plane motor control deficits of the hip (Trendelenburg) and/or thoracolumbar (lateral shift), which results in lateral loading strain to the low back (Fig. 29.22). These cases often present with conditioning deficits of the hip abductor (gluteal) muscles on the side of pain. Spinal repositioning deficits in these cases demonstrate a tendency to reposition into a lateral shifted position.

On palpation, these presentations are commonly associated with increased tension of the quadratus and lateral abdominal wall muscles on the side of pain. These presentations are common in sports related to limb loading such as running and jumping, landing sports.

### **Rotational plane pain pattern**

In other cases, LBP is associated with pain sensitivity related to rotational movement and activities. This may be seen in sports such as tennis, golf and hockey. In many cases, these pain disorders are linked to control deficits in other planes (i.e. active extension, flexion, frontal plane). Lumbar spine rotation is more limited when the spine is at the end range of flexion, extension or side bending, and therefore the addition of rotation to end-range sagittal postures may increase spinal loading to the lumbar spine (Fig. 29.23).

In other cases, rotational strain may be placed on the spine due to a dynamic impairment of hip or thoracic spine rotation, resulting in increased rotational strain being placed on the lumbar spine. Assessment of the relative flexibility and control through the whole kinetic chain is important when assessing these disorders.

**(a) Flexion pattern-pain provoked with lumbar flexion movements and loading**

**(b) Flexion pattern-corrected**

**Figure 29.21** Flexion pattern (a) Lower lumbar flexion with thoracolumbar extension and upper abdominal wall activation resulting in flexion loading (b) Correction of the flexion pattern via anterior pelvic tilt and relaxation of the thoracic spine into more flexed posture

**(a) Lateral control pattern-pain provoked with lateral lumbar movements and loading****(b) Lateral control pattern-corrected**

**Figure 29.22** Lateral control pattern (a) Lateral pain pattern associated with frontal plane motor control deficits of the hip (Trendelenburg) and/or thoracolumbar (lateral shift), which results in lateral loading strain to the low back (b) Correction of the frontal plane control focuses on gluteal activation and correction of the Trendelenburg and/or lateral shift

**Figure 29.23** The addition of rotation to end-range sagittal postures (e.g. extension) may increase lumbar spine loading (image exaggerated for illustrative purposes)

### **Multidirectional pain pattern**

In other cases, LBP may present where the spine is sensitive to movement in more than one plane (i.e. flexion, extension, rotational or lateral). This may be associated with high levels of underlying tissue sensitivity and related to a combination of various motor control strategies as described previously (i.e. passive extension and flexion pattern). These people may have difficulty finding a pain-relieving movement direction (Fig. 29.24). Neutral spine positions with trunk muscle relaxation may provide some relief. Spinal repositioning deficits in these cases demonstrate a tendency to overshoot in different directions and these are often associated with high levels of thoracic muscle co-contraction (abdominal wall and back muscles).

### **Management**

Management of these disorders involves targeting the cognitive, physical and lifestyle factors underlying the disorder.<sup>16, 138</sup> The cognitive aspects of the intervention involve educating the athlete regarding the factors associated with LBP and providing reassurance regarding the spine's resilience. Manual therapy is only used if movement impairments are present and provide a barrier to functional activation.

Functional rehabilitation strategies are directed by the clinical presentation of the athlete as outlined below. Motor control training is integrated with the use of

- (a) **Multi-directional pattern (passive extension and flexion)**  
 - pain provoked with lumbar flexion and extension movements and loading

- (b) **Multi-directional-corrected**

**Figure 29.24** Multidirectional pattern (a) Pattern associated with pain provoked in more than one direction. In this case, a combination of both passive extension and flexion control patterns is observed (b) Correction of these patterns

mirrors and video so the athlete has a clear understanding of how they move. Postural correction should always reduce their LBP during provocative tasks.

The training is then integrated back into conditioning and sports-specific programs. Modifying training volume and technical aspects of the sport may be important to integrate with this. Lifestyle factors are also addressed when present.

#### **Active extension pain pattern**

The athlete is provided strategies to reduce their lumbar lordosis with posterior pelvic rotation exercises (initiated via the posterior hip muscles and not the abdominal wall). This may first be taught in supine crook lying and progressed to sitting to reduce anterior tilt and relax their back muscles. This is then progressed into sit-to-stand and squat positions (Fig. 29.19). In standing, posterior pelvic tilt is instructed in order to reduce the lumbar lordosis. If the athlete is unable to relax their back and/or hip muscles, then soft tissue work (Fig. 29.25a) and muscle stretching can be carried out (Fig. 29.25b).

These patterns are then integrated into conditioning-based exercises (squat and single-leg squat exercise) with weights that target the gluteal muscles, as well as sports-specific exercises (training forward and backward bending) (Fig. 29.19).

#### **Passive extension pain pattern**

The athlete is provided strategies to correct their postural sway in standing by increasing their thoracic

and upper lumbar lordosis with control of the pelvis augmented with the posterior hip muscles. If the athlete is unable to relax their upper abdominal wall and extend their thoracic spine, then soft tissue work directed to the upper abdominal wall can be used, and lateral costal diaphragm breathing exercise integrated with thoracic spine extension mobilisation techniques (Fig. 29.20).

Squatting is trained with thoracic extension and neutral lordosis. Backward bending is trained by facilitating upper lumbar and thoracic extension with hip extension in order to reduce focal extension stress. These movement patterns are then integrated with conditioning exercises that target postural control in a sport-specific exercise, with mirror feedback as appropriate.

#### **Flexion pain pattern**

The athlete is provided strategies to reduce lumbar flexion with anterior pelvic rotation exercises. This may first be taught in supine crook lying and progressed to sitting in order to facilitate anterior tilt without over-activation of the thoracic erector spinae and abdominal wall. This is then progressed into sit-to-stand and squat positions facilitating the movement with anterior pelvic rotation and a relaxed thoracic spine (Fig. 29.21).

These movement patterns are then integrated into conditioning-based exercises that reinforce these motor patterns (Fig. 29.21), as well as sports-specific exercises.

(a)

(b)

**Figure 29.25** (a) Soft tissue therapy to lumbar extensors (b) Hip flexor stretch for active extension pattern

Utilising this cognitive functional approach has been found to be effective in rowers with flexion-related LBP.<sup>16</sup>

#### **Lateral pain pattern**

The athlete is provided strategies to control their frontal plane postural control in sitting, sit to stand and standing by centring their head position in relation to the pelvis. This is progressed to single-leg standing (with or without support), single-leg squatting with careful attention to control of the hip/pelvis (preventing Trendelenburg pattern) as well as the thoracolumbar spine alignment relative to the pelvis (nose in line with navel). Training can be integrated with conditioning exercises that target single-leg loading and load transfer, progressing towards dynamic loading and sports-specific exercises (Fig. 29.22).

#### **Rotational plane pain pattern**

The athlete is provided strategies to control their spine during provocative rotational movements. In some cases, this may involve adjustments to spinal posture as outlined earlier (Fig. 29.23). In other cases, this involves addressing impairments of movement of thoracic rotation (usually linked to co-contraction of the oblique abdominal wall muscles). This involves teaching relaxed thoracic spine rotation with breathing control (lateral costal breathing) during rolling, sitting, standing and functional rotational tasks. Where there is an impairment of hip rotation, addressing this with soft tissue work stretching and then active functional integration is trained. This can then be integrated into conditioning-based exercises with the use of pulleys.

### Multidirectional pain pattern

The nature of the training is an integration of any of the previously mentioned motor control strategies dependent on the athlete's presentation (Fig. 29.24). For example, this may involve training the control of both the forward and backward bending movement and single-leg loading (see Fig. 29.2, central pillar). This is integrated into functional and conditioning programs as required.

### Medium-complexity profile

A moderate number of athletes will present with medium-complexity profiles. (See Fig. 29.2, central pillar.)

#### Clinical presentation

This sub-group profile is characterised by moderate levels of pain, disability and distress. These athletes often avoid sporting activities due to pain. They may have a mixed pain picture with both pain at rest and with mechanical loading of the spine. Negative cognitive factors are dominant in these disorders such as negative beliefs (i.e. 'my discs are crumbling'), high levels of fear (i.e. 'I am too frightened to dance'), catastrophising (i.e. 'I think my back will collapse', 'it will never get better'), hypervigilance (i.e. 'I can't stop thinking about my

back pain'), low levels of self-efficacy (i.e. 'I don't have any way to control the pain', 'I can't play sport with the pain'). They may also report high levels of contextual stress (i.e. 'my current stress levels are 7-8/10').

These cognitive factors are related to pain amplification,<sup>153</sup> and in some may be linked to high levels of protective muscle guarding, slow cautious movement patterns and protective movement behaviours (i.e. bracing of the hands on the thigh with bending, breath holding, avoidance of limb loading). These movement behaviours are usually superimposed upon the movement patterns described under the low-complexity profile. With high levels of fear, it is common to see movement impairments (loss of functional range of movement), reflected in high levels of trunk muscle guarding associated with feared movement direction (Fig. 29.26).

In other cases, the level of distress may be disproportionate to the clinical presentation (i.e. high levels of pain and distress, but with pain-free movement and functional activity, no tissue hyperalgesia but pain with attention and at rest).<sup>154</sup> Lifestyle factors such as high levels of contextual stress, activity avoidance and poor sleep hygiene are common. These athletes present as medium risk on screening questionnaires.

**Figure 29.26** Protective patterns (a) Protective pattern with thoracic extension and bracing of the hand (b) Protective pattern with lumbar extension and bracing of the hand

## Management

Education regarding the multidimensional factors associated with LBP is essential for the person to understand that their LBP is not related to 'damage', but due to sensitised spinal structures related to negative thoughts, fears and pain-related behavioural responses. Reassurance regarding the spine's resilience is essential.

### PRACTICE PEARL

High levels of fear and catastrophising are addressed through education as well as providing the athlete with pain-control strategies such as relaxation, mindfulness techniques and graded movement training in a relaxed manner back towards fear activities where this is a barrier.

This is directed by their pain-related movement profile as outlined in the low-complexity group. (See also Fig. 29.2.)

Where movement impairments prevent functional activation, manual therapy and soft tissue techniques can be used to relax guarded muscles, so as to reinforce that spinal movement can be trusted. The athlete is gradually exposed to the feared movement pattern (i.e. fear of lumbar flexion is initially trained in supine with posterior pelvic tilt, hip flexion, lumbar flexion in stand and then progressed to standing). Once motor control patterns have been normalised, these are gradually integrated back into conditioning programs and then into the person's sport.

Where there is an absence of clinical signs linked to the patient's LBP, it is critical to reassure the athlete to reduce their focus on the back and trust the resilience of the spine. Manual therapies and specific exercises that direct attention to the back in these cases may be unhelpful.

Addressing lifestyle factors such as stress management (meditation techniques), sleep hygiene, alcohol intake and minimising sedentary behaviours is also important where indicated. Graduated physical activation is also central to this process where this has been avoided, and ideally this should be linked to their sport. This may require a graduated, paced process to recovery to avoid a boom-bust activity pattern.

## High-complexity profile

A small group of athletes present with high-complexity profiles. (See Fig. 29.2, right column.)

### Clinical presentation

This profile is characterised by moderate to high levels of pain, disability and distress. They will almost certainly be avoiding sporting and social activities due to their pain, or be exercising obsessively with pain. They usually have a mixed pain picture and may present as widespread and

constant pain that is exacerbated with minimal movement provocation. Consequently, they may easily flare up with minimal physical examination.

The other presentation as outlined earlier is the complaint that pain is distressing, but with an absence of clinical findings. In this profile pain is often worse at rest and when focused on, and better when moving and distracted. This profile is often linked to underlying anxiety and hypervigilance. These athletes also commonly report comorbid pains (headaches, migraine, stomach pain) as well as nonspecific health complaints (i.e. fatigue, lack of energy).

These athletes present with similar negative cognitive factors as outlined in the medium-complexity profile, (i.e. negative beliefs, high levels of fear, stress, hypervigilance, low self-efficacy and poor coping). They commonly have catastrophic beliefs about their pain (i.e. 'my pelvis is out', 'my disc is stuffed') coupled with high levels of perceptual body distortion. In addition, these athletes present with high levels of emotional distress, heightened anxiety levels and depressed mood. It is important to screen as to whether the athlete has a diagnosed comorbid anxiety and/or depressive disorder and if so whether this is being actively managed. These presentations usually present with maladaptive functional behaviours, muscle guarding and avoidance as outlined in the medium-complexity profile. This may also be coupled with hyperarousal (apical rapid breathing, agitation, sweating, fidgeting).

The athlete may also present with pain behaviours such as constant touching of the back, habitual self-manipulation and rubbing of the area, grimacing and an inability to relax. This may also be coupled with negative lifestyle factors (sleep disturbance, inactivity, alcohol intake and social isolation). These athletes may also tend to become reliant on passive therapies. They present as high risk on screening questionnaires.

## Management

A cognitive functional approach that provides a biopsychosocial understanding of pain, pain control strategies through body relaxation, mindfulness, movement retraining and functional activation is central to this process.<sup>155</sup> Education regarding the multidimensional factors associated with LBP is essential so that the person understands that their thoughts, emotions and behaviours can influence their pain responses and behaviours. Reassurance regarding the spine's resilience is central to the therapeutic process. Before movement training can be initiated, the athlete may need to be trained to relax using slow relaxed-diaphragm breathing, body relaxation and mindfulness techniques.

The approach to movement training is then guided by their movement profile (outlined in low-complexity profile). Focus is placed on discouraging protective movement behaviours (propping of the hands, breath

holding and tensing with movement). Pain behaviours (i.e. self-manipulation, repeated stretching and touching of the spine) are also actively discouraged.

#### PRACTICE PEARL

**Graduated physical activation and addressing maladaptive behaviours is usually more difficult in this group due to the dominance of central nervous system pain features. (See also Chapter 5.)**

Consequently, minimal movement may result in pain flares and over-zealous clinicians may find the athlete distressed with a pain flare. Slow graduated physical activation with a clear paced program to return to sporting activity is usually required. Addressing lifestyle factors such as sleep disturbance, contextual life stress and activity avoidance is central to this process. The use of exercise and sleep diaries may assist this process.

The presence of uncontrolled comorbid anxiety, panic disorder, depression and/or high levels of contextual stresses in the athlete's social life may necessitate psychological referral. Central nervous system pain features and sleep disturbances may require medical referral for targeted pharmacological treatments to provide a window of opportunity for functional restoration.

Reliance on passive therapies and interventional medicine is usually unhelpful and provocative and should be avoided in these cases.

## REHABILITATION FOLLOWING LOW BACK PAIN

Developing an ongoing plan based on the risk profile of the athlete is important in order to minimise the future risks. This includes managing *physical risk factors* such as training loads, technical skills, optimising body posture and control, conditioning and fitness specific to the sport's requirements. The nature of this training is specific to the individual presentation of the athlete. Integrating this into gym-based conditioning programs is crucial.

It also involves managing *psychosocial* and *lifestyle* risks such as energy levels, emotional and psychological health, stress resilience, incorporating relaxation strategies, sleep hygiene, healthy diet and minimising sedentary behaviours. There are many online resources to support both the clinician and the athlete in this process.

### Sporting technique

Poor technique in sporting activities may increase stress on the structures of the lumbar spine. The technique should be assessed with the aid of a coach and in some cases with high-speed film and biomechanical analysis. Any necessary corrections should be made under supervision and with the

guidance of the coach. Examples of sport-specific technique factors linked to lower back pain are covered in Chapter 9.

### Optimal motor control

There is a lot of controversy regarding core stability exercises in LBP. Systematic reviews support the idea that 'stabilisation' exercises are not more effective than general exercise for LBP.<sup>156</sup> Furthermore, studies investigating muscle changes suggest that changes in the stabilising muscles are not prognostic of superior outcomes. While trunk muscle strength and conditioning is critical for many sports, as previously reported, recurrent and chronic LBP is often associated with higher levels of co-contraction of the trunk muscles. Hence, rehabilitation programs need to be sports specific and attend to the individual impairments of the athlete rather than be prescriptive.

Control of the lumbar spine is influenced greatly by both the thoracic spine and the hip pelvic region. Hence, optimising control of the lower back involves attending to control of these proximal and distal regions. Adequate strength of the lower limbs is essential in sports involving limb loading to adequately dampen ground reaction forces and ensure trunk control. The double- and single-leg squat is an excellent rehabilitation exercise combining motor control and strengthening. Similarly, a lack of upper body (upper limb and thoracic) strength and control can compromise lumbar spine mechanics in sports demanding use of the upper limbs (e.g. tennis, cricket, throwing and swimming). In these cases, maintaining a balanced exercise program that ensures optimal control of these regions is important.

### Flexibility

Depending on the sport and the individual, addressing the relative flexibility of the hip muscles and/or the thoracic/shoulder girdle regions, as well as the lumbar spine, is important. Commonly, tense or 'shortened' muscles (i.e. erector spinae, hip flexors, gluteals, hamstrings, rectus abdominis, quadratus lumborum, pectorals and latissimus dorsi) may influence the biomechanics and motor control strategies of the lumbar spine. For example, tightness of the hamstrings may result in greater flexion strain of the lower back in a rower. Conversely, tight hip flexors may result in increased lumbar spine extension in a dancer or runner. On the other hand, tightness of the latissimus dorsi may result in excessive side bending of the lumbar spine in a fast bowler in cricket. The tension in these muscles should be addressed as part of the rehabilitation program. The various techniques are shown in Figure 29.27.

## CONCLUSION

The clinical approach to the athlete with LBP requires a multidimensional perspective. The first is to triage the athlete in order to rule out serious and specific

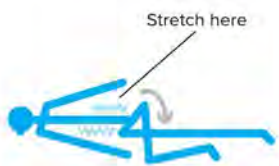

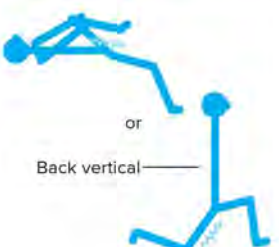

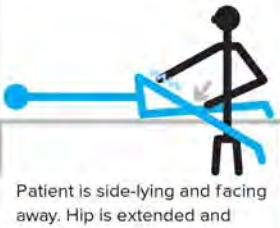

pathoanatomical disorders. The second is to identify the dominance and presence of potential physical, psychosocial and lifestyle risk factors that may be influencing pain and disability profiles both in the presence and absence of specific pathology. The integration of screening questionnaires is critical in this process.

#### PRACTICE PEARL

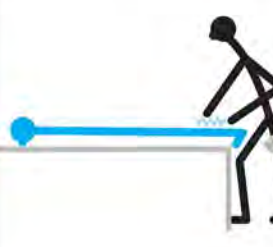

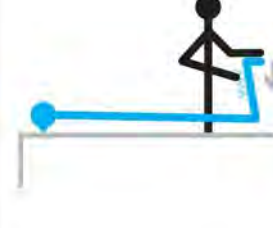

Considering non-specific LBP as a feature of sensitisation of the spine structures, rather than 'damage to the spine', is critical to change the clinician's and the athlete's mindset to their problem.

In the acute phase of a disorder, providing pain control, restoration of function and then targeting the intervention based on the individual's biopsychosocial profile allows for targeting of care. When LBP is persistent, identification of underlying modifiable drivers of pain sensitisation and disability is critical. This is tailored to the complexity profile of the athlete. In high-complexity cases, multidisciplinary care may be required.

There is growing evidence that an individualised approach is more effective than traditional structural, biomechanical approaches to LBP. Encouraging the athlete to develop a positive view of the spine's resilience, enhancing optimal motor control and confidence in their spine, as well as guiding the patient to make healthy lifestyle choices, are goals of this process.

Muscle	Self-exercise	Assisted exercise	Myofascial release
Erector spinae			 Patient is side-lying. Therapist's wrists are crossed over each other to provide traction.
Psoas			 Therapist's hand is over the psoas. Hip is extended from the flexed position.
Iliotibial band		 Patient is side-lying and facing away. Hip is extended and adducted.	 Patient is side-lying and facing away. Therapist uses elbow/forearm to perform release.

# Buttock pain

with ADAM MEAKINS

*Running has substantially shaped human evolution, it is one of the most transforming events in human history. We have literally evolved to run and our big incredible butts are evidence of this.*

Professor Dan Lieberman, evolutionary biologist, Harvard University

The assessment and diagnosis of an athlete with buttock pain can be a challenge for the clinician due to the complex anatomy as well as the many different structures that can refer pain into this area. Buttock pain can be experienced by a wide variety of athletes, but higher incidence is often seen in those who are involved in running, sprinting and kicking sports. Buttock pain can be either sudden or gradual in onset, it can occur in isolation or with low back, posterior thigh and even groin pain, and it can also be due to direct trauma from falls or collisions. A list of causes of buttock pain can be found in Table 30.1. Anatomy of the buttock region can be found in Figure 30.1.

### CLINICAL APPROACH

Assessment of any reported buttock pain should always first try to ascertain if there is any involvement from the lumbar spine. This can be challenging due to the complex nature of low back pain especially in chronic states. For

more on low back pain and lumbar spine assessment and treatment see Chapter 29.

Detailed, comprehensive and careful questioning around the onset, duration and nature of the buttock pain, together with identifying the aggravating and easing factors will help guide the clinician to probable causes and help plan the physical examination.

However when taking a history it is important for the clinician to focus not only on the painful area, but to recognise the many other factors that can contribute to injury and pain in athletes. Time should be taken to explore and obtain a detailed history of an athlete's lifestyle and other psychosocial factors. For example, lack of sleep, chronic levels of stress and fatigue have been found to contribute to injuries and recovery in athletes.<sup>1-4</sup> It is also important for a clinician to assess an athlete's psychological status. High levels of fear of re-injury, anxiety and catastrophisation have been shown to affect assessment and treatment outcomes.<sup>5, 6</sup>

**Table 30.1 A list of causes of buttock pain**

Common	Less common	Not to be missed
Myofascial pain	Piriformis syndrome	Spondyloarthropathies
Referred from lumbar spine	Ischiofemoral impingement	Ankylosing spondylitis
Proximal hamstring tendinopathy	Posterior thigh compartment syndrome	Psoriatic arthritis
Sacroiliac joint dysfunction	Ischial tuberosity injury	Reactive arthritis (Reiters)
	Proximal hamstring tendon rupture	Stress fracture sacrum
	Avulsion fracture (children)	Stress fracture pubic ramus
	Gluteus medius tendinopathy (see Chapter 31)	Malignancy
		Bone/joint infections

(b)

(c)

**Figure 30.1** Anatomy of the buttocks (a) Surface anatomy (b) Superficial muscles (c) Deep muscles

There are many physical examination tests described in the literature to diagnose specific structures or pathologies of buttock pain. However, the clinician should exercise caution when a positive or negative test is found in isolation, as the specificity and sensitivity (see below) of most of these tests are poor. A combination of objective tests combined with a good thorough subjective history will give the clinician much more confidence in his or her diagnosis.

### History

The onset of buttock pain can be reported either as sudden during a sporting activity or as a gradual insidious onset afterwards. Buttock pain that is deep, diffuse and hard to localise, accompanied with low back pain may suggest some lumbar spine involvement. However, it must be remembered that buttock pain without low back pain does not mean the lumbar spine is not involved.

Buttock pain combined with posterior thigh pain, with or without low back or neural symptoms, can be suggestive of a lumbar radiculopathy. However, consideration must also be given to facet joint and hamstring pathology.

Buttock pain felt around the ischial tuberosity (Fig. 30.1) or Tuber area (Fig. 30.2) may be suggestive of proximal hamstring pathology and/or ischiogluteal bursitis. Buttock pain felt more axially or directly over the sacroiliac joint, sometimes referred to as the Fortin area (Fig. 30.2), may suggest a sacroiliac joint or ligament dysfunction.<sup>7</sup> However, location of pain alone should never be used in isolation to make a diagnosis.

