportunity for targeted rehabilitation.<sup>150, 151</sup>

The following patterns are to illustrate the heterogeneous nature of lumbar spine motor control. While they are common clinical patterns, the clinician should not rigidly adhere to these presentations, but rather use them as a broad framework to guide management.

### Active extension pain pattern

Some people with LBP present with a pattern of pain sensitivity-associated extension loading and movement activities associated with maintaining lumbar hyperlordosis with co-contraction of the back extensors and abdominal wall muscles. This is called an 'active extension pattern' where a person actively holds their back in lordosis during functional tasks (such as sitting, forward and backward bending and lifting), resulting in extension loading of sensitised spinal structures (Fig. 29.19). This is also often associated with an inability to relax the back muscles during forward bending in standing and sitting.<sup>13</sup>

These pain disorders may be exacerbated with loaded squat exercises in the gym, and sports that involve spine extension coupled with side bending and extension such as tennis, fast bowling in cricket, throwing sports, swimming, running, dance and gymnastics. These patterns may be associated with conditioning deficits of the posterior hip muscles (gluteal and hamstrings) as well as tension of the hip flexors, resulting in anterior pelvic rotation. Spinal repositioning deficits in these cases demonstrate a tendency to reposition into lumbar extension from neutral.

On palpation, these presentations are commonly associated with increased muscle tension of the back muscles and quadratus lumborum and a lack of flexibility of the hip flexors. They report relief with lumbar flexion postures and movements.

**(a) Active extension pattern-pain provoked with lumbar extension movements and loading****(b) Active extension pattern-corrected**

**Figure 29.19** Active extension pattern (a) An 'active extension pattern' where a person actively holds their back in lordosis during functional tasks (such as sitting, forward and backward bending and lifting), resulting in extension loading of sensitised spinal structures (b) Correcting the active extension pattern with focus on posterior rotation of the pelvis and relaxation of the back extensor muscles, in order to reduce extension loading

**(a) Passive extension pattern**  
- pain provoked with extension movements and loading

**(b) Passive extension pattern-corrected****Passive extension pain pattern**

The other presentation related to extension pain sensitivity is associated with a sway posture in standing and a tendency to hinge through the lower lumbar spine, while maintaining the thoracic spine in flexion, during backward bending (Fig. 29.20). This results in focal stress to the lower lumbar spine and is commonly associated with the sports that involve backward bending, especially throwing sports, ballet and gymnastics and/or sports that involve overhead arm activities (such as tennis and throwing sports).

These cases often present with conditioning deficits of the iliopsoas and thoracic erector spinae muscles, and poor eccentric control of the upper abdominal wall muscles (tendency to maintain thoracic flexion). Spinal repositioning deficits in these cases demonstrate a tendency to reposition into thoracic flexion.

On palpation, these presentations are commonly associated with increased muscle tension of the upper

**Figure 29.20** Passive extension pattern (a) Sway posture in standing and a tendency to hinge through the lower lumbar spine, while maintaining the thoracic spine in flexion, during backward bending (b) Correcting their sway posture with thoracic extension and upper abdominal wall relaxation, during standing and backward bending

abdominal wall muscles. They report relief with lumbar flexion and when correcting their sway posture with thoracic extension and upper abdominal wall relaxation, during standing and backward bending (i.e. to reduce lower lumbar extension) (Fig. 29.20).

### **Flexion pain pattern**

In other cases, where LBP has a flexion pattern of pain sensitivity, this is associated with a tendency to initiate forward bending and lifting from the lower back while fixing the pelvis into posterior rotation. This may either be associated with thoracolumbar flexion or lower lumbar flexion with thoracolumbar extension and upper abdominal wall activation (Fig. 29.21).<sup>12, 13, 152</sup> This results in flexion loading stress to the lumbar spine and is associated with activities such as loaded squats in the gym and sports such as cycling, rowing and field hockey.

These cases often present with conditioning deficits of the hip flexors and lumbar back extensors and over-activation of the trunk flexors during bending activities. Spinal repositioning deficits in these cases demonstrate a tendency to reposition into lumbar flexion from neutral. On palpation, these presentations are commonly associated with increased tension, loss of eccentric relaxation and/or loss of flexibility of the gluteal and hamstring muscles.

### **Lateral pain pattern**

In other cases, LBP is associated with pain sensitivity related to lateral loading and spinal movements in the frontal plane. These presentations are associated with frontal