Buttock pain reproduced with movements and activities is also not diagnostic in isolation as many structures can be aggravated concurrently. However, it may give clues to possible structures as a source of pain. Suspicion of lumbar spine involvement is increased if low back, buttock or posterior thigh pain is either increased or decreased on repeated lumbar spine movements.<sup>8,9</sup>

Diurnal variation of buttock pain can be useful to establish a diagnosis. Morning pain and stiffness that lasts more than 30 minutes and eases with light activity is highly suggestive of inflammatory conditions such as sacroiliitis and ankylosing spondylitis, although further tests are needed to confirm.

### Physical examination

A visual inspection of the buttock and pelvic area with the lumbar spine and upper thigh is essential. Observation of bruising around the ischial tuberosity and down the posterior thigh may indicate a proximal hamstring avulsion in those with a history of severe sudden traumatic onset of buttock pain when sprinting or running.

Observation of muscle atrophy and gross asymmetry should be noted. However, there are questions about

the clinical usefulness of many of the commonly used observational tests to assess spinal curves and pelvic positions and postures. It is known that there are wide normal variations in skeletal morphology, posture and positions in the population.<sup>10-12</sup> Despite popular belief there is no evidence that any spinal or pelvic position or posture is more associated with pain or a risk of increased incidence of injury.<sup>13-17</sup>

Palpation of the lumbar spine, pelvis and buttocks for pain provocation may assist in the identification of a pathological structure, but again it cannot be used in isolation to make a diagnosis. Palpation tests to determine hypermobility or hypomobility of the spine and pelvic joints are commonly used, but are of questionable clinical utility. The very small movements that do occur around the sacroiliac joint make the ability to detect these with palpation highly unlikely.<sup>18</sup>

The reliability of all pelvic palpation tests used to assess sacroiliac joint movement is poor.<sup>19,20</sup> Palpation tests used to detect joint stiffness or laxity have been shown to have wide variation in forces applied by therapists.<sup>21</sup> When combined with wide variations in individual stiffness, it makes any interpretation of joint hyper- or hypomobility completely unreliable and down to individual clinician perception.<sup>22</sup> Finally it has been shown there is no correlation between spinal joint stiffness and pain.<sup>23</sup>

Neurodynamic examination tests (Chapter 15) may be included if there is a suspicion of lumbar radiculopathy as a cause of buttock pain. However, there are issues with false positives and the diagnostic accuracy of these tests, meaning again they cannot be used in isolation.<sup>24</sup>

Physical examination of the buttock can be divided into observation, movement and resistance tests, both isolated and dynamic.

1. Observation static
  - a. stance
    - i. alignment (shifted, inability to stand straight)
    - ii. atrophy (glutes/hamstrings)
    - iii. bruising (ischial tuberosity/posterior thigh)
  - b. single-leg stance
    - i. pain
    - ii. balance
    - iii. Trendelenburg sign
2. Observation dynamic (checking for pain/control/alignment)
  - a. gait
    - i. antalgic/Trendelenburg
  - b. squat
  - c. single-leg squat
    - i. valgus knee
    - ii. hip internal rotation
    - iii. trunk compensation

### Sensitivity and specificity of tests for buttock pain

Refer to Table 30.2.

### Key outcome measures

There is no validated outcome measure for general buttock pain. However, the VISA-H is a validated outcome measure that can be used for monitoring progress for those with proximal hamstring tendinopathy.<sup>25</sup> It consists of eight questions to assess severity of symptoms, function and sporting activity.

### Investigations

Pelvic radiographs can be used if there is suspicion of bony trauma as the cause of buttock pain such as a pubic ramus

**Table 30.2 Specificity and sensitivity of tests for buttock pain**

	Sensitivity	Specificity	Positive likelihood ratio	Negative likelihood ratio
<i>Proximal hamstring tendinopathy special tests</i>				
Bent knee stretch test	0.84	0.87	6.5	0.18
Modified bent knee stretch test	0.89	0.91	10.2	0.12
Puranen-Ovara stretch test	0.76	0.82	4.2	0.29
Supine plank test	NA	NA	NA	NA
<i>Sacroiliac joint special tests</i>				
Gaenslen's torque test	0.50	0.77	2.21	0.65
Patrick's test (FABER)	0.40	0.99	NA	NA
Femoral shear/thigh thrust test	0.88	0.69	2.80	0.18
Distraction test	0.60	0.81	3.20	0.49
Compression test	0.69	0.69	2.20	0.46
Sacral thrust test	0.63	0.75	2.50	0.50
Active straight leg raise test	0.58	0.97	NA	NA
Van der Wurff cluster (3 or more +ve from tests 1, 2, 3, 4, 5)	0.85	0.79	4.02	0.19

FAIR test	0.88	0.83	5.20	0.14

fracture or ischial tuberosity avulsion in the younger athlete. Loss of sacroiliac joint definition on a pelvic X-ray strongly suggests a spondyloarthropathy, but needs to be confirmed with blood tests and MRIs.

Lumbar X-rays can be used if a pars interarticularis fracture is suspected; however, these can be difficult to see and oblique views are best when looking for the 'Scotty dog' collar sign (see Chapter 29).

If there is a suspicion of a stress fracture or reaction of the pars interarticularis, ishium, scarum or pubic rami, then magnetic resonance imaging (MRI) should be considered. Isotopic bone or CT scans may also be an option but careful consideration should be given to exposure to radiation, especially in the younger athlete. Caution must also be used when interpreting imaging, because joint problems such as spondylosis or spondylolistheses can be very common in asymptomatic athletes.<sup>26</sup>

MRI can be used to confirm other soft tissue structures as a cause of buttock pain such as ischiogluteal bursitis, proximal hamstring tendinopathy and prolapsed

intervertebral disc. Again, caution is advised when interpreting imaging of the lumbar spine, as many so-called pathological findings are often seen in asymptomatic patients.<sup>27</sup>

Diagnostic ultrasound scanning can be used to assess tendons and bursa around the buttock area. However, they are highly user dependent and the reliability of the findings is based on the clinician's skill and interpretation.<sup>28</sup>

## MYOFASCIAL BUTTOCK PAIN

Strains to the lumbar, buttock and posterior thigh muscles, sacroiliac ligaments and other soft tissues are arguably the most common cause of back and buttock pain in athletes. It is estimated that up to 97% of all sporting injuries are soft tissue in nature.<sup>29</sup> A soft tissue injury is often reported as a fairly localised pain that is aggravated by continued activity or resistance.

The buttocks provide locomotion and power, but also have important stabilising roles. The buttock muscles can often become overloaded, strained and painful during

sports, and this may be due to poor training program design, training error, or a biomechanical deficit or muscle weakness. Palpation of the soft tissue is used to locate areas of myofascial pain, feeling for localised areas of tightness, muscle knots or taut bands. These are commonly referred to as 'trigger points' (see Chapter 4) and may be adverse areas of sustained muscle fibre contractions.<sup>30</sup>

## Examination

A lack of gluteal muscle strength can be a common cause for buttock pain in an athlete. A common sign of gluteal muscle weakness is the Trendelenburg sign.<sup>31</sup> This is a drop of the contralateral pelvis, or a compensated hitch or lateral lean of the trunk when standing on one leg. This can be difficult to notice in fit and strong individuals, and can sometimes only be identified when the athlete is fatigued or asked to stand on one leg for extended periods.<sup>32</sup>

To assess the strength of the gluteal muscles in athletes, isometric manual muscle testing can be used. For more accurate objective assessment and monitoring, hand-held dynamometry has been shown to have good reliability.<sup>33</sup> However, there are limitations on hand-held

dynamometry testing due to individual examiner strength differences.<sup>34</sup>

There is debate around the best positions to assess and strengthen the gluteal muscles.<sup>35, 36</sup> However, resisted side-lying hip abduction (Fig. 30.3d) is seen to produce high levels of activation in the gluteus medius and resisted prone hip extension produces high levels in the gluteus maximus.<sup>37</sup> These clinical tests are simple, quick and easy to perform.

## Treatment of myofascial buttock pain

If weakness is found in the gluteal muscles, a well-rounded, progressive strength and conditioning program needs to be adopted to address it that incorporates both isolated and functional multi-joint compound exercises in weight-bearing positions. For more on exercise prescription see Chapter 10. The levels of EMG activity of various exercises involving the gluteal muscles are shown in Figure 30.4.<sup>38</sup>

Treatment for tender tight muscle bands or 'trigger points' is often performed with soft tissue techniques such as ischaemic pressure with thumb or elbow, or via invasive techniques such as dry needling or injections.<sup>39</sup>

## REFERRED PAIN FROM THE LUMBAR SPINE

Buttock pain can often be referred from the lumbar spine and be associated with or without concurrent low back pain. For more on the assessment and treatment of the lumbar spine see Chapter 29.

The most common lumbar spine structures that can cause buttock pain are the zygapophyseal (facet) joints or intervertebral discs. An athlete with either of these may describe a dull, deep diffuse pain in the buttock that can vary in intensity and location.

Pain may be aggravated with repeated lumbar spine movements as well as prolonged static postures, such as sitting or standing. Palpation of the vertebral segments and paraspinal muscles may provoke local and referred pain.

## Examination

Repeated movements of the lumbar spine in one direction can cause low back and buttock pain to centralise, and when repeated in the other direction can cause the pain to peripheralise. This is highly suggestive of a discogenic lumbar radiculopathy.<sup>9</sup> Lumbar facet joint pathology can be almost conclusively ruled out if seated lumbar extension and combined rotation testing is negative.<sup>40, 41</sup>

Lumbar radiculopathy can also present with neural symptoms, such as pain and paraesthesia into the posterior

thigh or further distally. Buttock pain caused by nerve root compression or irritation can be aggravated with neurodynamic testing, such as the slump and straight leg raise tests (Chapter 15).<sup>42</sup>

However, it has been shown that pain that is not specific to lumbar radiculopathy, such as that associated with hamstring issues, may lead to false positives for the straight leg raise test and can inflate the sensitivity of these tests.<sup>24</sup>

## Treatment

Treatment of lumbar spine disorders requires an integrated multimodal approach to reflect the complex nature of low back pain. This can include passive treatment, such as manual therapy, but the primary focus should always be on active rehabilitation looking to restore mobility, movement and strength, with consideration given to any psychological factors, such as fear or apprehension that can contribute to increased central sensitisation. An individualised progressive strength and conditioning program should incorporate clear patient-centred goals and objectives based on a realistic schedule for increasing exposure, duration and intensity to activity, with the ultimate goal being to return the athlete to play and competition. See Chapter 29 for more on treatment of low back pain.

## PROXIMAL HAMSTRING TENDINOPATHY

The hamstrings are a commonly strained and injured muscle group during sporting activity. Although not as common as acute hamstring muscle tears (Chapter 34), proximal hamstring tendinopathy is a commonly encountered problem in sports that involve long distance running, jumping or repeated hip flexion. Tendinopathy has an unclear pathogenesis and there is even a lack of consensus over terminology; however, it is usually characterised as an activity overload-related condition culminating in pain, impaired performance and extended periods of rehabilitation.<sup>43</sup>

### Functional anatomy

The attachment of the three hamstrings onto the pelvis and the ischiogluteal bursa is complex (Fig. 30.5). All three hamstring tendons blend into a common tendon before they insert onto the ischial tuberosity. The hamstrings cross both the hip and knee joint, which means they are exposed to large eccentric tensile forces during activities that involve both hip flexion and knee extension, such as when decelerating the leg and foot to place it on the ground in the late swing phase of running.

The proximal hamstring tendon is also subject to high compressive loads when the hip is flexed (Fig. 30.6). This compression of the proximal hamstring tendon against the ischial tuberosity is absorbed and attenuated by the ischiogluteal bursa that is positioned between them.

The actions of the hamstrings are classically described as knee flexion and hip extension. However, as they also attach onto the tibia, their role in lower limb function and biomechanics, including the foot and ankle, cannot be overlooked.<sup>44</sup>

**Figure 30.5** Proximal hamstring anatomy

**Figure 30.6** High compressive loads of proximal hamstring with the hip in flexion. Ensure spine is straight

Proximal hamstring tendinopathy (PHT) was first described in 1988 as 'high hamstring syndrome',<sup>45</sup> with the common features of pain felt around the lower gluteal region and down the posterior thigh. PHT occurs frequently in association with ischiogluteal bursitis, but no clinical test can differentiate between these two conditions, except for MRI or ultrasound imaging. However, as the mechanisms and subsequent management are similar for both of these conditions, apart from the use of injection therapy for recalcitrant ischiogluteal bursitis, there is no need to separate them clinically.

PHT is experienced by athletes across a wide variety of sports, but it is often seen in middle and long distance runners, and occasionally sprinters.<sup>46</sup> Initially, PHT pain is mild during the sport or activity, but it soon progresses and completely stops the athlete from performing. PHT pain can then progress to be felt in normal daily activities, such as walking and climbing stairs, sitting for prolonged periods or when stretching the hamstrings or gluteal muscles.

PHT is often misdiagnosed in the early stages as a pulled hamstring muscle or mild sciatica. Early identification of PHT is critical, however, as it often progresses rapidly and recovery times can extend significantly if it is not managed appropriately in the early stages.

The primary cause of PHT is mechanical overload of the tendon, and the most common factor in its aetiology is a sudden change or increase in training duration, intensity or method. Therefore, a thorough and detailed subjective history of the athlete's training history is essential.

Attention should be given to any sudden increase in amount or intensity, or to activities that involve greater hip flexion movements, such as hill sprints, weighted deadlifts, lunges or squats. These activities create high levels of proximal hamstring tendon compression against the ischial tuberosity which, if not progressed steadily or given enough time for adaptation, can be a primary factor for development of tendinopathy.<sup>47, 48</sup>

## Examination

Physical assessment of an athlete with suspected PHT must first exclude the lumbar spine of any involvement. Lumbar flexion can aggravate the pain of PHT by compressing the proximal hamstring tendon against the ischial tuberosity and reproducing pain.

Neurodynamic testing can also be highly provocative for PHT simply due to the action of stretching the hamstring tendon insertion, but also by compressing the tendon onto the ischial tuberosity. In addition, the close proximity of the proximal hamstring tendon to the sciatic nerve can produce false positives due to biochemical irritation or even in some chronic cases due to fibrous adhesions developing around the sciatic nerve.<sup>49</sup>

PHT pain is usually well reproduced on passive stretch tests such as the bent knee stretch, modified bent knee stretch (Fig. 30.3f) and Puranen-Ovara tests (Fig. 30.3g). These tests have been shown to have high inter-examiner

reliability (range 0.82–0.88) and very high intra-examiner reliability (range 0.87–0.93). Sensitivity and specificity together with predictive values and likelihood ratios of these tests are shown in Table 30.2.<sup>50</sup>

Pain is also well reproduced on strong isometric contraction of the hamstrings, such as in the supine plank position (Fig. 30.3h) and on direct palpation of the ischial tuberosity, which is usually best performed in side-lying to avoid the bulk of the gluteals.<sup>46</sup>

Imaging of the suspected PHT and the ischiogluteal bursa can be used to confirm diagnosis. MRI (Fig. 30.7) and ultrasound scans can often show a thickened tendon, intra-substance heterogeneity and increased signal intensity.<sup>51</sup>

## Treatment

Research into the conservative treatment of PHT is limited to just a few case studies.<sup>52, 53</sup> However, using the principles and research into other tendinopathies (Chapter 4) can help guide the management of PHT.

### Initial treatment

Treatment for PHT should be focused to reduce pain and minimise compression of the tendon against the ischial tuberosity. Advise the athlete against stretching the hamstrings or gluteal muscles and to avoid positions of sustained hip flexion, such as prolonged sitting, as much as possible.

**Figure 30.7** T2 fat-suppressed axial MR image showing high T2 signal (arrow) equal to that of fluid involving right common hamstring origin at ischial tuberosity, consistent with partial tear

IMAGING IN SPORTS-SPECIFIC MUSCULOSKELETAL INJURIES, 2016, P.520, ALI GUERMAZI, FRANK W ROEMER, MICHEL D CREMA. © SPRINGER INTERNATIONAL PUBLISHING SWITZERLAND 2016. WITH PERMISSION OF SPRINGER

Treatment can also be directed towards relieving symptoms, using soft tissue techniques on the posterior thigh and gluteals, applying ice and prescribing analgesic medication if needed. Manual therapy techniques, such as deep transverse frictions across the ischial tuberosity and proximal hamstring tendon, are not advocated due to their potential to increase adverse compressive forces. Although they may provide a transient analgesic effect, the forces applied do not break adhesions or increase blood flow significantly.<sup>54</sup>

#### PRACTICE PEARL

**Primary treatment for any tendinopathy must always be staged, progressive loading.<sup>55</sup>**

This is no different in PHT and it should begin immediately. Initially in the acute, irritable and painful stages the musculotendinous unit loading should be done well within pain tolerance and in positions that do not compress the tendon.

Isometric contractions can also be very beneficial in the early stages of tendinopathy, producing an analgesic effect as well as maintaining load through the musculotendinous unit. Although the pain reducing effects of isometric contractions are not completely understood, they are believed to be via both peripheral and central nervous system mechanisms.<sup>56</sup> The most effective 'dosage' of isometric contractions is not fully known, but long duration, 45–60 seconds, at as near as pain tolerance allows to maximal force, seems to have the greatest effect. This should be done regularly and intermittently throughout the day in groups of 3–5 repetitions at a time.<sup>57</sup> Good examples are the prone hamstring curl (Fig. 30.8) and the supine bridge position (Fig. 30.9a).

Hydrotherapy can also be useful in the early reactive stages to allow loading and movement, while reducing weight-bearing forces and so pain. As pain and irritability

reduces, loading of the hamstrings is progressed steadily, aiming to create the mechanical forces needed to stimulate cellular activity to promote healing as well as restore strength, endurance and capacity to the tendon.<sup>58</sup>

Clear instructions should be given to the athlete that pain during and after tendinopathy loading is normal and to be expected, but it has to be monitored and managed sensibly every 24 hours to ensure daily loading can be completed. Using the visual analogue scale as a guide can be useful. Keeping pain under 4–5/10 when performing rehabilitation exercises seems best to prevent flare ups and allows daily progression.<sup>59</sup>

As the tendon continues to settle, heavier, slower, eccentric resistance training should be used for the hamstring muscles.<sup>60</sup> Eccentric phases of exercise allow for greater forces over greater durations of time to be tolerated within the musculotendinous unit compared to concentric phases. However, the loading should not focus solely on eccentric contraction. Concentric muscle action is also important, and a mixed and varied program of exercises incorporating both has been shown to achieve good results with tendinopathy.<sup>61</sup>

#### Intermediate stage treatment

Intermediate PHT rehabilitation exercises should incorporate eccentric action as well as increased load and resistance while minimising positions of high tendon compression. Prone hamstring curls (Fig. 30.8) are a simple, effective method to load hamstrings without any adverse compression, and can be easily adapted, depending on symptoms, with either increased or decreased load, intensity, speed of contraction and range of movement.

Body weight exercises, such as bridges, can be simply and easily progressed into more challenging variations. For example, simply doing them in single leg positions (Fig. 30.9a) or elevating the feet (Fig. 30.9b) or varying the amount

**Figure 30.8** Prone hamstring curl

**(a)**  
**Figure 30.9** (a) Single-leg hamstring bridge

(b)

(d)

(c)

(e)

**Figure 30.9 (cont.)** (b) Elevated single-leg hamstring bridge (c) to (e) Gym ball hamstring curls

of knee flexion or extension allows for greater or less force in the hamstrings to be felt. Bridging on a gym ball is a good progression for the intermediate stage of rehabilitation. It adds a dynamic component to the exercise as well as involving an element of proprioceptive training (Fig. 30.9c,d,e).

As symptoms continue to reduce, exercises in weight-bearing upright positions can be included. These exercises can also progressively introduce compressive forces by increasing the amount of hip flexion to allow the proximal hamstring tendon to start to adapt to them. Exercises such as 'good mornings' (Fig. 30.10a), deadlifts (Fig. 30.10b) and squats (Fig. 30.10c) are good examples, and can be easily and simply progressed by increasing the amount of hip flexion or increasing external loads carried or performing them on the single leg.

During the tendon loading phase, consideration should be given to identifying and addressing any weaknesses found in the kinetic chain or any biomechanical deficits seen around the lumbopelvic area. Static alignment tests,

such as planks and their different variations which ask an athlete's lumbopelvic area to resist external forces over a period of time, can give clues to potential weak areas that need addressing.

Dynamic tests, such as single-leg squats and lunges as well as functional tests that mimic an athlete's activity as closely as possible, can give a therapist clues to any possible biomechanical imbalances and lack of proprioceptive ability that may also be a causative factor, while also continuing the appropriate loading for the PHT.

There is no one best or more validated method to assess lumbopelvic strength or biomechanics. Each assessment will be based on, and guided by, the athlete's level of ability and sport, as well as the therapist's own clinical reasoning, experience and preference. Information taken from these tests is to be used with caution and is not to be used in isolation. There is scant evidence and little consensus on the role that biomechanics does or does not have in tendinopathy incidence.

(a)

(b)

**Figure 30.10** (a) Loaded double-leg good mornings  
(b) Single-leg RDL (Romanian dead lift)/toe touches  
(c) Single-leg squat

### Final stage of treatment

The final stages of rehabilitation should include progressive higher speed, plyometric and ballistic movements, such as bounding, hopping and jumping, heel flicks and high knee drives (Fig. 30.11). These types of activities expose the musculotendinous unit to sudden changes in eccentric and concentric action, and allow it to adapt to the normal stretch shortening cycle required in most

(c)

sporting activities. They are an essential component for full and safe return to sporting activity. Trying to closely mimic the functional demands, positions, speeds and types of muscle contraction the tendon will experience in its normal sporting activity is key in these final stages of rehabilitation.

When an athlete can return to running tasks depends on the type, frequency and intensity of their training and their pain levels. High-intensity, long-duration activity should be avoided until later, when the symptoms have settled and the musculotendinous unit has progressively adapted. However, less intense, reduced duration running that avoids excessive hip flexion, with instructions to the athlete to avoid hills and use shorter stride lengths to avoid overstriding, allow an athlete to return to running sooner and during their rehabilitation, as long as clear instructions are given to monitor pain levels both during and after activity.

### SACROILIAC JOINT DYSFUNCTION

The sacroiliac joint (SIJ) is a highly debated and controversial source of low back and buttock pain in sports, with it often being accused of moving too little, too much or even subluxating or popping out of position.

#### PRACTICE PEARL

SIJ dysfunction is a broad term and is often used as a scapegoat for low back and buttock pain that has no clear diagnosis.

(a)

(b)

**Figure 30.11** (a) Heel flicks (b) High knee drives

The prevalence of SIJ dysfunction varies greatly in the literature, with estimates ranging between 15–30%<sup>62</sup> and even as high as 50% in certain sporting populations.<sup>63</sup>

The true prevalence of SIJ dysfunction is extremely difficult to establish, not only due to the complex anatomy of the SIJ with its many ligaments and myofascial structures that can be a source of pain, but also due to the multifactorial nature of low back and buttock pain.

To confuse matters further, many of the gold standard tests, such as imaging and diagnostic local anaesthetic, cannot be relied upon for the SIJ. Imaging alone cannot differentiate symptomatic from non-symptomatic SIJs,<sup>64</sup> local anaesthetic injections leak out of the joint and affect other tissues and nerve roots around the pelvis.<sup>65</sup>

There is also controversy and disagreement on how and why the SIJ can cause pain. It is commonly believed that poor spinal or pelvic positions or poor posture may be factors in SIJ dysfunction, with excessive anterior or posterior tilt of the pelvis adversely stressing and sensitising either the joint itself, its many ligaments or the myofascial tissue across it.<sup>66</sup> However, there is no evidence that spinal or pelvic positions or postures have any association with pain or incidence of injury.

Poor strength of the pelvic floor, abdominal or lumbar spine muscles is also often proposed as a causative factor for SIJ dysfunction, in the belief that it allows for excessive SIJ movement and shear forces.<sup>67, 68</sup>

However, there are doubts around this commonly held theory. There is no correlation between excessive movement of the SIJ and pelvic pain post-partum.<sup>69</sup> It is even questionable if excessive movement actually occurs at the SIJ, even in those with diagnosed widespread hypermobility joint syndromes and chronic pelvic pain.<sup>18</sup>

Finally, despite claims for the need to improve trunk and pelvic strength to increase the stability of the SIJ, we have no idea what amount of trunk and pelvic muscle activity is needed to provide sufficient stability to the SIJ during different tasks, or if it is even a causative factor in developing SIJ pain.

All this uncertainty around the pelvis often leaves the clinician confused and frustrated when trying to determine whether the SIJ is or is not, dysfunctional or a source of pain, let alone how best to manage it.

### Functional anatomy

The sacroiliac joints are highly specialised joints that permit a stable, yet slightly flexible platform for the transmission of forces between the lower limb and the rest of the body. The SIJs are large, flat, part synovial, part fibrotic joints that have a highly congruent surface that provides a large friction coefficient, which together with its many strong ligaments, allows for effective and

(a)

There is wide variation described in the literature as to how much normal movement occurs at the SIJ. Some describe up to 8 mm of translation,<sup>71</sup> while others describe much less, between 1.4 and 3.1 mm.<sup>72</sup> However, it is agreed that although there is movement at the SIJ, it is minimal.

The role of the trunk musculature in providing movement, stability and control around the SIJ is also complex. The abdominals, gluteals, hamstrings, latissimus dorsi, spinal extensors and the extensive thoracolumbar fascia are all reported to work together in cross-like slings, assisting in the locking of the SIJ during movement. The term 'force closure' is often used to describe this effect of these muscles on the SIJ.<sup>74</sup>

## Clinical features

An athlete with SIJ dysfunction can report a deep, diffuse, usually unilateral buttock pain that may be triggered after a change in activity level. A full and detailed history of an athlete's training record must be thoroughly explored to locate any potential trigger. The onset, location and sensations of SIJ pain can closely mimic that of a lumbar spine issue. However, SIJ pain is more likely to be reported below the level of L5 and possibly more directly over the SIJ, but rarely over the ischial tuberosity. Pain can also

**Figure 30.12 (cont.)** Sacroiliac joint anatomy (b) Anterior view

occasionally be felt bilaterally and sometimes refer distally down the posterior and lateral thigh.<sup>75</sup>

Aggravating factors tend to be activities that increase forces or loads through the SIJ, such as sitting, walking, lumbar spine movements, and sporting tasks. Easing factors can be resting in supine positions, but side-lying can be uncomfortable.

Examination of the athlete with suspected SIJ pain should look globally at the quality of movement of the gait, hip and lumbar spine movements and check to see if any directional preference is produced with repeated movements which may indicate discogenic or lumbar radiculopathy symptoms rather than SIJ dysfunction.<sup>8</sup> The use of identifying the bony landmarks of the ASIS and PSIS to ascertain if the pelvis is symmetrical or in good alignment has little clinical utility and will not help in the diagnosis or treatment planning.

Other common tests used to assess the SIJ position, alignment or its hypermobility or hypomobility have also been shown to have poor specificity or sensitivity

and again have no place in an evidence-based clinical assessment.<sup>19, 20, 76</sup> In fact it has been demonstrated that using palpation tests that feel for movement of the SIJ exaggerate the small SIJ movements by up to five times.<sup>71</sup>

The best way to determine if the SIJ is a source of buttock pain is with a cluster of pain provocation tests.<sup>7, 9</sup> These tests can be seen in Figure 30.3 and the sensitivity and specificity of the combinations are shown in Table 30.2.

The active straight leg raise test (ASLR) has also been proposed as a valid test to assess the ability of the SIJ to withstand load (Fig 30.3o).<sup>9</sup> When it produces a sensation of heaviness or pain, it is thought to highlight trunk or pelvic muscle weakness or altered motor control that reduces SIJ force closure.<sup>77, 78</sup> However, when a positive ASLR test is measured, the increased movement is found at the symphysis pubis joint not the SIJ.<sup>79</sup> It is also not known if a positive ASLR test is a cause or an effect of SIJ dysfunction, as experimentally induced SIJ pain in

normal pain-free subjects has been shown to produce a positive test.<sup>80</sup>

## Treatment

The management of a patient with suspected SIJ dysfunction must be multimodal to reflect the psychosocial nature of pain, as well as the complex anatomy, biomechanics and relationships that this area has with surrounding structures.

Manual therapy techniques in and around the pelvis, lumbar spine and buttocks, such as soft tissue massage, joint mobilisations and manipulations have been advocated.<sup>81</sup> It must be remembered, however, that the SIJ is highly congruent and well supported by immensely strong ligaments and muscles, therefore these techniques do not and cannot change or alter an SIJ's physical position or affect its biomechanical properties in any way.<sup>82</sup>

The effects achieved with manual therapy around the SIJ are not fully understood, but it appears they are due more to central and peripheral neuromodulation of the soft tissue and joint mechano- and nociceptors that reduce sensations of stiffness and pain rather than biomechanical or structural mechanisms (see Chapters 6 and 7).<sup>83</sup>

Other passive treatment modalities such as taping, pelvic belts and braces have also been suggested to offer relief from SIJ pain. They are often thought to help assist weak trunk muscles in the force closure of the pelvis.<sup>84, 85</sup> However, the exact mechanism of action of SIJ belts is still unknown.<sup>86</sup>

Corticosteroid injections in and around the SIJ can help alleviate pain in the short term, but, as previously mentioned, the injected material often leaks out from the joint and can affect other surrounding tissues, which needs to be considered.

The use of sclerosing prolotherapy injections has been advocated in the management of SIJ pain.<sup>87</sup> There is a belief that these injections act as a trigger for fibrosis of the sacroiliac ligaments and help restore stability around the joint.<sup>88</sup> Good quality robust trials using control groups and placebo treatments are lacking with prolotherapy injections, and their use is usually based on anecdotal information.

Although initial treatments for an athlete with SIJ dysfunction can focus on pain relief and symptom modification, ultimately the primary treatment is to restore the capacity of the SIJ and its surrounding tissues to withstand load, stress, shear and strain with a progressive strengthening and functional exercise rehabilitation program.

In the initial stages this may begin with non weight-bearing exercises that focus on the muscles of the posterior chain, the erector spinae, gluteals and hamstrings. Exercises already mentioned in the proximal hamstring tendinopathy section can be used to good effect here.

Exercises such as bridges and their progressions can be combined with exercises that also strengthen the abdominals. Progression of exercises should include moving into weight-bearing positions, focusing on a single plane of movement, such as squats and deadlifts, progressing the resistance and load as symptoms improve. More complex movements involving different and multiple planes of movement, and variable loads and speeds, can be incorporated as the athlete improves, ultimately looking to return the athlete back to full participation in his or her sport.

## LESS COMMON CAUSES OF BUTTOCK PAIN

### Piriformis syndrome

Another highly debated diagnosis of buttock pain is piriformis syndrome or impingement. This diagnosis was first described in 1947 as an enlarged or inflamed piriformis muscle mechanically compressing the sciatic nerve causing buttock and posterior thigh pain.<sup>89</sup> The anatomy of the piriformis muscle and its relation to the sciatic nerve can be seen in Figure 30.13. Variation in the path of the sciatic nerve around or even through the piriformis has been described as a potential cause for this condition.<sup>90</sup>

It has been proposed that up to 5% of all buttock pain is related to piriformis syndrome.<sup>91</sup> However, there is disagreement over the true prevalence, with some authors arguing that piriformis syndrome is a neurological condition and therefore can only be diagnosed with electro-diagnostic evidence of a neurological deficit.<sup>92</sup> Others think that piriformis syndrome is a myalgia that occurs secondary to insufficiency or weakness of the larger hip and buttock muscles, such as the gluteals.<sup>93</sup>

Piriformis syndrome may be more common in sports that involve frequent hip flexion, internal rotation and adduction, such as cycling, skiing, dance and gymnastics. It can occur with a gradual insidious onset as well as through a traumatic event. Pain is usually reported in the mid buttock area and described as deep and diffuse. It tends to increase with seated positions more than standing and pain may be felt when stretching the buttocks.

Clinical examination of an athlete with suspected piriformis syndrome should try to exclude the more common causes of pain such as the lumbar spine, sciatic neuropathy, hamstring tendinopathy, and the SIJ and its ligaments.

The straight leg raise (SLR), the active side-lying piriformis test (Fig. 30.3p) and passive seated piriformis test (Fig. 30.3q) have been investigated to check their sensitivity and specificity to diagnose sciatic nerve

(a)

(b)

**Figure 30.13** Course of the sciatic nerve in the buttock  
(a) Normal (b) Aberrant

entrapment in the deep gluteal region and can be seen in Table 30.2.<sup>94</sup>

Special tests used to confirm piriformis syndrome are active resistance tests for the piriformis challenging its actions of hip extension from flexion and external rotation, and are often called the PACE and Beatty tests. Other special tests for piriformis syndrome are passive stretch tests of the muscle in positions of hip flexion and internal rotation, often called the FAIR and Freiberg tests. However, these tests have not shown reproducible validity and so must be used with caution as they also stress other structures. These tests can be seen in Figure 30.3.

(a)

(b)

**Figure 30.14** Treatment of tight piriformis muscle (a) Soft tissue therapy—piriformis. Sustained longitudinal pressure to the belly of the piriformis muscle, initially in passive external rotation and then moving into internal rotation (b) Stretching of hip external rotators

As with other causes of buttock pain, treatment should first be prioritised to help reduce pain and modify symptoms. This may be achieved with manual therapy techniques, such as soft tissue massage (Fig. 30.14a) and stretching of the piriformis (Fig. 30.14b). Self-applied methods using tennis and golf balls can be taught.<sup>95</sup> Although the evidence is limited, there can be a role for local anaesthetic injections in the management of piriformis syndrome; however, there seems no advantage in adding corticosteroid to these.<sup>96</sup>

Once symptoms have reduced, the focus should be directed towards strengthening the buttock muscles and their actions of hip extension and abduction. These have already been described in the myofascial pain section in this chapter.

Surgical treatment by open or arthroscopic release has been described in a few cases, but these are uncontrolled case studies and should only be considered as a last resort in chronic, refractory cases.<sup>97, 98</sup>

### Ischiofemoral impingement

The skeletal morphology of the hip joint is well known as a source of impingement in athletes. A rarer type of hip impingement between the lesser trochanter of the femur and the ischium exists, called ischiofemoral impingement (IFI), and this can manifest as atypical groin or buttock pain.

IFI is believed to be due to abnormal or repeated contact between the lesser trochanter of the femur and the ischium, usually when in positions of hip extension, adduction and external rotation, for example when ballet dancers perform their poses and positions.<sup>99</sup> It could also hypothetically be caused by weakness or fatigue of the hip and pelvic abductors allowing for a Trendelenburg position of excessive pelvic adduction during sports or tasks. This abnormal pelvic and leg position could cause adverse contact, compression and then injury to the quadratus femoris (QF) muscle, a strong adductor and external rotator of the femur and hip stabiliser.

True prevalence of IFI is not fully known, but estimates are around 4% with it predominantly seen in females (84%) and around 40% of cases being bilateral.<sup>100</sup>

An athlete with IFI can present with a similar presentation as an adductor or proximal hamstring tendinopathy, with pain felt in the deep buttock and/or groin when they perform sport or activity, that progressively worsens until it is felt in normal daily activity.<sup>101</sup> Painful popping and clicking sensations can be reported with IFI and can be misdiagnosed as a snapping iliopsoas or labral injury. IFI can also cause neural symptoms due to the close proximity of the QF muscle to the sciatic nerve.<sup>102</sup>

There are no clinical diagnostic special tests for IFI. IFI should be suspected when movements that compress the QF muscle, such as combined hip extension, adduction and external rotation, reproduce pain; however, these should not be used in isolation and should not be relied upon to diagnose IFI.

To diagnose IFI, an MRI is needed that shows QF muscle oedema and/or a reduced space between the ischial tuberosity and lesser trochanter of the femur (Fig. 30.15).<sup>103</sup>

### Treatment

Conservative management options for IFI are initially to provide advice and education regarding activity modification to reduce symptoms and allow for soft tissue recovery. Manual therapy can help reduce soft tissue pain, if needed. Once pain has settled, a progressive strengthening program should be started to address any weakness found around the hip, trunk or lower limb that may have predisposed the QF to adverse compression. Consideration should also be given to biomechanical effects, for example, ensuring there is no adverse or unnecessary crossing of the feet over the mid line when running, as well as to good lumbopelvic control during sporting activities.

The surgical management of IFI is highly controversial as it involves resection of the lesser tuberosity. This has risks to the blood supply to the femoral head as well as risks to the sciatic nerve and so should only be considered in the most extreme cases.<sup>104</sup>

### Posterior thigh compartment syndrome

Compartment syndrome develops due to increased soft tissue oedema or bleeding that increases tissue pressures within myofascial compartments, compressing

**Figure 30.15** MRI showing muscle oedema of the quadratus femoris muscle secondary to ischiofemoral impingement

and compromising the soft tissues, vascular and neural structures.<sup>105</sup> Posterior thigh compartment syndrome is a rare type of compartment syndrome, which causes buttock and posterior thigh pain.

Posterior thigh compartment syndrome can be associated with a traumatic event, such as a blow or a fall onto the buttocks or posterior thigh. It has been reported with acute traumatic hamstring muscle tears or tendon avulsions.<sup>106, 107</sup> It can also be atraumatic and caused by long periods of immobilisation and inactivity.<sup>108</sup>

Posterior thigh compartment syndrome pain is usually diffuse and progressive. It can be accompanied with distal neural and vascular occlusion type symptoms of weakness and paraesthesia. Examination reveals distended, tense and difficult to manipulate soft tissues, possibly with visible bruising if traumatic.

To confirm a diagnosis of compartment syndrome, elevated internal tissue pressures need to be recorded (Chapter 38), with levels between 30–50 mmHg being found to cause muscle necrosis if left more than 4–8 hours.<sup>109</sup> Early diagnosis and careful monitoring of this condition is essential to ensure symptoms do not deteriorate and to avoid any serious complications or adverse effects, such as tissue ischaemia or permanent neural injury.

Conservative management should be directed to help reduce compartment pressures with gentle active and passive movements, and elevation of the limb. Gentle soft tissue massage may help alleviate symptoms. In cases that do not respond with conservative management, or if compartmental pressures worsen, partial surgical fasciotomy is recommended.<sup>110</sup>

### Proximal hamstring tendon rupture

Complete disruption of the proximal hamstring tendon at its attachment onto the ischial tuberosity is rare compared to the more commonly encountered hamstring muscle tears or strains in sport. However, complete proximal hamstring tendon ruptures are seen in sports that have a risk of traumatic sudden hip flexion with the knee remaining in near full extension, such as water skiing, gymnastics and motorcross.<sup>111</sup>

These traumatic mechanisms cause the athlete to experience sudden, severe pain, frequently with a sensation of tearing or popping around the upper posterior thigh and usually the patient will not be able to bear weight.<sup>112</sup>

Over the next few hours to days, significant bruising and swelling will emerge extending down the posterior thigh. An observable and palpable deformity may be seen and felt in the posterior thigh on active knee extension when prone. Knee extension will be grossly weak and walking will be difficult due to pain. Confirmation of the extent of the avulsion is best done with MRI (Fig. 30.16) or ultrasound scanning.

### Treatment

The decision between conservative and surgical management for proximal hamstring rupture injury is not clear. Some advocate conservative treatment if there is less than 2 cm of retraction seen on imaging.<sup>113</sup> Others suggest all are surgically repaired to ensure complete return of normal muscle strength and power and to maximise chances for return to sport.<sup>114</sup>

Conservative management of complete hamstring ruptures is often challenging due to the large slow resolving haematoma that can complicate the healing

**Figure 30.16** MRI showing proximal hamstring rupture. The proximal (green arrow) and distal (yellow arrow) ends of the ruptured tendon are shown with the intervening region of haemorrhage which is the bright signal (white) in the left panel and overdrawn in purple proximal to the retracted muscle in the right panel

process and encourage excessive scarring. This can lead to complications such as adhesions to the sciatic nerve, sometimes called 'hamstring syndrome' and that might even need surgical release.<sup>49</sup>

Conservative treatment for hamstring avulsions should first recognise and ensure that the athlete's expectations are realistic and he or she is fully aware of the extended time this injury will take to recover. Treatment should focus on pain relief and offloading the hamstrings with crutches until weight-bearing can be tolerated. Gentle active and passive movement should be encouraged to prevent joint stiffness and encourage organised scar tissue formation; pool work is a good option here. Manual therapy needs to be used with caution so as not to interfere with normal healing processes. Once weight-bearing is comfortable then a progressive strengthening and conditioning program can begin. However long-term deficits in strength, power and endurance can persist.<sup>115</sup>

Surgical repair for hamstring avulsions is becoming an increasingly popular management option for both acute and chronic hamstring avulsions, with higher levels of patient satisfaction and return to play, greater strength and endurance, and less pain.<sup>116</sup> These injuries are discussed further in Chapter 34.

### Avulsion fracture of ischial tuberosity

Avulsion fractures of the ischial tuberosity are similar to complete proximal hamstring tendon ruptures, but are usually seen only in adolescents. They occur when the hamstring tendon fractures the ischial tuberosity, pulling it away from the pelvis.<sup>117</sup> They are most commonly seen in adolescent football and gymnastics.<sup>118</sup>

The age range for these injuries is between 11–17 years old (mean 13.8 years) with the mechanism of presentation usually being exactly the same as a proximal hamstring tendon rupture, a sudden acute pain being felt with a sensation of popping or tearing during a rapid hip flexion movement and an inability to weight-bear.<sup>118</sup>

Examination is the same as with a proximal hamstring tendon rupture, with bruising and swelling developing over the following few hours and days, weakness and pain on prone knee extension, and possibly a visible and palpable deformity of the hamstrings. Confirmation of an avulsion fracture can be made with an ultrasound or MR scan but it can also be seen on a plain radiograph showing a displaced bony fragment away from the ischium (Fig. 30.17).

Management is usually conservative and should be treated the same as a proximal hamstring tendon rupture, by offloading the hamstrings with crutches and with gentle active and passive movements to avoid joint stiffness. Once able to weight-bear, a progressive strengthening and return to play program can commence. However, if the bony fragment is seen to be displaced more than 2.5 cm,

**Figure 30.17** Radiograph of an avulsion fracture of the hamstring tendon from the ischial tuberosity  
COURTESY OF KYLE NAGLE

surgery may be recommended to restore congruity of the tendon and ensure return to sport.<sup>119</sup>

## CONDITIONS NOT TO BE MISSED

### Spondyloarthropathies

Buttock pain can be one of the first symptoms associated with a group of systemic inflammatory disorders, such as ankylosing spondylitis. There will usually be no history of trauma, rather a non-specific, insidious onset of buttock pain that is resistant to usual conservative treatments lasting for more than 3 months.

Ankylosing spondylitis is more prevalent in Caucasian races and has a mean age of onset around 23 years. It is rarely seen after the age of 40. It has a male-to-female ratio of 3:1. Buttock and spinal pain and stiffness is commonly reported, lasting more than 30 minutes first thing in the morning, and movement and exercise reduces the pain.<sup>120</sup> These conditions also tend to be associated with multiple joint pains and other enthesopathies in athletes, such as

plantar fasciopathy or tendinopathies, and may have extra articular symptoms as well, usually affecting the eyes.<sup>121</sup>

Diagnosis follows observation of a combination of subjective symptoms, imaging and genetic testing for the HLA B27 gene. However, in early manifestations imaging can appear normal. The New York criteria has been suggested as an aid to diagnosis.<sup>122</sup>

Treatment consists of patient advice and education regarding activity modification, with the emphasis on physical exercise and mobility. Nonsteroidal anti-inflammatory medications, corticosteroid injections and the use of disease-modifying anti-rheumatic drugs (DMARDs) have also been found to help.<sup>123</sup>

### Stress fracture of the sacrum

Sacral stress fractures are a rare and uncommon cause of buttock pain in the athlete, however the diagnosis is often missed or delayed due to a lack of awareness. There is little epidemiological data, but they are most frequently seen in osteopenic female runners, possibly secondary to menstrual and/or eating disorders (Chapter 4).<sup>124</sup>

The clinical presentation can be variable and very similar to a SIJ dysfunction. The main complaint is usually acute low back or pelvic pain, associated with a severe reduction in mobility and a possible radiation to the leg, groin, buttocks and thighs.

Symptoms are increased with weight-bearing activity, and improve with rest and lying supine. Tenderness over the sacral area is common. There can often be associated tenderness over the symphysis pubis, due to the high incidence of pubic rami fractures in association with sacral stress fractures.<sup>125</sup> Neurological defects are usually absent.

Physical examination may reveal many positive tests for SIJ dysfunction including sacral tenderness on lateral compression; the flexion-abduction-external rotation (FABER) test, Gaenslen's test and the squish test are often positive.<sup>126</sup> Diagnosis of a sacral or pubic ramus fracture is done with imaging. Radiographs can be inconsistent as they will only show complete fractures and even then abdominal and bowel contents can shadow fracture lines.<sup>127</sup> MRI (Fig. 30.18) and CT scans are the best options.

**Figure 30.18** Coronal MRI of a sacral stress fracture (arrow)

IMAGING IN SPORTS-SPECIFIC MUSCULOSKELETAL INJURIES, 2016, P.646, ALI GUERMAZI, FRANK W ROEMER, MICHEL D CREMA. © SPRINGER INTERNATIONAL PUBLISHING SWITZERLAND 2016. WITH PERMISSION OF SPRINGER

There are no guidelines for best practice in the management of sacral stress fractures, with some advocating 3-6 months non weight-bearing, and others just a week or two.<sup>128</sup>

The use of non-steroidal anti-inflammatory medications is not recommended in the presence of fractures due to the potential detrimental effects they can have on bone healing (Chapter 4).<sup>127, 129</sup>

The principle treatment is a short period of rest to reduce pain and then progressive early mobilisation to

encourage weight-bearing stimulation of osteoblastic activity as well as maintaining bone density, muscle tone and tension, and limiting atrophy and stiffness.

Hydrotherapy is a good early option as body weight can be loaded or offloaded depending on symptoms. As pain continues to settle, a progressive strengthening and conditioning program can be designed and implemented. It has been suggested that return to running activity can be as soon as 2 months after diagnosis, despite pain remaining for around 6 months.<sup>130</sup>

# Hip pain

with JOANNE KEMP, KAY CROSSLEY, RINTJE AGRICOLA, ANTHONY SCHACHE  
and MICHAEL PRITCHARD

*...Lionel Messi returned to Barcelona early from international break due to an inflammation in his hip, pain that has also plagued other players such as Raul, Xabi Alonso, Aduriz, Busquets and a host of Athletic Club's current squad. There are different options in terms of treatment, and each player has undergone their own decision towards recovery to get back onto the pitch as quickly as possible.*

www.Marca.com, 4 September 2016

Recently, the hip joint has been recognised as a possible cause of problems in the athletic population. This is reflected in the published literature describing hip pathology and its treatment. The advent of magnetic resonance imaging (MRI) and then hip arthroscopy increased the awareness of hip labral pathology and anatomical variants that can lead to femoroacetabular impingement (FAI) syndrome as a potential underlying cause of hip and groin pain in young and middle-aged people. Lateral hip pain is also increasingly recognised as a substantial clinical problem.

### EPIDEMIOLOGY

Pain reported by patients as being in the hip region ('hip pain' for convenience in this chapter) is a common cause of activity restriction in athletes. Hip and groin pain is the third most common injury reported in the Australian Football League (AFL),<sup>1</sup> accounting for between 5-15% of all AFL-related injuries,<sup>2</sup> and is commonly seen in many other sports, including tennis, football of all codes and hockey. People with 'cam'-type FAI are four times more likely to develop hip pain over 4 years than those without this morphological variant.<sup>3</sup> Burnett et al. demonstrated that 92% of patients with arthroscopically confirmed labral tears complained of moderate to severe groin pain.<sup>4</sup> Philippon et al. described labral tears and FAI in 100% of professional National Hockey League ice hockey players presenting for hip arthroscopy for the treatment of longstanding hip and groin pain.<sup>5</sup> However, cam-type morphology is also associated with labral and cartilage hip damage in asymptomatic males where adjusted odds ratios range from 2.45 to 2.77.<sup>6</sup> Therefore the relationship

between activity, pain, morphology and pathology is complex and not fully understood.

The likelihood of an athlete sustaining an injury to the hip joint can be increased by the demands of the sport, in particular sports that require repetitive hip flexion, adduction and rotation,<sup>7</sup> but may also be caused by inherent or acquired individual anatomical variations within the joint, such as FAI or developmental dysplasia of the hip.<sup>5, 8-13</sup>

Intra-articular hip pathologies, including chondral and labral pathology contribute to a reduced ability to participate in sporting or physical activities as well as pain and reduced function during activities of daily living.<sup>14</sup> In addition, people with pathology such as FAI, labral tears and chondral pathology have impairments in hip range of motion, hip muscle strength, balance and functional task performance.<sup>14, 15</sup> These physical impairments are themselves associated with further pain, limitations in daily activities, sporting participation and quality of life in affected individuals.<sup>16</sup> Given the increased recognition of hip pathology as a source of hip and groin pain in active individuals, it is important that clinicians have a thorough understanding of likely diagnoses and appropriate treatment options in these patients.

### FUNCTIONAL ANATOMY AND BIOMECHANICS

The hip has three functions, which are to allow mobility of the lower limb, to transmit loads between the upper body, trunk and lower limb, and to provide a stable base in weight-bearing activities. The anatomy of the hip allows it to perform these functions.

The hip joint is supported by a number of dynamic and passive supports, which include its bony morphology, passive restraints such as capsule and ligaments, and a complex system of interplaying muscle groups. The biomechanics of the hip joint are generally under-reported in the literature and as such are poorly understood. An appreciation of the functional anatomy of the hip and the role of the various structures surrounding the hip will assist in this understanding (Fig. 31.1).

### Morphology

The hip joint (femoroacetabular joint) is a tri-planar synovial joint, formed by the head of femur inferiorly and the acetabulum superiorly. The acetabulum sits within the bony pelvis and is normally anteverted (forward facing) by approximately  $23^\circ$  (Fig. 31.2a).<sup>17</sup> The acetabulum also faces inferiorly and laterally.

The head of femur is also anteverted, which refers to the angle between the axis of the femoral neck and the transcondylar axis of the knee (Fig. 31.2b). This angle is normally between  $10\text{--}15^\circ$  in adults. The head of femur also faces superiorly and medially.

Any orientational or morphological deviation from this normal anatomy can result in unnecessary stresses within the hip joint. An undercoverage of the femoral head by the acetabulum as seen in acetabular dysplasia can place high static loads on the anterosuperior acetabular cartilage due to a decreased contact area. In contrast, an overcoverage of the femoral head by the acetabulum can lead to 'pincer'-type FAI. A cam deformity can lead to a biomechanically imperfect hip joint, as it may cause cam-type FAI. The anteversion of the proximal femur and acetabulum and the neck-shaft angle can in turn influence the susceptibility of the hip joint to FAI. The concept of FAI will be discussed in more detail below.

This morphological structure allows the hip to achieve its  $3^\circ$  of movement, flexion and extension, adduction and abduction, and external and internal rotation. It also allows the athlete to move freely in three planes of movement.

### Acetabular labrum

The acetabulum forms the socket of the hip joint and is lined with articular cartilage. The acetabular labrum (Fig. 31.3) is a ring of fibrocartilage and dense connective tissue which is attached to the bony acetabular rim. The acetabular labrum is thinnest in its anterior aspect.

The blood supply of the labrum enters through the adjacent joint capsule. Only the outer third of the labrum is vascularised.<sup>19</sup> The labrum is innervated by a branch of the nerve to quadratus femoris and also by the obturator nerve.<sup>20</sup> Nocioceptive free nerve endings are distributed throughout the acetabular labrum, while labral cells are capable of releasing cytokines when damaged, suggesting

(a)

(b)

**Figure 31.1** Anatomy of the hip and groin area (a) Plain radiograph of the pelvis (b) The hip joint

a pain and inflammation-producing capacity.<sup>21-23</sup> In addition, the labrum contains nerve end organs which suggest that, as well as a capacity to mediate pain, it can also assist in proprioception and generate neurosecretion that may assist in connective tissue repair.<sup>20</sup>

(a)

(b)

**Figure 31.2** (a) Computed tomography showing acetabular anteversion<sup>17</sup> (b) Transverse views of a normal hip (upper figure) and a dysplastic hip (lower figure)<sup>18</sup> (1) Angle of torsion—rotation of the femoral neck relative to the shaft (transcondylar axis), normally 10–15° of anteversion. Dysplastic hips usually have increased angle (2) Acetabulum anteversion angle—the anterior direction of the acetabulum is normally 20–40° of anteversion. Dysplastic hips usually have increased angle but it may be decreased

**Figure 31.3** Transverse acetabular ligament, acetabular labrum and ligamentum teres (resected)

The acetabular labrum has several functions. These are primarily to deepen the acetabulum, to distribute the contact stress of the acetabulum over a wider area (increasing contact area by 28%)<sup>24</sup>, and to assist in synovial fluid containment and distribution by virtue of the fluid seal mechanism.<sup>22, 24, 25</sup> The acetabular labrum is continuous with the acetabular rim and adjacent acetabular articular cartilage, providing nutrition to, and assisting in, modulating loads within the acetabulum of the hip.

Normally, the fluid seal of the labrum and synovial fluid pressure is greatest in activity involving external rotation of the femur, while activity involving flexion and internal rotation (impingement) reduce the fluid seal and synovial fluid pressure.<sup>26</sup> Also people with cam-type FAI do not achieve maximal fluid seal and synovial fluid pressure during external rotation.<sup>27</sup> Given that adequate labral seal and synovial fluid pressure are essential for labral and cartilage nutrition, this has the potential to cause problems. These findings may help explain why hip impingement is associated with hip pain and pathology such as labral and chondral lesions, and why people with cam-type FAI are more susceptible to these associated pathologies.

## Ligaments of the hip

The transverse acetabular ligament (Fig. 31.3) traverses the acetabular notch, connecting the anterior and posterior edges of the labrum. The deepest layer of labral tissue blends into this ligament. The transverse acetabular ligament is under greatest load in weight-bearing, when the head of femur relocates in the acetabulum, widening the acetabular notch and placing the transverse acetabular ligament under a tensile load.<sup>25</sup>

Originally thought to be a histological vestige that becomes redundant early in childhood, it is now assumed that the ligamentum teres (Fig. 31.3) plays an important proprioceptive role, especially in weight-bearing activities.<sup>28</sup>

The hip capsule contains ligaments that act together to restrain excessive motion of the hip joint. These are the iliofemoral ligament, the pubofemoral ligament and the ischiofemoral ligament (Fig. 31.4). The iliofemoral ligament ('Y ligament of Bigelow') reinforces the anterior capsule and originates from the anterior iliac spine, fanning into an inverted Y shape to insert into the intertrochanteric line. It is taut in hyperextension and also provides stability in relaxed standing. The pubofemoral ligament arises from the anterior surface of the pubic ramus and inserts into the intertrochanteric fossa. It is

**Figure 31.4** Capsular ligaments of the hip

taut in abduction and extension and also reinforces the anterior capsule. The ischiofemoral ligament arises from the posterior surface of the acetabular rim and labrum and extends into the femoral neck just proximal to the greater trochanter. Its fibres run in a spiral pattern and are also taut in hyperextension. These three ligaments act to restrain hyperextension, which is of particular relevance in relaxed standing.

## Chondral surfaces

Both articular surfaces of the hip are lined with articular cartilage. These chondral surfaces rely upon adequate function of the synovium and movement of synovial fluid within the joint to provide nutrition, as articular cartilage is avascular. As detailed above, the degree of synovial fluid distribution is affected by the functional position of the hip, as well as by the presence of cam-type FAI, indicating that both the position of the hip and cam-type FAI may impact on cartilage nutrition. Both acetabular labrum and ligamentum teres have been reported to attach to synovium, and thus both may also play a role in the nutrition and normal function of articular cartilage within the hip joint.

In a normal, healthy hip joint, the articular cartilage assists in smooth movement as well as absorbing loads, protecting the subchondral bone and adjacent intra- and extra-articular structures. Glycosaminoglycans (GAGs) are molecules contained within the extracellular matrix of cartilage. They provide the strength and shock-absorbency characteristics typical of healthy cartilage. When reduced, the strength of cartilage and its ability to absorb forces are greatly inhibited. Lower levels of GAGs are reported in the early stages of osteoarthritis (OA) and also in people with cam deformity, pain on impingement testing and painful FAI.<sup>29</sup> There is an increased risk of chondral injury when coexisting labral pathology and cam-type FAI are present,<sup>14</sup> while it has been suggested that chondral injury may represent hip OA in its earlier stages.<sup>30</sup>

It appears that the interrelated nature of cam-type FAI, labral pathology and chondral injury all contribute to the breakdown of normal hip function and that abnormal hip mechanics may also contribute to these pathologies. Strategies that are focused on optimising the mechanics of the hip joint may be important targets when improving function, reducing pain and slowing hip-joint disease progression.

## Muscle function

Dynamic hip stability is provided by a complex interplay between various muscles surrounding the hip joint. In particular, the primary hip stabilisers provide a posterior, medial and inferior force on the femur to control the

**Figure 31.5** Muscle attachments around the greater trochanter

#### PRACTICE PEARL

The concept of deep hip stabilisers as the hip 'rotator cuff'<sup>31</sup> has grown in popularity in recent years.

position of the head of femur within the acetabulum.<sup>32</sup> Ultimately, the dynamic control provided by the deep hip stabilisers has potential to minimise stress on vulnerable structures, such as the anterosuperior acetabular labrum and the anterosuperior acetabular rim (Fig. 31.5).

Reports detail the role of hip muscles with respect to muscle morphology, primary action of joint movement and lines of action in relation to the axes of joint movement.<sup>31, 33, 34</sup> Some muscles have greater capacity to generate torque over larger ranges of motion (prime movers), while other muscles are better placed to act as dynamic hip joint stabilisers.

#### Short hip stabilising muscles

The six short hip external rotators (obturator internus and externus, the superior and inferior gemellus, quadratus femoris and piriformis), also known as short hip stabilising (SHS) muscles, provide hip joint compression and hence dynamic stability during most weight-bearing and nonweight-bearing activities.<sup>33</sup> The gluteus medius is the dominant hip abductor and is the primary lateral stabiliser of the hip during one-leg stance activities.<sup>34</sup>

#### Clinical biomechanics

For the patient with hip pain and/or pathology, the clinician should also consider the lines of actions for each of the deep hip stabilisers.<sup>33</sup> For example, although all of the SHS muscles provide dynamic hip stability in the anatomic position, the quadratus femoris also has a line of action that is inferomedial. Therefore, it has a greater capacity to resist superior translation of the hip. Similarly, the gluteus maximus and four SHS muscles (piriformis, gemellus inferior and superior, obturator internus) have a line of action that is posteromedial and may be able to resist anterior force of the hip.<sup>35</sup>

In contrast, although the gluteus medius is an important lateral stabiliser of the hip, its line of action is both medial and superior<sup>33</sup> and it is the greatest contributor to both medial and superior hip contact force during walking.<sup>35</sup> Furthermore, the anterior fibres of gluteus medius and minimus become hip internal rotators when the hip is flexed. The relevance of these factors to the rehabilitation of the patient with hip pain and pathology will be described below.

In healthy people without hip pain, men are generally stronger than women in most hip muscle groups, while there is no difference between the dominant and non-dominant leg.<sup>36</sup> Hip muscle strength can be measured reliably in the clinic using hand-held dynamometry.<sup>36, 37</sup> In certain populations, the relationships between agonist and antagonist muscle groups have been reported,

providing further evidence of how hip muscles function together in healthy groups<sup>37, 38</sup> and how this function might be impaired in people with hip pain and pathology.

## CLINICAL APPROACH

Hip region pain can be multifactorial and therefore difficult to diagnose. Hip pain also commonly coexists with groin-related pathology, such as the adductor, iliopsoas, inguinal and pubic-related entities (Chapter 32). These entities can present as hip pain. This makes definitive diagnosis and provision of appropriate management programs difficult and often multifactorial.<sup>39</sup> Therefore, the key to the effective management of hip pain is an accurate diagnosis of the likely source of and reason for the pain and understanding important differential diagnoses. The causes of hip pain are shown in Table 31.1.

### PRACTICE PEARL

One major issue facing clinicians when encountering a patient with pain in the hip and groin region is the poor specificity of the majority of clinical tests,<sup>40</sup> making accurate diagnosis of the source of pain difficult (see also Chapter 14).

Fortunately, a number of clinical tests have good or excellent sensitivity, meaning clinicians can have a reasonable degree of certainty that a patient with a negative test finding does not have pain whose source is the hip joint.

A second issue is the potential for intra- and extra-articular sources of hip pain, as well as remote factors to contribute to the patient's symptoms. Finally, imaging modalities are useful, but are not equal or superior to arthroscopy when diagnosing hip pain. Therefore, clinicians need to consider a range of possible sources of pain when making the diagnosis from a combination of subjective and objective findings and imaging results.

Hip region pain and associated pathologies have not been well managed in the athletic population until recently. A large cohort study of patients with FAI in the USA indicated that most patients had hip pain for 12–36 months.<sup>41</sup> Weir and colleagues reported a mean duration of hip and groin pain in athletes of 22 weeks,<sup>42</sup> with the maximum duration 250 weeks (5 years), while many other studies report symptom duration of greater than 2 years.<sup>18</sup> Byrd and Jones reported an average of 7 months from initial assessment and multiple other diagnoses being made before a definitive diagnosis of hip pathology was made.<sup>43</sup>

In the fourth edition of *Clinical Sports Medicine*, we mentioned the debate regarding the efficacy of hip

arthroscopy as an appropriate intervention for athletes with hip pain. The efficacy of both surgical and non-surgical interventions for hip pain remains unknown. The danger of both surgical and non-surgical procedures being perceived as being fashionable is that practitioners can become polarised in their opinions and not assess each case and therefore the most appropriate intervention on its merits. Future studies determining the efficacy of both surgical and non-surgical management of hip pain are essential.

When assessing the hip, the reliability and clinical utility of assessment findings should be considered. These are contained in Table 31.2. A comprehensive discussion of the key components of a clinical history, physical examination and appropriate referral for investigations is outlined below.

## History

The only feature from a clinical history with known validity is painful clicking; it has a low likelihood ratio (Table 31.2). This indicates that a patient without painful clicking is unlikely to have a labral tear. Nonetheless, it is important to obtain a full history from a patient prior to undertaking a physical examination or obtaining any investigations. This history should include:

- age, general health, past medical history (including presence or absence of childhood conditions such as 'clicky hips', slipped upper femoral epiphysis or infantile dysplasia), past family history of hip pain and hip OA (there is a greater risk of FAI if it is present in other family members<sup>50</sup>) and medications
- weight and height (BMI >25 can increase severity of symptoms of OA and tendinopathy, as well as increase joint loads; also, patients with FAI and related pathology tend to have a BMI >25<sup>14, 41</sup>)
- exact mechanism of injury (if known), was onset sudden or insidious?
- time since onset of symptoms (patients with FAI often have had symptoms for 1–3 years<sup>41</sup>)
- pattern of symptoms since onset (worsening, improving or not changing)
- presence of mechanical symptoms such as locking, clicking or giving way (suspect labral or possibly ligamentum teres pathology)
- location of pain (hip pathology may present as groin, lower back, lateral hip, buttock or thigh pain<sup>51</sup> and secondary sources of pain such as muscle spasm, which complicate the assessment)
- Note that lateral hip pain is usually *not caused* by hip joint pathologies

Table 31.1 Causes of hip pain

Common	Less common	Not to be missed
<b>Anterior pain</b>		
Labral tear	Stress fracture of the neck of femur (see Chapter 32)	Avascular necrosis of the head of femur
Chondropathy		Synovial chondromatosis
Osteoarthritis	Traction apophysitis (anterior inferior iliac spine–rectus femoris; anterior superior iliac spine–sartorius; lesser trochanter–iliopsoas)	Slipped capital/upper femoral epiphysis
Synovitis		Perthes' disease (see Chapter 44)
Ligament teres tear		Tumour
Hip joint instability (hypermobility or developmental dysplasia of the hip)		
Groin-related pain (see Chapter 32)		
<b>Lateral pain</b>		
Gluteus medius tears and tendinopathy	Referred pain lumbar spine	Fracture of neck of femur
	Pain from the trochanteric bursa	Nerve root compression
		Tumour
<b>Posterior pain</b>		
Posterior labral tear	Referred pain lumbar spine and pelvic joints	Nerve root compression
Posterior chondral lesion		Tumour
Ligamentum teres tear	Proximal hamstring-related pain (see Chapter 34)	
Posterior micro-instability secondary to anterior impingement	Sciatic nerve entrapment in short posterior rotators (see Chapter 30)	

- nature of pain (intensity, severity, constancy, time of day, latency will provide clues as to presence of inflammation, synovitis, bursitis or tendinopathy in addition to intra-articular pathology)
  - neurological signs and low back pain (the lumbar spine can refer pain to the hip and should be eliminated as a potential primary source of pain)
  - aggravating factors (be specific regarding position of hip and potential for impingement during these activities, how long it takes for these activities to provoke pain and latent pain)
  - current level of activity (frequency and intensity, differentiate between upper and lower limb workouts. Tendon pain tends to be load dependent over a period of 3 days, thus aggravating factors related to gluteal tendinopathy may be difficult to determine if the person has very limited 'unloaded leg days')
  - factors easing pain (be specific regarding positions of ease as well as time required for pain to ease)
  - current sporting history (including level of sport, such as community, state, national; and position played within the team as certain positions will place the hip under more load)
  - previous sporting history (certain sports played may increase the likelihood of a hip injury such as dancing, gymnastics, martial arts, tennis and hockey)
  - desired level of future sporting activity (this is important to establish in order to determine level of intervention as well as future risk of injury)
  - activities of daily living, including occupation, length of time spent sitting, amount of hip flexion and rotation, and degree of manual labour within occupation, family situation including the presence of young children
  - any past treatment, including investigations, conservative treatment or surgical intervention.
- During the history, appropriate patient reported outcome measures (PROMs) should be given to the patient to complete to establish a baseline score for severity of the condition, to explore specific areas of concern and to allow accurate monitoring of the patient's progress over time (see below).

**Table 31.2 Diagnostic accuracy of clinical tests (history, physical exam) in patients with hip pain**

Assessment finding	What is a positive finding?	Sn	Sp	LR–	LR+
<b>History</b>					
<b>Labral tear</b>					
Painful clicking in hip <sup>44</sup>	Clicking	100	85	0.00	6.7
<b>Physical examination tests</b>					
<b>Intra-articular pathology (not specific)</b>					
Flexion, abduction and external rotation (FABER) <sup>40</sup>	Pain	42–81	18–75	0.72–0.73	1.1–2.2
Scour test <sup>45</sup>	Pain	50	29	0.70	1.72
Thomas test <sup>46</sup>	Pain and reduced range	89	92	0.12	11.1
<b>Labral tear</b>					
Flexion, adduction and internal rotation (FADIR) (vs magnetic resonance arthrogram) <sup>40</sup>	Pain	94	9	0.48	1.02
FADIR (vs arthroscopy) <sup>40</sup>	Pain	99	5	0.15	1.06
Flexion internal rotation <sup>40</sup>	Pain	96	25	0.27	1.12
<b>Femoral fracture</b>					
Patellar-pubic percussion <sup>40</sup>	Reduced percussion on side of pain	95	86	0.07	6.11
<b>Gluteal tendinopathy</b>					
Trendelenburg <sup>40</sup>	Drop in NWB pelvis	61	92	0.25	6.83
Resisted hip abduction <sup>40</sup>	Weakness and pain	71	84	0.37	5.50
Resisted internal rotation <sup>47</sup>	Weakness and pain	55	69	0.66	1.77
Resisted external de-rotation test <sup>48</sup>	Pain	88	97.3	0.12	32.6
Single-leg stance hold for 30 seconds <sup>48</sup>	Pain during single-leg stance	100	97.3	0.0	37
<b>Combination of findings</b>					
<b>Hip OA (vs X-ray)<sup>49</sup></b>					
Squatting aggravates symptoms	5/5	14	98	0.87	7.3
Lateral pain on active hip flexion	≥4/5	48	98	0.53	24.3
Scour test positive	≥3/5	71	86	0.33	5.2
Pain with active hip extension	≥2/5	81	61	0.31	2.1
Passive internal rotation ≤25°	≥1/5	95	18	0.27	1.2

Sn = sensitivity; Sp = specificity; LR– = negative likelihood ratio; LR+ = positive likelihood ratio. High sensitivity indicates a test is useful for ruling out a condition (good screening tool), while high specificity indicates a test is useful for ruling in a condition (good diagnostic tool).

Blue = large change in likelihood (LR– <0.1, LR+ >10). This indicates that a positive test is likely to indicate a 'true-positive' finding, while a negative test is likely to indicate a 'true-negative' finding, meaning the test has high clinical utility.

Red = rarely important change in likelihood (LR– >0.5, LR+ <2.0). This indicates that a positive test is unlikely to indicate a 'true-positive' finding, while a negative test is unlikely to indicate a 'true-negative' finding, meaning the test has poor clinical utility.

## Physical examination

In this section, the clinical tests that are valid are identified with a double asterisk (\*\*). Other tests that have not had their validity reported but are likely to be useful are also listed.

Examination involves:

1. Observation
  - a. standing:
    - i. general lower limb alignment
    - ii. femoral alignment
    - iii. muscle tone and symmetry
  - b. walking
    - i. pain
    - ii. limp
    - iii. lateral pelvic stability 'Trendelenburg sign'
2. Active movements
  - a. hip flexion/extension
  - b. hip abduction/adduction
  - c. hip internal\*\*/external rotation at 90° flexion
3. Passive movements
  - a. flexion (Fig. 31.6a)
  - b. anterior impingement test\*\*—flexion, adduction and internal rotation (FADIR) (Fig. 31.6b)
  - c. internal rotation at 90° flexion\*\*
  - d. flexion, abduction and external rotation\*\* (FABER or Patrick's test) (Fig. 31.6c)
  - e. quadriceps muscle stretch
  - f. psoas muscle stretch/impingement (Thomas position) (Fig. 31.6d)
4. Tests of muscle function
  - a. adductor squeeze test\*\* (Fig. 31.6e)
  - b. hand-held dynamometry of hip muscle strength bilaterally
    - i. flexion/extension
    - ii. adduction/abduction
    - iii. internal/external rotation

(a)

**Figure 31.6** (a) Measurement of hip flexion range of motion

(b)

(c)

**Figure 31.6 (cont.)** (b) Passive movement—anterior impingement (hip quadrant: flexion, adduction and internal rotation—FADIR) (c) Passive movement—flexion, abduction and external rotation (FABER or Patrick's test). Range of motion, apart from extreme stiffness/laxity, is not that relevant. Some caution needs to be exercised, as it is possible to sublux an unstable hip in this position. Pain felt in the groin is very non-specific. Pain in the buttock is more likely to be due to sacroiliac joint problems. However, pain felt over the greater trochanter suggests hip joint pathology

(d)

(e)

**Figure 31.6 (cont.)** (d) Passive movement—psoas stretch (Thomas position). Pain in the hip being stretched suggests psoas abnormality. Pain in the hip being compressed can be significant for anterior impingement of the hip joint (e) Resisted movement—squeeze test. Examiner places fist between knees as shown. Patient then adducts bilaterally against the fist (f) De-rotation test—in 90° flexion, the hip is taken into external rotation and the patient asked to return the leg to the axis of the table against resistance. The test result is positive when the usual pain is reproduced (g) Palpation of iliopsoas in muscle belly and at anterior hip joint

(f)

(g)

- iv. de-rotation test<sup>48</sup> (Fig. 31.6f). In 90° flexion, the hip is taken into external rotation and the patient asked to return the leg to the axis of the table against resistance. The test result is positive when the usual pain is reproduced.
5. Palpation
  - a. anterior hip joint line
  - b. adductor muscles/tendons/entheses
  - c. pelvis including pubis symphysis, ischial tuberosities and proximal hamstring attachment
  - d. iliopsoas in muscle belly and at anterior hip joint (Fig. 31.6g)
  - e. superficial hip abductors including tensor fasciae latae, gluteus medius and superior gluteus maximus
  - f. greater trochanter and tendons of gluteus medius and minimus
6. Functional movements
  - a. double-leg and single-leg squat, looking at range of motion, femoral alignment and balance
  - b. hopping (to reproduce pain)
  - c. forward hop
  - d. step up and down forwards on the affected leg (observe stability, pain level and pain location)
  - e. side step up and down on the affected leg
  - f. hip hitch (in neutral, internal rotation), keeping the knee extended. Identify the pain location and severity. Reproduction of sacroiliac joint or low back pain probably indicates a low back or sacroiliac joint problem rather than a hip problem
  - g. kicking (if appropriate)
  - h. balance and proprioception in dynamic tasks

- i. trunk strength and control (for example, side bridge test).

### Key outcome measures

A patient-reported outcome measure (PROM) is the gold standard when evaluating an outcome in a clinical population (Chapter 16). When choosing a PROM, the psychometric properties of all possible PROMs should be considered, specific to the patient. Other questionnaires such as the Hip Outcome Score (HOS)<sup>55</sup> and the Modified Harris Hip Score<sup>55</sup> are not recommended as their validity and responsiveness have not been established.

#### PRACTICE PEARL

We recommend the Copenhagen Hip and Groin Outcome Score (HAGOS),<sup>52</sup> the Hip Dysfunction and Osteoarthritis Outcome Score (HOOS)<sup>53</sup> or the international Hip Outcome Tool-33 (iHOT-33)<sup>54</sup> (Table 31.3).

### Investigations

Plain radiography, MRI and ultrasonography are the mainstay of imaging for diagnosis of hip pathology. Plain radiographs are often overlooked by clinicians, but usually should be the first investigation ordered as they can provide valuable information. FAI can often be seen on an anteroposterior view or a lateral view of the pelvis, such as a Dunn view (Fig. 31.7), cross-table view or frog-leg view

**Table 31.3 PROMs for hip pain**

Copenhagen Hip and Groin Outcome Score
<ul style="list-style-type: none"> <li>• Self-administered questionnaire evaluating symptoms and function in patients with hip and groin pain</li> <li>• Six subscales scored separately: symptoms, pain, activities of daily living, sport and recreation, physical activities and quality of life</li> <li>• Raw scores converted to score from 0 to 100 (100 = best possible score)</li> <li>• Test–retest reliability: ICC 0.82–0.91</li> <li>• MDC95%: 8–19 points</li> <li>• MCID: 6–10 points</li> <li>• Available online: <a href="http://www.koos.nu">www.koos.nu</a></li> </ul>
Hip Dysfunction and Osteoarthritis Outcome Score
<ul style="list-style-type: none"> <li>• Self-administered questionnaire evaluating symptoms and function in patients with hip arthroscopy, hip osteoarthritis and intra-articular causes of hip pain</li> <li>• Five subscales scored separately: pain, other symptoms, daily living, sport and recreation, and quality of life</li> <li>• Raw scores converted to score from 0 to 100 (100 = best possible score)</li> <li>• Test–retest reliability: ICC 0.93–0.96</li> <li>• MDC95%: 9–17 points</li> <li>• MCID: 6–11 points</li> <li>• Available online: <a href="http://www.koos.nu">www.koos.nu</a></li> </ul>

Table 31.3 Cont.

The international Hip Outcome Tool-33	
• Self-administered questionnaire evaluating symptoms and function in younger, active patients with a variety of hip pathologies	
• Thirty-three items	
• Each of the 33 items scored out of 100. Points summed and divided by number of items to get an overall score out of 100 (100 = best possible score)	
• Test–retest reliability: ICC 0.78	
• MDC95%: 16 points	
• MCID: 6 points	
• Available as appendix to Mohtadi et al. 2012 <sup>54</sup>	

**Figure 31.7** Dunn 45° flexion view indicating sclerotic cam lesion at femoral head–neck junction (arrow), pincer impingement at acetabulum and bony cyst at femoral head–neck junction

of the hip. Similarly, these plain radiographs can also guide the clinician to the presence of OA and abnormalities in morphology such as acetabular dysplasia, acetabular retroversion or anteversion, the presence of os acetabulare, and not-to-be-missed pathologies such as a slipped upper femoral epiphysis, Perthes' disease, tumours, fractures of the neck of femur and avascular necrosis. Unfortunately, a plain radiograph does not provide information about soft tissue injuries such as labral, chondral, ligamentum teres or tendon pathology.

MRI is commonly used in the diagnosis of soft tissue injuries of the hip. Pathologies such as labral tears, ligamentum teres tears, tendon and bursae pathology, and occasionally chondral defects may be seen on an MRI scan. In recent years, the sensitivity and specificity of MRI to these injuries has improved (see Table 31.4), although false-negative results are often noted. Therefore, imaging findings should be taken in combination with the patient's history and physical examination in order to obtain a correct diagnosis.

Due to the depth of the joint, diagnostic ultrasound is not especially useful for the diagnosis of intra-articular hip

pathology; however it can be useful in determining the presence of bursae of the greater trochanter or iliopsoas tendon, and tendinopathy of these regions. Real-time ultrasound can be used to assess the function of the deep lumbar and hip stabilising muscles.

Diagnostic injections of local anaesthetic are used frequently in the hip to determine the presence of intra-articular pathology of the hip. These are generally performed under imaging guidance. A reduction in symptoms following an injection generally confirms the presence of intra-articular pathology, although a negative response does not necessarily indicate that no pathology is present, and further investigation and management may still be warranted.

Surgeons may obtain specific computed tomography (CT) scans pre-operatively to assist them in planning surgery for the treatment of FAI, but these are not routinely used in clinical practice for diagnosis of the source of hip pain.

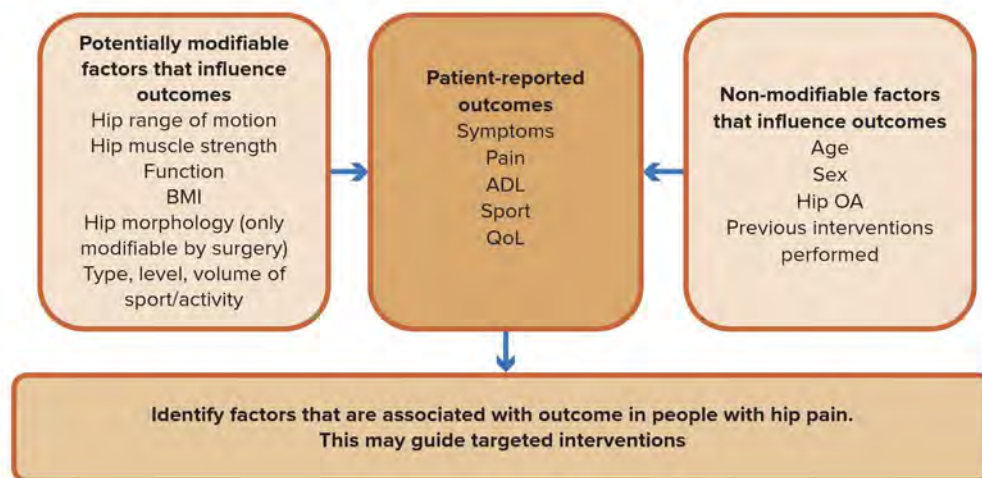

## PREDISPOSING FACTORS FOR HIP PAIN

A number of intrinsic and extrinsic factors can contribute to hip region pain (Fig. 31.8). Such factors may be modifiable or non-modifiable. Modifiable factors should be targeted for treatment as they can alter the loads on the hip joint.

Extrinsic factors may include the type of sport played, particularly those involving repeated combined hip flexion, abduction and adduction, and loaded rotational or twisting movements. These factors may also include the volume of sport and activity undertaken, footwear worn or type of surface played upon. Of these extrinsic factors, the type of sport and volume of load undertaken are probably the most important when evaluating the athlete with hip pain. Sport and activity involving repeated hip flexion, abduction and adduction; and rotation and twisting are reported throughout the literature as influencing the likelihood of the development of hip pathology. The clinician must examine these loads in

**Table 31.4** Diagnostic accuracy of imaging tests in patients with hip pain

	Sn	Sp	LR–	LR+

CT	92–97	87–100		

**Figure 31.8** How modifiable and non-modifiable factors contribute to hip-related symptoms

detail and modify accordingly for those athletes that are experiencing hip pain.

Intrinsic factors can also influence the development of hip pain and pathology. These factors may also alter loads within the joint, predisposing the hip to injury. Intrinsic

factors are either 'local', 'remote' or 'systemic', and must be considered for comprehensive assessment of the athlete with hip pain. Identifying these factors via a thorough assessment is essential if the clinician is to successfully modify the loads within the joint to protect potentially

vulnerable structures. An understanding of all possible contributing factors to hip pain will assist the clinician in devising a targeted treatment plan.

### Local factors

A number of modifiable local factors can contribute to hip pain and are potential targets for treatment, as shown in Table 31.5.

### Remote factors

Proximal and distal remote factors may contribute to the development of hip pain. Those factors that are modifiable should be targeted when planning treatment programs for patients with hip-related pain.

### Proximal factors

Increased pelvic tilt and/or lumbar hyperextension may increase the load on the anterior margins of the hip, due to the more distal placement of the anterior acetabular rim. Patients with increased pelvic tilt and

reduced trunk strength can have increased acetabular retroversion and reduced femoral internal rotation range.<sup>73</sup> This increased load may be a source of increased hip pain and eventually anterior hip pathology. The clinical assessment of pelvic symmetry and lumbar spine is outlined in Chapter 29.

Inadequate control of the lumbopelvic segments may result in a number of asymmetries, which alter the loads on the hip joint. In particular, lateral pelvic tilt may increase the load on both the lateral and medial structures of the hip joint, due to the increased adductor and internal rotation moment seen on the stance leg.

Hip and lumbopelvic control can be assessed using the single-leg squat (Chapter 8), other single-leg activities, gait or sport-specific activities. In some cases, the athlete should also be videoed whilst running, particularly when fatigued, as altered control may become more pronounced. The demands on the lumbopelvic region for the individual's sport must be considered, as this may predispose certain athletic groups to fatigue and subsequently altered load on the hip joint.

**Table 31.5 Local factors that can contribute to hip-related pain and their possible mechanisms**

Factor	Possible mechanisms	Confirmatory assessments
Reduced hip flexion range of motion	Structural <ul style="list-style-type: none"> <li>• Cam and/or pincer impingement</li> <li>• Chondrolabral pathology</li> </ul>	Plain radiograph <ul style="list-style-type: none"> <li>• Anteroposterior pelvis</li> <li>• Dunn view 45°/90°</li> </ul> Positive FADIR (Fig. 31.6b) MRI
Reduced hip internal rotation range of motion	Structural <ul style="list-style-type: none"> <li>• Acetabular retroversion</li> <li>• Cam and/or pincer impingement</li> <li>• Femoral retroversion</li> <li>• Osteoarthritis changes (osteophytes)</li> </ul>	Plain radiograph <ul style="list-style-type: none"> <li>• Anteroposterior pelvis</li> <li>• Dunn view 45°/90°</li> </ul>
	Functional <ul style="list-style-type: none"> <li>• Reduced strength hip internal rotators</li> <li>• Tight gluteals and piriformis</li> <li>• Muscle spasm</li> </ul>	Hand-held dynamometry Muscle-length tests
Increased hip rotation range (external rotation and/or internal rotation)	Structural <ul style="list-style-type: none"> <li>• Acetabular anteversion</li> <li>• Acetabular dysplasia</li> <li>• Capsular laxity</li> </ul>	Plain radiograph
Altered movement patterns	Reduced muscle strength <ul style="list-style-type: none"> <li>• Reduced hip abductor, adductor, extensor strength, external rotator strength</li> </ul> Muscle inhibition, disuse atrophy Reduced performance in single-leg squat, neuro-motor control and balance tasks	Hand-held dynamometry Palpation, observation, real-time ultrasound Functional and balance tests

### Distal factors

Increased subtalar pronation may lead to an increase in tibial internal rotation. This in turn may lead to an overload on the iliotibial band (ITB) and the lateral structures of the hip. Increased ITB tension results in increased compression over the greater trochanter and the development of gluteus medius and minimus tendinopathy and trochanteric bursitis. Increased tibial internal rotation may also create increased internal rotation of the femur, thus heightening load on the hip, particularly in athletes with an increased risk of impingement. The clinical assessment of the subtalar joint is outlined in Chapter 41.

Adequate range of ankle dorsiflexion during the stance phase of gait is essential in order to minimise excessive loads further up the kinetic chain. In addition, reduced ankle dorsiflexion range can increase the amount of adduction at the knee in single-leg squatting tasks, therefore potentially increasing hip impingement. If this movement is limited, the gait pattern may be altered to achieve onward forward propulsion of the athlete. One adaptation commonly seen is an increase in hip adduction and rotation at the middle of the stance phase of gait. This may increase load on the hip joint in similar ways outlined above. The clinical assessment of ankle dorsiflexion range of motion is outlined in Chapter 41.

### Systemic factors

Common 'systemic' factors contributing to hip joint loads include patient age, sex, BMI and family/genetic predisposition. Of these, BMI is the only factor that is potentially modifiable. Patients with a BMI >25 should be advised to seek appropriate guidance to reduce BMI to a healthy level. Other non-modifiable factors should be considered when considering a patient's likely outcomes, prognosis and expectations, as well as appropriate surgical versus non-surgical treatment options.

### FEMOROACETABULAR IMPINGEMENT

Femoroacetabular impingement (FAI) is defined as a pathological mechanical process by which morphological abnormalities of the acetabulum and/or femur combined with vigorous hip motion can damage the soft tissue structures within the hip joint itself.<sup>74</sup> For the clinical diagnosis of FAI, the hip should be symptomatic. There are two types of FAI which differ in both the anatomical site of the morphological abnormality and the mechanism by which it causes intra-articular damage.<sup>75</sup>

### Types of FAI—cam and pincer impingement

The first FAI type is 'cam impingement', in which the morphological abnormality is located on the femoral side

of the hip joint. The cam deformity is extra bone formation at the anterolateral head-neck junction, causing a non-spherical femoral head.<sup>11</sup> During hip motion, particularly flexion and internal rotation, the cam deformity can be forced into the acetabulum, causing shear forces at the chondrolabral junction (Fig. 31.9b).<sup>8</sup>

The second type of FAI is referred to as 'pincer impingement' (Fig. 31.9c). This refers to a morphological or orientational abnormality of the acetabulum leading to an over-coverage of the femoral head. This can either manifest as a deep acetabulum or as a retroverted acetabulum, which are most commonly seen anteriorly. Particularly during hip flexion, the femoral neck can impinge against the over-covered acetabulum, causing an impaction on the labrum. This type of impingement might lead to labral and also cartilage damage throughout the acetabulum in a small thin strip around the labrum.<sup>8</sup>

A cam deformity and a pincer deformity may exist together and when this leads to symptoms it is referred to as a mixed type of FAI. It is very important to recognise that a cam deformity or a pincer deformity will not always cause FAI. Susceptibility is highly dependent on many co-factors including other anatomical characteristics of the hip such as femoral and acetabular version, on the type and intensity of hip movement, and on the vulnerability of the labrum and cartilage itself.<sup>76</sup>

### Prevalence of FAI

As the mechanical impingement seen in FAI is difficult to quantify, most studies on the prevalence of FAI have

(a)

**Figure 31.9** Hip joints with and without FAI

(a) Hip joint without FAI

(b)

(c)

**Figure 31.9 (cont.)** (b) Cam lesion—additional bone arises as a ‘bump’ on the femoral surface (c) Pincer lesion—bone spur extends from the acetabular surface

focused on the morphology, that is, the presence of a cam or pincer deformity. It is important that the clinician understands that the morphology that can lead to FAI is highly prevalent and is in itself not a pathology.

The prevalence of cam deformity in the general asymptomatic population has been estimated at around 10–25%.<sup>6, 77</sup> Cam deformity is more prevalent in males (25–50%) than in females (0–10%).<sup>6</sup> Interestingly, the prevalence can be extremely high in male athletes—up to 89%—compared to only 9% in non-athletic controls.<sup>78</sup>

Pincer deformities are generally more prevalent in women, but the prevalence varies widely between studies because of the heterogeneity in what is considered a pincer deformity. General over-coverage is a condition in which the femoral head is positioned deep in the acetabulum or when there is an overgrowth of the acetabular rim. This type of pincer deformity is present in about 20% of the population.<sup>79, 80</sup> When focal over-coverage or acetabular retroversion is also taken into account, the prevalence can be as high as 60%.<sup>81</sup> Whether the latter should be regarded as a pincer deformity is still under debate.<sup>82</sup> It is unknown if pincer deformity is more prevalent among athletes.

### Aetiology

Hip loading during adolescence is emerging as a key factor in the aetiology of a cam deformity. Cam deformity was first recognised by Murray et al. in 1971,<sup>83</sup> and more recently,<sup>78</sup> hip loading during skeletal maturation has appeared to be related to development of a cam

deformity (Fig. 31.10a and b). Since 2011, two cohort studies described the development of a cam deformity during adolescence.<sup>78, 84</sup> The prevalence was higher in both football players and basketball players than in non-athletic controls.<sup>78, 84</sup> In these young athletes, the extra bone formation in the anterolateral head-neck junction becomes radiographically visible from around the age of 13 years and the cam deformity develops gradually until the growth plate closes.<sup>85</sup> After growth plate closure, the morphology of the proximal femur appears to change minimally.<sup>85</sup> This is supported by the high prevalence of cam deformity in adult athletes participating in high-impact sports ranging from 60% to 89%.<sup>78, 81, 86</sup> Therefore, a cam deformity is most likely a bone adaptation in response to vigorous hip loading when the growth plate is still open. During the time of skeletal maturation, there might be a dose-response relationship between the intensity of sports practice and the development of a cam deformity. Genetics might also play a role, as a cam deformity might have a familial pattern, with siblings being three times more likely to have a cam deformity than controls.<sup>50</sup> The aetiology of a pincer deformity is unknown and there are no studies available that investigate how a pincer deformity develops.

### Association with pain and pathology

A prerequisite of the FAI definition is the presence of hip pain and symptoms. Without hip pain, the diagnosis of FAI cannot be made. The presence of a cam or a pincer deformity in isolation have been associated with hip pain

(a)

(b)

**Figure 31.10** (a) Development of a cam deformity over time during skeletal maturation (b) Extension of the growth plate towards the femoral neck during the development of a cam deformity

in young adults,<sup>87</sup> but only 26% of people with a cam deformity complain of hip pain.<sup>88</sup> Asymptomatic young adults with a cam deformity have a 4.5 times higher risk of developing hip pain within 4 years than those without a cam deformity. This was shown in a cohort of 170 subjects, in which 16% of asymptomatic hips with a cam deformity at baseline had at least one episode of hip pain lasting longer than 6 weeks within the next 4 years.<sup>3</sup>

However, athletes might have a higher risk of developing hip pain resulting from a cam deformity, particularly when they experience repetitive movements of flexion and internal rotation of the hip. In American football (gridiron) players, the presence of a cam deformity is associated with greater hip and groin symptom prevalence, whereas a pincer deformity is not.<sup>89</sup> In ice hockey players, hip pain together with symptoms of FAI is associated with a cam deformity at a mean age of 19 years.<sup>90</sup> The association between a cam deformity and hip pain is likely also true for other sports requiring movements of deep flexion, rotation and pivoting.

Following the anterolateral location of a cam deformity, the anterosuperior region of the acetabulum is mostly affected corresponding to the site where the cam deformity is forced into the acetabulum with

#### PRACTICE PEARL

Cam impingement is associated with intra-articular pathology, whereas the association between pincer impingement and intra-articular pathology is less clear.

flexion and internal rotation.<sup>8</sup> This results locally in high shear forces at the acetabular chondrolabral junction. Resultant damage to the labrum can progress to its detachment from the acetabular rim and involvement of the acetabular cartilage. This can range from slight softening and swelling of the cartilage in the early stage, to delamination of the cartilage from the subchondral bone in later stages, a so-called carpet lesion. The size of the cam deformity is positively correlated with more severe cartilage damage.<sup>91</sup>

Severe intra-articular hip damage is already seen in athletes around their twenties. Even in asymptomatic males with a mean age of 20 years, those with a cam deformity are 2.8 times more likely to have labral lesions and a decreased combined femoral and acetabular cartilage thickness of 0.19 mm.<sup>6</sup> In the presence of a pincer deformity, labral lesions and a more circumferential pattern

of acetabular cartilage damage have been described based on intra-operative findings, but epidemiological data on intra-articular hip pathology in those with asymptomatic pincer deformities is lacking.<sup>8</sup>

### Osteoarthritis

A cam deformity is associated with hip OA, whereas the association between a pincer deformity and OA is conflicting. Since a cam deformity is present immediately after skeletal maturity, prospective studies to evaluate the risk for developing OA would require a long-term follow-up of decades. Therefore, current cohort studies consist mostly of individuals aged over 40 years. In this population, there is strong evidence that a cam deformity is a risk factor for development of OA.<sup>76, 92</sup> A prospective study found that a cam deformity conferred a four times higher risk of developing OA within 5 years and up to 10 times higher risk with a greater cam deformity.<sup>93</sup> Individuals with a cam deformity and decreased internal rotation  $\leq 20^\circ$  had a 53% chance of developing OA compared to only 2% in people without these features. Most other case-control, cross-sectional and retrospective cohort studies also show an increased risk for OA.<sup>79, 94, 95</sup> Regarding the higher prevalence of cam deformity in athletes and the higher chance to experience FAI in the presence of a cam deformity because of the repetitive movements they undertake, athletes might even be more likely to develop OA due to cam-type FAI.

The relationship between pincer deformity and OA is less clear. Some studies show a moderately increased risk for having OA in the presence of a pincer deformity,<sup>79</sup> while others, including higher-quality studies, showed no association or even a protective effect of a pincer deformity on development of OA.<sup>94, 96</sup>

#### PRACTICE PEARL

This association between FAI and increased incidence of other hip pathology has resulted in considerable debate regarding the benefit of prophylactic surgery to correct deformity associated with FAI in athletes who do not have hip or groin pain. As there is no conclusive evidence at this stage which indicates that all athletes with FAI will develop other hip pathology, prophylactic surgery to correct deformities in athletes who do not have signs of hip pathology is not recommended.

The early identification of FAI in athletes with hip and groin pain is essential. Unfortunately there is no gold standard for clinical diagnosis of FAI. Clinical signs that are often reported to indicate the presence of FAI include

**Figure 31.11** Appearances of the different types of FAI

reduced range of hip internal rotation, particularly when the hip is flexed, and a positive FADIR test. Unfortunately these tests are not specific to detect FAI and may result in a high number of false-positive results. Therefore, radiological examination is required.<sup>42</sup> Plain radiographs can be useful and generally a plain anteroposterior view of the pelvis will indicate the presence of FAI when read by an experienced radiologist (Fig. 31.11).

Athletes who present with FAI should be encouraged to avoid the position of impingement as much as possible. This position of impingement is usually flexion, internal rotation and adduction or any combination of these (Fig. 31.12). This may involve activity modification on a day-to-day basis, as well as during athletic pursuits. For example, in ball sports this may involve playing in a different position which requires less time changing direction and getting down low to the ball. It may also involve reducing the time spent on the field. Maximising dynamic neuromotor control around the hip will also assist in achieving this goal.

### LABRAL TEARS

Acetabular labral tears (Fig. 31.13) are seen frequently in the athletic population, with 22% of athletes with groin pain having labral tears, and 55% of patients with mechanical symptoms and hip pain having labral tears.<sup>18, 22, 44, 97</sup> The aetiology of labral tears is well described in the literature. However, studies have also shown that there is a high prevalence of labral tears in the asymptomatic population, especially as people age, and as with many other parts of the musculoskeletal system, pain does not always match pathology.

### Pathology

The presence of both cam-type FAI<sup>5, 8, 11, 98, 99</sup> and developmental dysplasia of the hip (DDH)<sup>100, 101</sup> can increase the risk of a labral tear. Mechanisms include impingement

**Figure 31.12** Hip impingement during kicking motion—flexion, internal rotation and adduction  
ISTOCK/VICKY EARLE

of the labrum in the presence of FAI and increased shear forces on the outer joint margins, including the labrum, in the presence of DDH. In addition, patients with labral tears are 40% more likely to have coexisting chondropathy.<sup>14</sup> The inability of a damaged labrum to adequately sustain chondral nutrition via the synovial fluid, as well as the reduced load-bearing capacity of a damaged labrum, may provide an explanation for these findings.

The prevalence of labral tears in the USA and Europe is greatest anteriorly.<sup>18, 22, 97, 102</sup> Various causes for the high number of anterior labral tears have been postulated, including reduced thickness of the labrum anteriorly, the prevalence of FAI lesions seen anteriorly resulting in anterior impingement, and common functional activities, especially those with repetitive twisting and pivoting of the hip.<sup>5</sup> The reduced bony support seen anteriorly in the hip due to the anteverted position of the acetabulum, which results in higher shear forces on anterior soft tissue structures, is also a likely cause of labral pathology. It has been shown that in the last 20–30% of the stance phase of gait and in more than 5° of hip extension, increased forces are placed on anterior soft tissue structures by the head of femur.<sup>18, 103</sup>

**Figure 31.13** Labral tear

Tears of the acetabular labrum are usually classified as type I or type II tears.<sup>22, 104</sup> Type I is described as a detachment of the labrum from the articular hyaline cartilage at the acetabular rim. Type II is described as cleavage tears within the substance of the labrum. The location of these tears relative to the vascularisation of the labrum influences the potential for healing of the tear and the most appropriate type of intervention. Recently it has been suggested that the innervation of the labrum may allow for the capacity for regeneration and repair.<sup>20</sup>

Clinically, the identification of labral tears in patients remains difficult. The patient often complains of mechanical symptoms such as locking, clicking, catching and giving way. The location of pain is usually reported to be within the anterior hip or in the anterior groin region, although some patients report pain in the posterior buttock.

Clinical examination is also difficult. While clinical tests such as FADIR (Fig. 31.6b) and FABER (Fig. 31.6c) have high sensitivity, meaning a negative test will rule out intra-articular hip pathology, they have low specificity, meaning they are not good at determining which intra-articular hip structure is the cause of pain (Table 31.2). The Thomas test (Fig. 31.6d) has a high likelihood ratio, where a positive test (pain on testing) is likely to indicate the presence of intra-articular hip pathology (Table 31.2). This may also reflect the common situation of multiple intra-articular

**Figure 31.14** T1 fat suppressed coronal MR image showing an anterior-superior labral tear (arrow)

hip pathologies coexisting. The diagnostic accuracy of radiological investigations for labral tears has improved in recent years, with MRI and MRA (magnetic resonance arthrography) (Fig. 31.14) both having a reasonable degree of sensitivity and specificity (Table 31.4).<sup>40, 66</sup> However, labral tears may be suspected but not confirmed until patients present for hip arthroscopy, which remains the gold standard to diagnose labral pathology.<sup>18, 22</sup>

Athletes with labral pathology may respond to conservative management and this should always be trialled prior to undergoing surgery. Management should be directed to unloading the damaged labrum which is almost always anterior and/or superior. Repetitive hip flexion, adduction or abduction and rotation at the end of range should be avoided through activity modification. Improving hip joint neuromotor control via activation of the deep stabilising muscles, initially in an unloaded then a progressively loaded manner, appears to assist in the unloading of the labrum.

Gait retraining may also be undertaken to minimise excessive hip extension at the end of stance phase of gait, as increased hip extension has been demonstrated to increase the loads on anterior hip joint structures.<sup>105</sup> Neuromotor control of the hip should be maximised as outlined above, and any remote factors influencing the mechanics of the hip should be addressed.

### LIGAMENTUM TERES TEARS

Ligamentum teres tears (Fig. 31.15) are commonly reported in athletes undergoing hip arthroscopy and are being reported more frequently in the literature. Studies have found up to 70% of athletes undergoing hip arthroscopy for FAI and labral tears also have tears of the ligamentum

**Figure 31.15** Coronal T2-weighted MR arthrogram of a hypertrophied, irregularly thickened, partially torn ligamentum teres that carries greater signal than a normal dark ligament (between arrows)

teres.<sup>5</sup> Tears of the ligamentum teres are classified as type I which is a partial tear, type II which is a complete rupture and type III which describes a degenerate ligament.<sup>106</sup> Ligamentum teres tears can occur in isolation, but often coexist with FAI, dysplasia and synovitis, probably due to the altered joint loads seen in these conditions.

The mechanism of injury for ligamentum teres most commonly involves forced flexion and adduction, and often internal or external rotation.<sup>106</sup> Twisting motions and hyperabduction injuries have also been reported to cause a tear to this ligament. With the likelihood of the ligamentum teres playing a large proprioceptive and stabilisation role of the hip becoming increasingly recognised, the prompt diagnosis and management of these injuries in the athlete is essential. Likewise, any surgical procedure that sacrifices the ligamentum teres through open dislocation should be carefully considered.

If suspected, the principles of management are similar to those of labral pathology, with a particular emphasis on regaining neuromotor control, excellent proprioception and avoiding positions that place the ligament under most stress using activity modification.

### SYNOVITIS

Synovitis (Fig. 31.16) is often seen in athletes with other intra-articular hip pathology, whether it is FAI, labral tears, ligamentum teres tears or chondropathy. It is rarely seen as a primary entity. Synovitis can cause considerable pain in the hip joint, with night pain and pain at rest being common presentations.

**Figure 31.16** Synovitis

Synovitis is a concern to the clinician due to the pain and associated changes in muscle activation that are seen around the hip in the presence of pain. In addition, the implications of synovial dysfunction on cytokine production, nutrition and hydration of articular cartilage, which may already show signs of chondropathy, is significant for the long-term health of the hip joint.

Management should aim to address the other coexisting pathology, restore normal neuromotor control around the hip, modify loads as well as introduce anti-inflammatory measures such as oral non-steroidal anti-inflammatory drugs (NSAIDs) or intra-articular injections. Peak synovial fluid pressure is reduced in positions of hip flexion and internal rotation, already reducing potential nutrition to chondral surfaces.<sup>26</sup> When synovitis is present, these positions should be avoided to try and optimise movement of synovial fluid through the joint.

## CHONDROPATHY

Changes to the chondral surfaces of the hip are often seen in conjunction with other hip pathologies (Fig. 31.17). It is well reported that the presence of FAI,<sup>8, 9, 13, 14, 107</sup> decreased acetabular anteversion,<sup>10</sup> labral pathology<sup>14, 18, 101</sup> and DDH<sup>9, 10, 101</sup> can increase the risk of chondropathy and ultimately OA of the hip. In patients with significant labral pathology, chondral loss is often up to 70% of the full thickness or Outerbridge grade III or IV.<sup>108</sup> It is also proposed that the presence of longstanding synovitis may also affect the nutrition of chondral surfaces, possibly exacerbating chondral damage.

The presence of chondropathy at arthroscopy is associated with worse patient-reported outcomes, up to 3 years post-operatively, especially compared to healthy controls. In addition, outcomes are unlikely to improve over time.<sup>14</sup> Patients with severe chondral

**(a)**

**(b)**

**Figure 31.17** (a) Coronal MR arthrogram showing full thickness chondral defect in the central acetabulum (b) Arthroscopic view of severe chondral damage secondary to FAI

lesions are more likely to have worse outcomes than those with mild lesions<sup>14</sup> and have a much higher risk of progressing to total hip replacement within 2 years of an arthroscopic procedure.<sup>109</sup> Outcomes for people with severe chondral lesions look similar to those reported for people with advanced hip OA,<sup>14</sup> and it is now thought that chondropathy may represent hip OA in its early stages.

The majority of chondral lesions are seen on the anterior or superior aspect of the acetabular rim, at the chondrolabral junction. This is not surprising considering

that this is also the location for the majority of cam and pincer lesions and the majority of labral tears (see above). DDH also involves a reduction in the bony coverage of the femoral head by the acetabulum, thus the anteriorly directed forces of the femoral head will be concentrated on a smaller surface area on the anterior aspect of the joint.

The clinical diagnosis of chondropathy is unlikely to be confirmed with plain radiographs because early chondral changes will not be visible, unless the disease is well advanced. MRI may identify earlier chondral lesions, although the extent of chondropathy is often only evident on hip arthroscopy.<sup>14</sup> The presence of FAI, labral tears and DDH should also increase the suspicion of chondropathy as these often coexist. Clinical tests such as FADIR, which have high sensitivity for intra-articular pathology, may increase suspicion of a chondral lesion; however, this is often only confirmed arthroscopically.

Chondropathy is difficult to manage and may be difficult to confirm in the early stages without arthroscopic confirmation. If suspected, the management again is similar to that of labral pathology, as the majority of chondral lesions of the hip occur in the anterior aspect of the acetabular rim at the chondrolabral junction. As such, this region should be unloaded in the same fashion as labral pathology, with an emphasis on regaining normal neuromotor control of the hip. Recent evidence has shown atrophy in the inferior gluteus maximus and hypertrophy in gluteus medius in early OA, with atrophy also occurring in gluteus medius in severe OA.<sup>110, 111</sup> As chondropathy is likely to represent hip OA in its early stages, aspects of treatment that have been described as being effective for hip OA should be introduced. This may include weight reduction where appropriate, lifestyle factors, general fitness programs, aquatic exercise programs and specific strengthening exercises for hip muscles.

Attempts to minimise synovitis should also be made as the synovium and synovial fluid plays an important role in articular cartilage nutrition. As outcomes of hip arthroscopy for individuals with significant chondral loss are generally worse than for those with no chondral loss and the risk of hip replacement is high,<sup>5, 109, 112-114</sup> conservative measures should be attempted first and in some cases the athlete counselled to modify the amount of weight-bearing activities they undertake.

## HIP INSTABILITY

Hip instability is increasingly being recognised as an important potential source of hip pain. Gross instability of the hip is seen in DDH and generalised hypermobility, while localised directional instability may be present in cam-type FAI (as a contra-coup lesion), ligamentum teres tears

(due to reduced proprioception), hips with large amounts of anteversion (as capsular insufficiency anteriorly) and in 'normal' hips that are subjected to extremes of range of motion, such as dancers and gymnasts. There is no good clinical or radiographic test for instability and diagnosis is usually one of clinical suspicion when extremes of range of motion, poor balance, poor control in functional tasks, observable excessive translation of the femoral head, and clicking and clunking are present. Treatment for hip instability involves restoring hip muscle strength, improving balance and functional control, modification of functional tasks to avoid extremes of range, and education regarding the risks of repeated activity in unsafe and extremes of range. Some surgeons have reported treating hip instability by arthroscopic shortening of the hip capsule, but outcomes for this procedure are unknown. In extreme cases of DDH and abnormal acetabular version, patients may consider major orthopaedic procedures such as peri-acetabular osteotomy.

## TREATMENT OF HIP IMPAIRMENTS

This section will describe the impairments associated with hip pathology and explain how to treat them. The subsequent section will then outline the application of those same principles of management to patients post hip arthroscopy.

### Principles of rehabilitation of the injured hip

Rehabilitation of the injured hip requires careful consideration of the interplay between pain and loading (including progression of exercises and activities). Importantly, due to its role in all activities of daily living, including simple activities such as sit-stand, standing and walking, it is hard to 'rest' the hip. Given this, it appears the most provocative loading for the hip occurs when rotational loads, loading at extremes of range and overload in the impingement position occur, rather than excessive amounts of walking, running or other weight-bearing activities that do not involve extremes of rotation, impingement and other end-range positions. It is vital that the patient and the clinician have a good understanding around monitoring joint loads and the loading response.

Unfortunately, there is no level I or II evidence that supports the ideal rehabilitation program or evaluates the effectiveness of particular principles of rehabilitation of the hip. However, the general principles of management of hip pathology are straightforward and are consistently reported in clinical commentaries available concerning rehabilitation of the hip.<sup>5, 18, 115-118</sup> In addition, several recent studies have detailed the physical impairments that exist in people with hip pain and pathology, around which an impairment-based rehabilitation guideline can be based.

The most commonly reported physical impairments seen in hip pain and pathology:

1. reduced hip joint range, especially flexion and internal rotation<sup>15, 119, 120</sup>
2. reduced hip muscle strength in all hip muscles, especially abductors and adductors (men and women), extensors (mostly women) and external rotators (mostly women)<sup>15, 119, 121, 122</sup>
3. reduced balance in single-leg dynamic tasks<sup>123</sup>
4. increased femoral adduction in single-leg squats
5. reduced trunk muscle strength
6. alterations in gait biomechanics (primarily reduced range of hip motion in gait)<sup>124, 125</sup>
7. reduced functional performance, especially in hopping and squatting tasks<sup>15</sup>
8. probably adverse loading within the hip due to morphology, changes in range of motion, hip muscle weakness and poor functional performance
9. abnormalities of the kinetic chain.

## Nine principles of rehabilitation for hip pain patients

### 1. Restore hip range of motion

Hip range of motion may impact on load within the hip. Hip flexion<sup>35, 127</sup> and hip extension<sup>127</sup> may increase load on the anterior<sup>103, 127</sup> and superior<sup>35</sup> regions of the hip. As most FAI lesions and associated hip pathology occur in the anterior and superior regions of the hip,<sup>41, 88</sup> loads associated with these regions of the hip require consideration. Range of motion may be limited in this group if movement at the end of range loads damaged tissue in a manner that provokes pain. Often a patient's range of motion is limited to protect damaged regions of the hip and, as such, gaining greater range of motion may also worsen symptoms. Manual techniques such as soft tissue release and needling, stretching and muscle activation may improve range, but should be done with respect to the athlete's pain during and after treatment.

B

## 2. Restore hip muscle strength

Restoration of hip muscle strength should follow these principles.

### Phase 1: Deep hip stabiliser retraining

The SHS muscles are those with the greatest capacity to provide dynamic stabilisation of the hip (see above). Retraining of these deep hip stabilisers may be undertaken in the early stages of rehabilitation. As with other pain conditions,<sup>128</sup> clinical observation indicates that pain appears to inhibit effective activation of the SHS muscles. Therefore, pain must be well controlled.

The initial step involves educating the patient in the role of the SHS muscles to provide dynamic hip stability, and the location and actions of these muscles. The second step involves facilitating independent contraction of these muscles. This is often best commenced in 4-point kneeling (Fig. 31.18a), where the patient is taught to activate the SHS muscles and then perform an isometric external rotation or adduction contraction against minimal resistance. The aim is to produce a low-level tonic hold of these muscles. In this position (90° hip flexion), the contribution from the larger external rotator (gluteus maximus) is reduced (see section on joint structure

(a)

**Figure 31.18** Deep hip stabiliser strengthening exercises  
(a) Activation of the SHS muscles in 4-point kneel with TheraBand™ resistance. The degree of difficulty can be progressed by decreasing or increasing the level of resistance, changing the speed of activation and increasing the number of repetitions. The challenge to the core can also be increased by lifting one hand off the floor in this position, and the degree of hip flexion or extension and abduction or adduction can be altered based on the needs of the athlete

(b)

**Figure 31.18 (cont.)** (b) Progression of activation of deep hip stabilisers into a closed chain position, ensuring adequate deep hip external rotators, gluteus maximus, lateral pelvic and core stability

and muscle function), thus enabling more specificity of activation for the SHS muscles.

Both the patient and the clinician must be confident that the deep hip stabilisers are activated and a real-time ultrasound (RTUS) machine may assist with providing feedback. Progression of the retraining includes providing different levels of resistance, number of repetitions and speed of movements. Other progressions include increasing the amount of hip flexion and decreasing the support (i.e. lifting one hand) to increase the balance demands and challenge to lumbopelvic stability.

Further progressions include activation of the deep hip stabilisers (Fig. 31.18b) in a variety of degrees of hip range of motion and in various functional positions as the activity of the athlete demands, and these can be assessed using an RTUS in these varying positions. For example, an athlete that performs regularly in positions of hip flexion such as a deep squat should ultimately perform muscle activation in this position.

### Phase 2: Gluteus maximus retraining

Gluteus maximus plays an important role in generating extension, adduction and external rotation torque, and has the potential to provide hip stabilisation by resisting anterior hip force.<sup>33, 35</sup> Facilitation of independent gluteus maximus contraction may be best commenced in prone (Fig. 31.19a and b), where the patient is taught to perform an isometric external rotation contraction against minimal resistance (low-level tonic hold of these muscles). As with the SHS muscles, feedback may assist in ensuring that the muscle is activated. Since the gluteus maximus is more superficial, feedback may be provided by palpation, surface electromyography biofeedback or RTUS machine.

(a)

(b)

**Figure 31.19** Gluteus maximus retraining exercises. Two examples of activation of gluteus maximus, in combination with short hip external rotator (SHER) muscles in prone. RTUS assessment can also be undertaken in this position (a) Prone—knee extension (b) Knee flexion

The activation of the gluteus maximus should be undertaken in a variety of degrees of hip range of motion as the functional demands of the athlete's activity require and can be assessed using an RTUS in these varying positions. For example, hip abduction and external rotation or hip adduction and internal rotation for an athlete who performs cutting manoeuvres, or in hip flexion for an athlete that is required to perform in a deep squatting position. It should be then progressed from open chain to closed chain and then functional positions.

### Phase 3: Generalised strengthening exercises

Generalised hip strengthening exercises should only be commenced when the patient and clinician are confident that the key stabilising muscles can be activated and the activation maintained. During this phase, the aim

is to restore muscle function (strength, endurance) and proprioception. This phase remains low impact (Fig. 31.20a). Exercises should initially be undertaken with specific activation of the deep stabilisers prior to completing the exercises. This ensures that the athlete has adequate control of the hip prior to placing it under load, which will assist in protecting vulnerable or damaged structures within the hip.

Generalised hip strengthening exercises should be undertaken, based on clinical assessment, for example targeting hip abductors (predominantly gluteus medius), for those with reduced hip abduction strength.

Strengthening exercises need to be targeted to the needs of the individual, progressed according to patient responses and targeted to the sporting/physical requirements. For example, an athlete who regularly jumps and lands such as a netballer or gymnast should incorporate these actions into their rehabilitation program (Fig. 31.20b).

Exercises are frequently commenced in prone (to ensure specificity and isolation of muscle activations) or in 4-point kneeling and then progressed into

functional/weight-bearing positions, bilaterally and then unilaterally (Fig. 31.20c-e). Such exercises also address the rehabilitation goals of balance and functional task performance.

### 3. Improve balance and proprioception

Retraining of balance can commence immediately in low-impact dynamic functional tasks and be progressed as symptoms and performance allow. It is important that during balance tasks, the athlete is reminded of correct alignment of the pelvis and femur, and to maintain activation of the SHS muscles to facilitate control.

### 4. Improve hip control in functional task performance

Reducing load on the anterior aspect of the hip joint may require assessment and treatment of movement patterns during functional tasks. Patients with chondrolabral pathology demonstrate reduced balance and increased femoral adduction during a single-leg squat.<sup>123</sup> This potentially places the hip into a position of impingement and loads vulnerable anterior structures.

(a)

(b)

**Figure 31.20** Generalised hip strengthening exercises (a) An example of low-impact functional retraining of deep hip stabilisers, ensuring adequate activation of these muscle groups in a challenging situation without excessive impact or load through vulnerable hip structures (b) A jumping and landing task ensuring adequate activation of deep hip, lateral pelvic and core stabilisers at take-off and landing

(c)

(d)

**Figure 31.20 (cont.)** (c) and (d) Two examples of later-stage functional activities with concurrent SHER muscle activation, core activation, and functional balance and proprioceptive challenges

Improving the motions of the hip (i.e. reducing hip internal rotation and adduction) and trunk lateral lean may reduce load on the anterior hip. This may be addressed through hip abductor, adductor and rotator strengthening; balance, trunk strength and movement retraining programs described previously. Increased femoral adduction during single-leg tasks will result in increased impingement and may prolong the athlete's symptoms. Adequate femoral control without excessive adduction must be gained in all balance and functional tasks.

Athletes with specific strength deficits of the trunk, hip abductors and hip adductors should address these in targeted strength programs as well as in functional and balance retraining. Adequate control of the femur during single-leg tasks is essential before an athlete can return to sport (see box), especially when fatigued. This can be achieved using specific motor-control training of

functional tasks as well as training to address strength-endurance to prevent fatigue-related loss of control.

### 5. Improve trunk muscle strength

Trunk muscle strength is an important target for athletes with hip pain, given that it is impaired in people with hip pathology, and when reduced, increases acetabular retroversion and impingement. Principles of exercise prescription to optimise spinal stiffness and mobility are given in Chapter 11. When the patient performs trunk exercises, the clinician should ensure the exercises are pain free and the hip is not placed in positions of impingement. The patient should avoid over-using secondary trunk muscles such as iliopsoas, as this may increase impingement and hip pain. Exercises such as sit-ups, where the hip flexors are commonly used, may exacerbate these symptoms and should be avoided.

(e)

**Figure 31.20 (cont.)** (e) Example of a later-stage functional exercise incorporating deep hip and core stability with proprioceptive and neuromotor control retraining

## 6. Optimise gait biomechanics

Specific activities to normalise gait biomechanics and improve gait performance and endurance are outlined in Chapter 8 and should be progressed in a structured, graduated fashion. It should also include running, direction

change and cutting manoeuvres specific to the athlete's functional demands. If required, it should also include stairs and hill training (up and down). Generally, patients with hip pain have a reduced step length to avoid increased joint loading seen at end-range hip extension. Any modification to gait should not increase the athlete's hip pain.

## 7. Optimise functional task performance

Once good neuromotor control of the deep hip stabilisers and global hip muscles has been regained, functional and sports-specific activities should be assessed and then undertaken, both to retrain these movement patterns, but also ensure the athlete can cope with these activities without failing.

Any retraining of functional activities should focus on pre-activation of the deep hip stabilisers, adequate control of the lumbar spine and pelvis during the activity, and correct alignment of the femur during weight-bearing tasks (Fig. 31.21).

Retraining of hip stabilisers should be performed in the positions that place the hip at greatest risk of overload, such as direction change and pivoting, deep squatting and kicking. They should also be undertaken in a repeated fashion, again to ensure the athlete does not fail in a controlled environment.

## 8. Address adverse loading

The most effective way to unload and protect specific structures of the hip varies slightly for different pathologies, based on our understanding of the functional anatomy and biomechanics of the hip. When addressing the loads on structures outlined below, the principles of management of neuromotor control and remote factors should also be applied. Managing the load on the hip can be particularly difficult as the athlete may need to increase provocative loads on the hip in daily tasks. Thus it is vital that the ability to climb stairs, squat, put on shoes and perform

**Figure 31.21** Retraining of functional activities—single-leg hop for distance

### Criteria for returning to sport as the final stage of hip rehabilitation

The decision regarding a patient's readiness to return to sport is made using clinical judgment of the individual's functional capacity. In the absence of robust scientific evidence, the following criteria are suggested:

- performance on the one-leg hop test (or other single-leg functional tests) at least 90% of the uninjured side (if unilateral symptoms)

- performance on strength tests at least 90% of the uninjured side (if unilateral symptoms)
- performance of functional tasks and sporting activity that does not reproduce hip pain, and that the athlete has adequate control of the hip to avoid impingement, even under conditions of fatigue.

B

everyday activities such as getting in and out of a chair is undertaken in such a way that these activities do not aggravate the underlying pathology.

### 9. Address other remote factors that may be altering the function of the kinetic chain

As outlined previously, a number of remote factors (e.g. lumbopelvic control, ankle dorsi-flexion range) are likely to influence the rehabilitation of hip pain and pathology. Therefore, all potential contributing factors should be addressed and treated appropriately.

### Surgical management of the injured hip

Hip arthroscopy is now commonly performed to manage intra-articular hip pathologies, including FAI, labral tears, chondropathy and ligamentum teres tears.<sup>129</sup> Hip arthroscopy has revolutionised hip surgery, since this minimally invasive procedure is associated with considerably less morbidity than open procedures. Internationally, the number of hip arthroscopy procedures now performed is growing rapidly. In the USA, the number of hip arthroscopies has increased 18-fold in the past decade<sup>41</sup> and in Australia it has doubled in recent years. Hip arthroscopy is a technically challenging orthopaedic procedure and should only be undertaken by high-volume, fellowship-trained surgeons.

Clinically, patients presenting for hip arthroscopy surgery tend to be grouped into two categories—those diagnosed with morphological variations, with or without soft tissue injuries, requiring surgical intervention, and those not requiring bony intervention but presenting with soft tissue injuries requiring intervention.

The first group includes patients with FAI, which may be cam, pincer or mixed impingement. This group may also have coexisting labral pathology, ligamentum teres pathology or chondral lesions.

The second group includes those with soft tissue pathologies, but without morphological change requiring surgical intervention. This group may include labral pathology, ligamentum teres pathology, chondral lesions or

any combination of these. They may have coexisting issues such as dysplasia or hypermobility, which predispose them to such injuries, but do not themselves require surgical intervention. This group may also include patients with essentially normal morphology, but who undergo a massive single episode of excessive range (usually rotation), which causes trauma to the associated soft tissues.

The body of evidence examining outcomes following hip arthroscopy is growing rapidly. Systematic review evidence shows that patients without chondropathy have favourable outcomes for up to 10 years (no osteoplasty) and 3 years (with osteoplasty).<sup>129</sup> Patients with chondropathy have worse outcomes than those without, especially when chondral damage is severe, and risk progressing to total hip replacement within 2 years.<sup>109</sup> Prior to surgery, it is important that patients trial the conservative treatments outlined above. There are still no known published randomised controlled trials examining the effectiveness of hip arthroscopy, although these studies are underway internationally and will provide definitive evidence of the efficacy of hip arthroscopy for subgroups of patients with intra-articular hip pathology in the coming years. The majority of the literature focuses on outcomes following surgery for FAI, labral pathology, chondropathy or combined pathology, and is level III and IV evidence.

### Rehabilitation following hip arthroscopy

Rehabilitation following hip arthroscopy has been described in the literature in a number of clinical commentaries and a systematic review.<sup>115, 117, 130, 131</sup> Rehabilitation programs essentially follow the same conservative principles of management outlined above. The individual pathology treated during hip arthroscopy should influence the post-operative rehabilitation program to ensure it is adequately unloaded and protected whilst healing. This generally involves a period of partial weight-bearing as tolerated on crutches until a pain-free normal gait pattern is achieved.

Generally osteoplasties performed for the correction of FAI must be protected for at least 6 weeks, while

microfracture surgery performed for chondral defects may be protected through non and partial weight-bearing for at least 3 months.

Labral debridement and repairs should be protected for at least 6 weeks, ensuring the athlete avoids potential positions of impingement through activity modification and normalisation of neuromuscular control around the hip.

Injuries to the ligamentum teres should be protected for at least 6 weeks by avoiding end-range positions that place the ligament under stress, and ensuring excellent neuromotor and proprioceptive control around the hip.

During this initial protective phase, the athlete should commence active rehabilitation of the deep hip stabilisers, initially in an isolated fashion and then progressing into functional activity in a safe manner. The therapist should also address any overactivity of the secondary stabilisers such as the long adductors, the proximal gluteals, the tensor fasciae latae and the hip flexors in this period.

Once this protective phase is complete, the athlete should undertake a dynamic rehabilitation program ensuring full strength of all muscle groups around the hip, and normal function of the whole kinetic chain and sports-specific activity. A full assessment of the muscle strength and function around the hip using RTUS and hand-held dynamometry at this time can also assist in providing targeted exercise programs to address any ongoing residual deficits in strength or muscle activation. Generally, most athletes return to full sport between 3 and 5 months postoperatively following hip arthroscopy, although this will vary depending on the level and type of sport played, as well as the specific pathology and surgery performed.

## LATERAL HIP PAIN

with ALISON GRIMALDI

Lateral hip pain signals very different pathologies to the medial or anterior hip region pain the chapter has focused on so far. It is a common presentation particularly among distance runners and women over the age of 40. Local soft tissue pathology may mimic or coexist with hip joint and lumbar spine pathologies so a full differential diagnosis as described earlier in this chapter will be required. Hallmarks of a local pathology include specific areas of pain and tenderness either at the greater trochanter or iliac crest.

### Greater trochanteric pain

Patients with trochanteric pain complain of pain and significant tenderness over the greater trochanter, particularly lying on their side at night. The pain may radiate from the greater trochanter, most commonly down the lateral aspect of the thigh to the knee, and occasionally extending into the upper lateral leg along the line of the ITB. Tasks that involve a single-leg weight-bearing phase such as standing on one leg to dress, ascending stairs or

hills and particularly those involving higher eccentric loads or a stretch-shortening cycle, such as running, bounding or hopping, are usually reported as provocative.

Traditionally the primary local source of trochanteric pain was thought to be the trochanteric bursa; however, there are a number of soft tissue structures at the greater trochanter that have nociceptive capacity. Less common findings include thickening of one or more of the three associated bursae and the region of the ITB crossing the greater trochanter.<sup>132-134</sup>

### PRACTICE PEARL

Imaging studies have demonstrated that soft tissue pathology in this patient population most commonly presents in the gluteus medius and/or minimus tendons.

The same pathological mechanism is likely to underlie all of these local soft tissue changes, and therefore the relative local contributions to nociception may be less pertinent in early conservative management than attending to the underlying issues. While medical comorbidities may compromise tendon function and load-bearing status,<sup>135-137</sup> mechanical loading is a potent driver of biological processes responsible for soft tissue structure and health.<sup>138, 139</sup>

### Relevant anatomy

Mechanical load within the local soft tissues will be influenced by the relative anatomical relationship between these tissues and the underlying bony greater trochanter in different postures and dynamic function. As the gluteus medius and minimus tendons wrap around the greater trochanter on their course to their insertion sites, they are separated from the underlying bone by their relevant bursae (subgluteus medius and subgluteus minimus bursae) (see Fig. 31.5 for general anatomy of this region).

The trochanteric bursa, often now referred to as the subgluteus maximus bursa, sits superficial to these tendons and beneath the thick, fibrous ITB. This relationship is illustrated in Figure 31.22. Mechanical load may be applied longitudinally (tensile load) or transversely (compressive load) across the tissues. Excessive compressive load is an important aetiological factor in the development of insertional tendinopathies,<sup>140, 141</sup> engendering changes within the soft tissues that may ameliorate compression but subsequently reduce tensile loading capacity.

### Role of compression in pathology

The gluteal tendons and bursae may become compressed between the underlying greater trochanter and overlying ITB, while the ITB itself may also be exposed to compression against the greater trochanter. Compression increases tenocyte production of larger

## PRACTICE PEARL

Compressive loading of the trochanteric soft tissues may be accumulated during static postures such as standing 'hanging on one hip' in adduction, sitting with knees crossed or together, or during dynamic functional tasks completed with excessive lateral pelvic tilt or shift.

proteoglycan molecules (aggrecan and versican)<sup>142</sup> that bind water within the tendon resulting in a thicker tendon more resistant to compression. There may also be a shift within a compressed tendon to cartilage-like cells, which are particularly robust for compressive loading. Thickening of the associated bursae and the ITB are also likely to represent a response to excessive compression. Unfortunately this seemingly successful adaptation to compression results in reduced tensile loading capacity of a tendon due to concurrent disorganisation and enzymatic resorption of large type 1 collagen fibres.<sup>143</sup>

Tendons that have adapted to compression may then fail at lower tensile strain rates.<sup>141</sup> Consistent with this scenario, gluteal tendons in those with lateral hip pain have been shown to be either thicker than normal (likely in the earlier adaptive stage), or attenuated and thinner with partial or full thickness tearing (later stage when the compromised collagen fibres yield under tensile loads).<sup>132, 72</sup>

Compressive loading of the lateral soft tissues is strongly influenced by hip joint position and particularly by hip adduction. Birnbaum and colleagues determined that, as the hip moves from neutral adduction, where the ITB exerts 4 N of compressive load on the greater trochanter and

intervening tissues, loads rise nine-fold by 10° of adduction and over 25-fold by end-range, 40° adduction.<sup>144</sup> Running with a midline or cross-midline striking pattern, on the camber of a road or the same direction around a track, may increase the risk of developing lateral hip pain,<sup>145, 146</sup> perhaps due to the cumulative loading stimulus.

### Iliac crest pain

Lateral hip pain may also emanate from soft tissue sources at the iliac crest, with local pain and tenderness over the region of origin of the TFL and ITB and adjacent fascia, with pain radiating most commonly over the anterolateral hip towards the greater trochanter. In such patients, thickening, increased water content and partial tearing have been noted on MRI in the TFL tendon of origin, the proximal ITB and the gluteal aponeurotic fascia that covers the gluteus medius, all of which anchor along the iliac crest.<sup>134, 147, 148</sup> While an in vivo study such as Birnbaum et al.'s<sup>144</sup> has not been replicated at the iliac crest, it is reasonable to conceive that, as the hip moves into adduction, the ITB and the gluteal aponeurotic fascia will also wind firmly around the iliac crest, with the iliac tubercle providing the most prominent bony cam region. In running athletes, this condition is an overuse injury with reports of gradual onset worsening with activity over a number of months.<sup>134, 148</sup> The clinician should be aware of the same issues as for greater trochanteric pain—assessing and controlling exposure to hip adduction during static postures and functional loading.

### Examination of the patient with lateral hip pain

Distinct tenderness on direct palpation over the greater trochanter or iliac tubercle is a key finding that determines

**Figure 31.22** Adaptation of soft tissue of the greater trochanter to compressive loading. Structural changes include production of larger proteoglycans, a hydrophilic gel matrix, increased water content and a shift to cartilage-like cells

whether lateral hip pain is originating from a local soft tissue source. A lack of local tenderness would strongly indicate that other more remote conditions should be considered. However, tenderness alone is not sufficient for a firm diagnosis. Lumbar screening and a full hip joint assessment, as described in the preceding physical examination section, should be undertaken. Range of motion tests are usually unremarkable, helping to differentiate from primary hip joint pathology. Similarly, the FABER test is usually not significantly limited in range, but reproduction of lateral hip pain on this test, in the absence of difficulty manipulating shoes and socks (which is usually associated with limited FABER), has been shown to be useful in differentiating local greater trochanteric pain from hip OA.<sup>149</sup>

Despite the anecdotal assumption that those with lateral hip pain have tightness in the lateral soft tissues of the hip and thigh, particularly the ITB, the adduction range on the Ober's or Modified Ober's test is not correlated with the presence of gluteal tendon pathology.<sup>150</sup> About 25% of participants were positive for local pain at the greater trochanter during the Ober's test.<sup>150</sup> This may reflect the potentially provocative action of compressing the soft tissues between the greater trochanter and the ITB. This adducted position will also wrap the proximal ITB and TFL tendon around the iliac tubercle and therefore may be clinically useful as part of a test battery. Diagnostic utility of the Ober's test for proximal ITB/TFL pathology is currently unknown, as no clinical tests apart from palpation have been described or analysed for such conditions.

Passive compressive tests may become more valuable with the addition of an active tensile load. Isometric abduction tests have, however, only been described to date from a hip-neutral or abducted position. While abductor muscle weakness is common in those with lateral hip pain and is important to assess, the diagnostic usefulness of such tests is limited by the fact that patients with no lateral hip pain or other conditions also commonly present with hip abductor muscle weakness.<sup>150</sup> Pain reproduction on resisted hip abduction showed some weak diagnostic properties.<sup>150</sup> Further research is required to assess whether isometric abduction performed in an adducted hip posture may be more useful in differential diagnosis of lateral hip pain.

In a meta-analysis of diagnostic accuracy of clinical hip tests, the only test to show a strong ability to influence the likelihood of a positive diagnosis of gluteal tendinopathy was the resisted external rotation de-rotation test (Fig 31.6f).<sup>40</sup> The test winds the ITB and fasciae latae over the greater trochanter in hip flexion and external rotation, and then superimposes an active contraction of the gluteus medius and minimus via resisted internal rotation, combining compressive and tensile loads across the greater trochanter. Adding hip adduction will further increase compressive load and therefore may be useful as a test variation.

(a)

(b)

**Figure 31.23** MRI appearances of gluteus medius abnormalities (a) Coronal fat-suppressed T2 image showing tendinopathy of the gluteus medius tendon near its greater trochanteric insertion (b) Fat-suppressed T1 image showing partial tear of the gluteus medius tendon (arrows)

Functional movement tests are employed to highlight functional deficits and may provide helpful treatment direction. These tests generally do not perform well as diagnostic tests as dysfunction around the hip and pelvis is common to many lower quadrant disorders. One exception may be the 30-second sustained single-leg stance test as described by Lequesne et al.<sup>48</sup> When performed as a pain provocation test, rather than a traditional Trendelenburg test, reproduction of pain over the greater trochanter

within 30 seconds of standing on one leg was shown to have good sensitivity and specificity for the detection of gluteal tendinopathy.

Diagnostic ultrasound can be performed to determine if thickening is present in the bursae or ITB or to look for thickening, thinning or hypoechoic changes that are consistent with tendinopathy and tears.<sup>72, 132, 133</sup> MRI is the gold standard for assessing tendinosis and tears of the gluteus medius and minimus tendons (Fig. 31.23).<sup>151, 152</sup> While imaging studies are useful as an adjunct to clinical assessment where the diagnosis is unclear or the patient is failing to respond to treatment, they should not be used as a stand-alone medium for determining the source of lateral hip pain. This is due to the high prevalence of soft tissue abnormalities in this region that may occur in the absence of lateral hip pain.<sup>152</sup>

### Treatment of the patient with lateral hip pain

The principles of treating lateral hip pain are consistent with other insertional tendinopathies. First, manage the pain by controlling soft tissue loads at the greater trochanter or iliac crest. Introduce graduated strengthening of the involved musculotendinous complex, aiming to improve load tolerance and optimise abnormal movement patterns. Return to sport is closely monitored to ensure volume of tendon load is controlled, time for adaptation is allowed and recurrence is avoided.

### Managing pain

Managing pain will primarily involve removing or minimising potentially provocative loads and instituting pain-relieving loading techniques. Reduction of compressive loading will require minimisation of sustained, repetitive or loaded end-range adduction. Positional habits such as sitting with knees crossed or together or standing 'hanging on one hip' in adduction should be discouraged. Sleeping postures should also be addressed, educating the patient to sleep in supine, quarter from prone or, if side-lying is unavoidable, to use pillows between the legs to reduce adduction of the uppermost side. An eggshell overlay for the lowermost side is recommended.

ITB and gluteal stretches involving hip adduction should be avoided. Provocative physical activities should be suspended or modified, such as long-distance, high-speed and hill running or, for the more severe presentation, all running may need to be temporarily suspended. Runners should stay on the flat or run in straight lines rather than on a camber or around a track; plyometric drills such as jumping, bounding and hopping particularly using stairs or boxes should be avoided.

While corticosteroid injection may reduce pain in the short term via interactions with local neuropeptides and

neurotransmitters,<sup>153, 154</sup> the effect is not long lasting. It fails to address the underlying pathoetiological issues and may even hinder a tendon's capacity to respond appropriately to loading (see Chapter 17) via the down-regulation of fibroblastic production of collagen.<sup>155, 156</sup>

Shock wave therapy reduces lateral hip pain.<sup>154, 157</sup> However, it is recommended that shock wave therapy is reserved for those who fail a load management and exercise approach.<sup>158, 159</sup>

### Managing load: First line treatment

Exercise for the hip abductor musculature begins with isometric abduction in neutral or slight hip abduction to minimise compression. This may be completed in side-lying (affected side up with pillows between legs) (Fig. 31.24a), supine with a belt around the lower thighs or standing (Fig. 31.24b). The patient should *slowly* ramp up the contraction to a 25% maximum voluntary isometric contraction level initially, which allows time for a good gluteus minimus and medius recruitment, and avoids dominance of the TFL. The level of force development may be increased if well tolerated and early and dominant gluteal contraction is achieved. The primary aim at this point is pain relief, provided by isometric exercise via activation of segmental and/or extra-segmental descending pain inhibitory mechanisms,<sup>160, 161</sup> and now recommended in the early management of lower limb tendon pain.<sup>162, 163</sup>

The strengthening phase includes exercises that directly target the hip abductors and functional loading tasks with a focus on strict control of hip adduction through graduated levels of difficulty (Fig. 31.25). Spring-resisted sliding platforms such as Pilates reformers provide frontal plane weight-bearing resistance with applied load easily titrated and progressed.

#### PRACTICE PEARL

Side-lying 'clams' (hip abduction/external rotation–hip adduction/internal rotation) are generally provocative, possibly due to the compression and friction that the ITB imparts on the soft tissues as it passes over the greater trochanter; they should therefore be avoided.

Bridging (Fig. 31.26) and functional strengthening progressions (Fig. 31.27) begin with bilateral loading, progressing to offset and then single-leg tasks, allowing hand support where necessary to optimise pelvic control and minimise hip adduction and therefore compression, which is the first priority.

Athletes can then progress to more complex sports-specific tasks, as described in the management of hip joint

(c)

(d)

(e)

**Figure 31.27 (cont.)** (d) Step up (e) Landing training—requires control of pelvic and femoral alignment during a dynamic landing task

pathologies earlier in this chapter. For running athletes, visual biofeedback and increases in cadence have been shown to be effective in reducing peak hip adduction.<sup>164</sup> Increasing cadence by 10% enhanced pre-activation of gluteus medius prior to stance phase and improves in lateral pelvic control during the subsequent stance phase.<sup>165</sup> As stretching into adduction is to be avoided, athletes may require massage, needling or home use of a trigger ball or vibratory hand-held massager to control

muscle soreness or tightness arising secondary to the loading program.

For those who fail conservative management, usually older non-athletic individuals, there are surgical options that include ITB release around the greater trochanter  $\pm$  bursectomy and tendon repair as required.<sup>166-169</sup> While outcomes are generally reported as good to excellent, athletes are much less likely to progress to a surgical intervention.

# Groin pain

with ADAM WEIR, PER HÖLMICH and KRISTIAN THORBORG

*Soccer was my first love, and I enjoyed playing on the left wing until a groin injury forced me out of the game in 2008.*

Chad le Clos, South African swimming gold medallist

This chapter discusses both acute and longstanding groin injuries in athletes. It covers the anatomy where the complexity and degree of interconnections is highlighted. Epidemiology and risk factors have been updated using systematic reviews. The 2015 Doha agreement meeting on terminology and definitions in groin pain in athletes is included and the chapter follows the terminology agreed upon during this expert meeting. Clinical examination and assessment is covered including a practical guideline for systematic assessment of an injured athlete. There is a new section on imaging highlighting the lack of evidence in this area. Treatment with specific sections on adductor, iliopsoas, inguinal and pubic-related groin pain as well as acute groin injuries is covered with suggestions for rehabilitation.

## ANATOMY

The word groin most likely originates from the ancient English word *grynde* which meant abyss or void. Confusion surrounding the groin region has made clinicians refer to this region as the 'Bermuda triangle' of the body.<sup>1</sup> In this section, we explain and simplify the complex anatomy of the groin. The groin region, where the abdomen meets the lower limbs via the pelvis, contains not only musculoskeletal structures, but also important internal organs and urogenital structures. In this section we focus on the musculoskeletal anatomy of the groin. The anatomy of the hip joint is described in Chapter 31.

We will focus on the pubic symphysis, hip adductors, hip flexors, abdominals and the inguinal region. An overview of the anatomy is depicted in Figure 32.1a.

## Pubic symphysis

The pubic symphysis is a secondary cartilaginous joint connecting the two pubic rami. It is supported superiorly by ligaments and inferiorly by the superior pubic ligament and the inferior or arcuate pubic ligament respectively.<sup>2</sup> The joint is lined with hyaline cartilage. A fibrocartilaginous disc separates the two pubic bones. The pubic symphysis is the site of numerous musculotendinous attachments, which act to dynamically stabilise the anterior pelvis and the transference of large

(a)

**Figure 32.1 (cont.)** (b) Anatomy of the aponeurosis on the anterior side of the pubic symphysis (c) Anatomy of distal iliopsoas tendon

forces acting across this joint, especially during specific sporting activities such as kicking and cutting.

### Hip adductors

The hip adductors include pectineus, gracilis and adductor longus, brevis and magnus. The adductors are

(d)

**Figure 32.1 (cont.)** (d) Anatomy of the muscles in the inguinal region

the most commonly injured groin muscle in soccer<sup>3, 4</sup> and the adductor longus is the most commonly injured adductor muscle.<sup>5</sup> It inserts at the middle one-third of the linea aspera of the femur and has an interesting proximal origin. The origin is predominantly muscular (around 60%). The anterior tendinous portion continues across the front of the symphysis to fuse with the distal rectus and external oblique forming an aponeurosis.<sup>6</sup> This aponeurosis has fibres that insert from the adductors and rectus directly into the pubic symphysis joint capsule and disc.<sup>2</sup> The adductor longus not only acts as an adductor but also as an important hip flexor when the hip is in an extended position, and therefore is also highly involved in kicking.<sup>7</sup>

The anatomy of the aponeurosis on the anterior side of the pubic symphysis is shown in Figure 32.1b.

### Hip flexors

The iliopsoas is the primary hip flexor but rectus femoris, sartorius, tensor fascia lata and a number of hip adductors also contribute to hip flexion. The iliopsoas is made up of the iliacus, which originates from the iliac fossa in the pelvis and the psoas muscle.<sup>8</sup> The psoas arises from the vertebral bodies of T12 and L1-5 and the intervertebral discs. The two muscles converge distally to form the iliopsoas. Although the tendon is often depicted as a common tendon, the lateral portion of the iliacus extends distally to insert directly onto the femur and at the level of the hip joint there are distinct tendons.<sup>8</sup>

The distal iliopsoas tendon anatomy is shown in Figure 32.1c.

## Inguinal region

The anatomy of the inguinal canal is complex and extensively described in detail in classic anatomical texts. The abdominal muscles—transversus abdominis, internal and external obliques and the rectus abdominis—are all intimately related in this region. The inguinal ligament is formed by a distal shelving of the external oblique and the conjoined tendon from a convergence of transversus abdominis and the internal oblique at the medial ends. The conjoined tendon also inserts into the lateral rectus sheath.<sup>9</sup>

The anatomy of the muscles in the inguinal region is shown in Figure 32.1d.

## Summary of anatomy

The anatomy of the groin has clinical implications as it demonstrates a high degree of confluence of the muscle, tendon, bone and joint structures. This connectivity means that pain provocation or stress tests do not load a single anatomical structure in isolation. This may explain why patients who present with groin pain often have diffuse, poorly localised pain and multiple clinical findings.

## EPIDEMIOLOGY

Groin pain and injury is common with sports that involve kicking, rapid acceleration and deceleration, and sudden change of direction.<sup>10, 11</sup> Until recently, there was no agreement on terminology, definitions or classification of groin pain in athletes.<sup>12</sup> This makes comparing epidemiological studies difficult for two main reasons. Firstly, multiple injury definitions and classifications systems have been used; some combined hip and groin, some classify groin separately, and almost all use different terminology for various groin injuries, which are often not specifically described.<sup>13</sup> Additionally, the nature of injury onset is often poorly reported (e.g. acute versus chronic; traumatic versus overuse).

The second difficulty is that groin injury is often only recorded when an athlete misses a training session or match. Therefore, the prevalence of groin injury may be underestimated as those athletes who continue to train and play through injury often are not recorded.

## Incidence—soccer

A recent systematic review on the incidence of groin pain in soccer included 34 articles.<sup>14</sup> In general, there was risk of bias in the studies due to participant selection (18 studies), exposure (17 studies) and precision of the estimates given (18 studies).

The main findings of the review were:

- groin injuries in male club soccer accounted for 4–19% of all injuries
- groin injuries in female club soccer accounted for 2–14% of all injuries

- analysis of 29 studies found a higher proportion of groin injuries in men (12.8%) than women (6.9% with an absolute difference of 5.9%, 95% with a confidence interval of 4.6–7.1%)
- groin injury rates in males were 0.2–2.1/1000 hours and 0.1–0.6/1000 hours in women (rate ratio 2.4, 95% with a confidence interval of 2.0–2.9).

In adductor-related injuries in elite male soccer the re-injury rate has been reported to be 15%.<sup>3</sup> The recovery period for a re-injury in elite soccer players is almost twice as long compared to the original injury emphasising the importance of avoiding re-injury by finishing treatment properly the first time.<sup>3</sup>

## Incidence—elite sports other than soccer

A recent review identified 31 papers where more than 10 team seasons of groin or groin region injury incidence were reported.<sup>11</sup> These studies used varying injury definitions and also considered varying injury categories from general to specific (all groin/hip region injuries, groin injuries, adductor muscle strains, intra-articular hip injuries). The main findings were as follows.

- When playing the same sport, males had greater injury incidence of groin injury than females (RR 2.45, 95% with a confidence interval of 2.06–2.92).
- The sports with a high rate of groin injury were ice hockey and the football codes where field kicking is common (Australian rules football, Gaelic football).
- Within the football codes, player positions involving more kicking had a higher incidence.
- Uniform injury classification and definitions would improve comparison of results across studies.

## Prevalence

As mentioned previously, using only time loss or medical attention definitions to count athletes as being injured probably misses many less-severe injuries. The injuries leading to time loss are thought to represent the tip of the iceberg. A study on football players showed that 49% had experienced groin pain in the previous season and that this had lasted longer than 6 weeks in 31%.<sup>15</sup>

## Distribution of acute injuries

Few studies have closely examined which proportion of groin injuries has an acute onset. In a Danish study of 998 soccer players it was found that on the 58 injuries registered, 20 had acute onset, 31 were classified as overuse and 7 could not be classified.<sup>4</sup> This would suggest that acute onset injuries represent a significant proportion of the total injuries in soccer players. Defined terminology using specific classification systems for

injury distribution have not been used in many studies. The study of 998 soccer players used a terminology and classification system almost identical to the one we use in this chapter (see section below) to classify the 58 injuries.<sup>4</sup> Of the 58 injuries, 16 (27%) could not be classified and 24% had multiple entities. Adductor-related groin pain was the most frequent injury (51%) with iliopsoas (30%) and abdominal (19%) also being diagnosed frequently.

A recent study examined acute onset groin injuries in 110 athletes presenting to a sports medicine hospital within 7 days of injury.<sup>5</sup> The majority (76%) were football code players with 10% basketball and 8% handball players. In the football codes 40% of the injuries occurred during kicking, where change of direction was the most frequent activity (31%) during onset in other sports. Clinical examination and imaging (MRI or ultrasound) were performed in all 110 athletes. The majority of injuries affected the adductors (66%), with iliopsoas (17–25%) and rectus femoris (15–23%) injuries also being frequent.

Other case series have examined the distribution of groin pain in those presenting to different clinicians in multiple countries. These series found adductor-related groin pain,<sup>16</sup> inguinal-related groin pain<sup>17</sup> and hip-related groin pain<sup>18</sup> to be the most common problems. As these studies all suffer from referral bias, they are less helpful than studies where a single cohort is followed over time. They do, however, all report multiple problems occurring in a significant number of those who present.

#### PRACTICE PEARL

Adductor-related groin pain is the most common groin injury in the football codes and ice hockey.

### RISK FACTORS

A lack of agreement on definitions and terminology of groin pain and the various definitions of when injury is present make the literature on risk factors challenging to understand. A previous comprehensive review<sup>19</sup> was updated in 2015.<sup>20</sup> This systematic review covered 29 studies and summarised literature with a levels-of-evidence approach. The majority of studies were prospective cohort studies. The review found that there was level 1 and 2 evidence that the following are associated with an increased risk of groin injury in athletes:

- previous groin injury (level 1)
- higher level of play (level 1)
- reduced hip adduction (absolute and relative to abduction) strength (level 2)
- lower levels of sport-specific training (level 2).

Whittaker et al. also highlighted that to date there has been virtually no investigation of the relationship between exposure/athletic load and risk. Future studies should be large enough to ensure around 50 injury cases to examine for moderate to strong associations and include clear injury definitions.<sup>20</sup>

Where risk factor studies should ideally be prospective in design, cross-sectional and case control studies allow multiple factors to be examined in smaller populations. While no prospective relationship can be determined, these factors can be considered in future studies on risk factors, investigations and treatment. A systematic review with a meta-analysis examining these cross-sectional factors differentiating athletes with and without groin pain was carried out in 2015.<sup>21</sup> Seventeen cross-sectional studies were included, of which 10 were high quality. In total, 62 different measures were investigated. Eight studies were suitable for meta-analysis. Meta-analysis showed that athletes with hip and groin pain had:

- pain and lower strength on adductor squeeze test
- reduced hip internal rotation and bent knee fall out, but that hip external rotation was the same as controls.

For other factors, a levels-of-evidence synthesis was performed. There was strong evidence that athletes with hip and groin pain have an association with:

- lower patient-reported outcome (PROM) scores
- altered trunk muscle function.

### TERMINOLOGY AND DEFINITIONS

A systematic review on the treatment of groin pain in athletes included 72 studies, in which 33 different diagnostic terms were used.<sup>13</sup> The 'Doha agreement meeting on terminology and definitions in groin pain in athletes' was convened to attempt to resolve this problem.<sup>22</sup> The aim was to agree on a standard terminology, along with accompanying definitions. A Delphi process was used to inform agreement. Unanimous agreement on the following terms and definitions was reached. Some considerations are presented here as a preamble to the terms.

#### PRACTICE PEARL

The preferred umbrella term was 'groin pain in athletes'. This was favoured over others (e.g. athletic pubalgia, athletic groin pain, sports groin pain, athletes' groin) because it is clearly descriptive and cannot be misunderstood to be a diagnostic term.

A number of previously popular terms were considered and rejected during the meeting. The terms that the group chose not to recommend were: adductor and

iliopsoas tendinitis or tendinopathy, athletic groin pain, athletic pubalgia, biomechanical groin overload, Gilmore's groin, groin disruption, hockey-goalie syndrome, hockey groin, osteitis pubis, sports groin, sportsman's groin, sports hernia and sportsman's hernia. The term 'entity' was chosen to reflect the recognisable pattern of symptoms and signs exhibited by the athlete.

To ensure generalisability and straightforward use in everyday practice, a clinically based classification system is recommended. This means that a thorough history and physical examination are essential. In the history, in all cases the athlete should report pain in the affected region that worsens on exercise. Palpation is important to identify the painful structures and must be precise, as numerous structures in the groin region are in close proximity and can refer pain to overlapping areas. The term 'tenderness' is defined in this system as discomfort or pain when the area is touched and that the athlete recognises this to be their specific injury pain.

Pain on resistance testing should also be felt in the affected structure. For example, in adductor-related groin pain, the pain on resisted adduction testing should reproduce the athlete's recognisable pain in the adductors. Pain felt in a different location (e.g. the inguinal region on resisted adduction testing) would not signify adductor-related groin pain. The techniques of physical examination are covered in the 'Clinical overview' section.

## Classification

### Acute groin injuries

Acute injuries refer to the manner in which the athlete first felt the pain (i.e. sudden onset). In general, the system proposed in this section could potentially be used to classify the majority of acute groin injuries into entities. There is far less literature on acute groin injuries when compared to longstanding groin pain.

Consequently, a careful history—along with examination comprising palpation, resistance testing and stretching—is critical. In cases with severe pain, it may be hard to perform a thorough physical examination. It should be recognised that some acute groin injuries such as proximal rectus femoris injuries do not readily fit into the current Doha classification system. Further work will be needed to refine this system to fully encompass the entire spectrum of acute groin injuries.

### Longstanding groin pain

The exact duration considered to be longstanding is not further defined. Longstanding groin pain can start either gradually or suddenly and does not refer to the mechanism of onset, but only to the duration of symptoms.

The classification system has three major subheadings of groin pain in athletes.

#### 1. Defined clinical entities for groin pain:

- adductor related
- iliopsoas related
- inguinal related
- pubic related.

The locations of the four entities for groin pain are shown in Figure 32.2.

#### 2. Hip-related groin pain. Pain from the hip joint (Chapter 31) should always be considered as a possible cause of groin pain.

#### 3. Other conditions causing groin pain in athletes. Besides the defined clinical entities and the hip, there are many other possible causes for groin pain in athletes. A high index of clinical suspicion is needed to identify these and clinicians need to be alert to the possibilities, especially when the complaints cannot easily be classified into one of the common defined

**Figure 32.2** Defined clinical entities for groin pain

REPRODUCED WITH PERMISSION OF BRITISH JOURNAL OF SPORTS MEDICINE

**Table 32.1 Overview of some possible causes of groin pain in athletes**

Entities defined during Doha agreement meeting	Other musculoskeletal causes	Not to be missed
Adductor-related groin pain	Inguinal or femoral hernia	Stress fracture
Iliopsoas-related groin pain	Post-hernioplasty pain	– neck of femur
Inguinal-related groin pain	Nerve entrapment:	– pubic ramus
Pubic-related groin pain	– obturator	– acetabulum
Hip-related groin pain	– ilioinguinal	Hip joint
	– genitofemoral	– slipped capital femoral epiphysis (adolescents)
	– iliohypogastric	– Perthes' disease (children and adolescents)
	Referred pain	– avascular necrosis /transient osteoporosis of the head of the femur
	– lumbar spine	– arthritis of the hip joint (reactive or infectious)
	– sacroiliac joint	Inguinal lymphadenopathy
	Apophysitis or avulsion fracture	Intra-abdominal abnormality
	– anterior superior iliac spine	– prostatitis
	– anterior inferior iliac spine	– urinary tract infections
	– pubic bone	– kidney stone
		– appendicitis
		– diverticulitis
		Gynaecological conditions
		Spondyloarthropathies
		– ankylosing spondylitis
		Tumours
		– testicular tumours
		– bone tumours
		– prostate cancer
		– urinary tract cancer
		– digestive tract cancer
		– soft tissue tumours

clinical entities. An unclear relationship between the pain and loading during sport, nocturnal or extremely severe pain or a lack of response to treatment should trigger more suspicion. There are numerous possible causes, a number of which are listed in Table 32.1. The main categories are orthopaedic, neurological, rheumatological, urological, gastrointestinal, dermatological, oncological and surgical; however, this list is not exhaustive as many rare conditions could possibly cause pain in the groin region.

A careful history and physical examination covering more than only the musculoskeletal system, and appropriate additional investigations or referrals are critical for identifying other possible causes. Some of these conditions are discussed in more detail at the end of this chapter.

## CLINICAL OVERVIEW

As previously alluded to, it is important to appreciate the anatomy of the hip and groin, and undertake a careful history and examination. The clinical approach can be difficult as the anatomy around this region is complex and often multiple pathologies coexist. Pain may be difficult to localise and be accompanied by vague symptoms. An insidious onset with varying locations of the pain may also cloud the clinical presentation.

## History

The athlete experiences groin pain, which is usually located in the medial upper thigh around the proximal adductors and pubic rami. The pain can also be more central in the upper thigh inferior to the inguinal ligament around the hip joint/distal iliopsoas region. The pain frequently starts

in one region and is unilateral, but it can gradually spread to other regions and become bilateral. Pain superior to the inguinal ligament can be felt in the region of the inguinal canal. Groin pain in athletes is aggravated by exercise, with running, twisting/turning and kicking being the most challenging activities. The athlete and coach usually notice a decrease in sports performance, especially related to performing explosive sporting actions such as kicking, accelerating/decelerating, turning and so on.

### Pain pattern

The onset of groin pain in athletes can be acute or gradual, but with both types of onset, groin pain can become longstanding. In the early stages, the longstanding groin pain patient typically presents late during the physical activity or after activity, with pain and stiffness next morning. The pain and stiffness then gradually lessen with daily activities and warming-up for the next training session or match. When the condition worsens, pain is present immediately upon exercise. Non-steroidal anti-inflammatory drugs (NSAIDs) tend to decrease pain, but will usually not result in a lasting cure. Short periods of rest reduce the severity of the symptoms, but on resumption of sporting activities the pain often returns to its original intensity and severity. The natural history is one of progressive deterioration with continued activity until symptoms prevent participation in the sporting activity.

### Where is the pain located?

The localisation of the pain is important in determining which structure may be causing the pain. Adductor-related groin pain is often located at the attachment of the adductor longus tendon to the pubic bone. Iliopsoas-related groin pain is located more centrally in the groin and proximal thigh. The type of activity that aggravates the pain gives a clue to the primary site of the problem. Side-to-side movements, kicking, twisting and turning activities which aggravate the pain suggest adductor-related groin pain. Straight-line running or jogging suggests iliopsoas-related groin pain. Pain with sit-ups and/or coughing, may suggest an inguinal-related groin pain. Note that these clinical observations are guidelines rather than hard and fast rules, as many of the symptoms overlap.

Pain that becomes progressively worse with exercise may suggest a stress fracture or an apophysitis in young athletes. A history of associated pain such as low back or buttock pain indicates that the groin pain may be referred from another site (such as the hip, the sacroiliac joint or the spine). A full training history should be taken to determine if any recent changes in training (e.g. a generalised increase in volume or intensity, the introduction of a new exercise or an increase in a particular component of training) may have led to the development of the groin pain.

### Clinical examination

Clinical examination includes the adductor muscles, the pelvic bones, the hip joint, the hip flexors (including tensor fascia lata and sartorius) and the lower abdominal muscles. The lumbar spine and sacroiliac joints should also be examined. Pelvic alignment must be assessed and large leg length discrepancies (>2 cm) noted.

Examination involves the following.

1. Observation
  - a. standing
  - b. walking (Fig. 32.3a)
  - c. squatting, running, jumping
2. Active movements
  - a. hip flexion/extension (Chapter 31)
  - b. hip abduction/adduction
  - c. hip internal/external rotation
  - d. lumbar spine movements (Chapter 29)
3. Passive movements
  - a. passive movement–adductor muscle stretch (Fig. 32.3b)
  - b. modified Thomas Test (Fig. 32.3c)
4. Resisted movements
  - a. resisted movement–single leg (Fig. 32.3d)
  - b. resisted movement–squeeze test
    - i. with hips in 45° flexion (Fig. 32.3e-i)
    - ii. with hips in neutral (Fig. 32.3e-ii)
  - c. hip flexion (Fig. 32.3f)
  - d. abdominal muscles (Fig. 32.3g)
5. Palpation
  - a. adductor (Fig. 32.3h)
  - b. psoas above inguinal ligament (Fig. 32.3i)
  - c. psoas below inguinal ligament (Fig. 32.3j)
  - d. inguinal region–external inguinal ring (Fig. 32.3k)
  - e. inguinal region–scrotal invagination (Fig. 32.3l)
  - f. pubic symphysis (Fig. 32.3m)
6. Hip-related groin pain
  - a. examination of the hip joint (Chapter 31)
7. Screening for other pathology
  - a. stress fractures–neck of femur and pubic ramus
  - b. thoracic spine (Chapter 28) and lumbar (Chapter 29)
  - c. sacroiliac joint (Chapter 30).

### Assessment of severity

While clinical examination is essential for diagnosing and classifying groin pain in athletes, it gives little objective information on the severity of the condition. The severity, insights into the impairments, activity limitations and accompanying participation restrictions can be measured with strength, range of motion and patient-reported outcome tools.

### Strength

The assessment of muscle strength provides better understanding of the degree of impairment in athletes

(a)

with groin pain. It can be quantified objectively, and is a great help in monitoring clinical progress or deterioration. Adductor strength can be reliably assessed using handheld dynamometry and quantified either unilaterally (Fig. 32.4a) or as a squeeze test (Fig. 32.4b and c) and is especially relevant in athletes with adductor-related

or pubic-related groin pain. It may also be relevant to include abductor strength (Fig. 32.4d) before return to sport in athletes with adductor-related groin pain or acute injury, as an eccentric hip adductor/abductor ratio of  $<0.8$  appears to increase the risk of future adductor injuries.

For isometric and eccentric measures, the minimal detectable change when using the same tester is around 10–15%, while being around 20% for the isometric adduction/abduction (ADD/ABD) ratio.<sup>23</sup> While eccentric ratios for ice hockey players<sup>24</sup> and isometric ratios for soccer players seem to be around 1.0,<sup>25</sup> these ratios may be sport-specific. Clinically, this means that reductions in strength of 15% can be measured at the individual level. This may indicate that athletes either have, or are

at increased risk, of developing groin pain. Studies in European and Australian soccer players and Gaelic football players with groin pain have shown that strength deficits of around 20% or more seem to exist in eccentric strength and during the squeeze test.<sup>26-29</sup>

### Range of motion

Passive hip joint internal rotation range of motion in degrees can also be reliably assessed using a goniometer or inclinometer, although severe restrictions in passive range of motion are more closely related to hip intra-articular conditions, and less often to groin pain related to tendon attachments and the pubic bone. Assessment of the hip joint is demonstrated in Chapter 31.

### Patient-reported outcome measures (PROMs)

The use of validated outcome measures should also be encouraged. In a systematic review from 2015 on the clinimetric properties of PROMs for young physically active individuals with hip and/or groin pain, the

Copenhagen Hip and Groin Outcome Score (HAGOS) was recommended.<sup>30</sup> HAGOS is reliable, valid and responsive in athletes with hip and/or groin pain, and therefore not restricted to any specific pathology or entity. Reference values for soccer players have been provided.<sup>31</sup> It measures six relevant subsets related to groin pain in athletes, including pain, symptoms, activities of daily living, participation in physical activity, sports function and quality of life. Reference values have been given for soccer players without groin pain, and while their average and upper boundary is 100 points, the lower boundary goes down to 70 points in the sporting function and participation scores.<sup>32</sup> On average, Gaelic footballers and soccer players with adductor-related groin pain display scores in the area of 50 points and below when having had pain for at least 4 weeks.<sup>26, 27</sup>

### Imaging

The current evidence for the use of radiographs, MRI and ultrasonography in groin pain is based on relatively

## Outcome measures

Physical assessments should include some of the following valid and reliable measures according to relevance to the clinical findings. The following measures are of relevance.

Strength (hand-held dynamometer (HHD) or sphygmomanometer)

- hip adduction strength—squeeze, isometric, eccentric (Fig. 32.4(a)–(c))
- hip abduction strength—squeezing, isometric, eccentric ADD/ABD ratio (Fig. 32.4(d))
- hip flexion strength—squeezing, isometric, eccentric

Range of motion (goniometer or inclinometer)

- hip internal rotation
- hip external rotation

- hip abduction
- hip extension (Thomas test position)

Patient-reported outcome measures (PROM)

- Copenhagen Hip and Groin Outcome Score, six subscales
  1. Pain (0–100)
  2. Symptoms (0–100)
  3. Activities of daily living (0–100)
  4. Sport and recreation (0–100)
  5. Participation in physical activity (0–100)
  6. Quality of life (0–100).

few heterogeneous studies which are of varying methodological quality.<sup>33</sup> The correlation between clinical findings, athletes' symptoms and the identified radiological abnormalities is quite weak.

Two recent studies have illustrated this.<sup>34, 35</sup> Branci et al. compared the standardised MRI findings of three groups of male adult athletes matched for level of sports activity.<sup>34</sup> Positive MRI findings were significantly more frequent in soccer players compared with non-soccer players irrespective of whether or not the soccer players had symptoms, suggesting that these MRI changes may be associated with soccer play itself rather than clinical symptoms. In a 4-year prospective cohort study of young soccer academy players using serial clinical and imaging assessments, Robinson et al. found a high prevalence of positive imaging findings, including pubic bone marrow oedema (BMO), in asymptomatic soccer players as well as in those with injury.<sup>35</sup> These two studies show that imaging should not be used in isolation when diagnosing groin pain in athletes.

### Radiography

Plain radiographs of the pelvis are commonly recommended in many cases to evaluate the hip joints and the pubic bones. If the patient history and the clinical examination suggest that the groin pain could be hip-related, an anteroposterior pelvic radiograph and a true lateral radiograph should be obtained. The  $\alpha$  angle, the centre-edge (CE) angle and other relevant measurements can be examined, looking for any bony morphology that can result in femoroacetabular impingement (FAI).

FAI morphology has been found to coexist with longstanding adductor-related groin pain and the presence of FAI morphology is not necessarily a sign of hip joint

pathology (Chapter 31).<sup>36</sup> In this study of athletes with longstanding adductor-related groin pain, 94% had at least one radiographic sign of FAI on the X-ray. In a different cohort of athletes with longstanding adductor-related groin pain who also had plain radiographs performed, follow-up was done after 8–12 years. The study found no evidence that bony hip morphology related to FAI or dysplasia prevented successful outcome of an exercise treatment for this musculotendinous injury.<sup>37</sup>

Plain radiograph of the pubic symphysis often shows osteolytic changes, irregular widening and sclerosis along the rami of the os pubis in soccer players. Historically these changes were interpreted as a diagnosis using the term 'osteitis pubis' (Fig.32.5a). These changes can also be seen before radiographic changes are present as pubic BMO on MRI. As described earlier, this is not that specific for injury, but probably reflects the considerable strain that the pelvic girdle is exposed to in the kicking sports in particular.<sup>34</sup>

It is likely that there is a continuum of bone stress and that there is not a strong relationship between the degree of stress and the pain felt by an athlete. This was alluded to by Harris et al. in 1974,<sup>38</sup> and the case control study of Branci et al.<sup>34</sup> found that higher grades of pubic BMO, along with protrusion of the disc in the symphyseal joint, were associated, but not strongly, with pain compared to soccer-playing controls. A bone biopsy study of athletes with pubic-related groin pain found evidence of new woven bone formation but a lack of inflammation, and so using the term 'osteitis pubis' cannot be recommended.<sup>39</sup>

In the skeletally immature adolescent athlete, plain radiographs are used to detect osseous avulsions in musculotendinous distraction injuries and epiphysiolysis of the growth plate of the femoral neck. The plain radiograph is also a good primary examination for

neoplasms of the bone. Even in seemingly healthy athletes, this should be considered as a possible cause of unexplained groin pain or when there is an unusual response to treatment. Radiographs are often used as a first-line investigation if a pelvic stress fracture is suspected; if a stress fracture is visible, radiographs can confirm the clinical suspicion. Clinicians should note that radiographs are frequently negative when stress fractures are present and cannot be used to rule out stress fractures.

### Magnetic resonance imaging

Magnetic resonance imaging (MRI) is a very sensitive, but not always equally specific, imaging technique. It is used widely, but the results should be interpreted with caution.<sup>33</sup> The high sensitivity means that when imaging athletes with MRI many 'abnormalities' will be seen, but that the clinical relevance of these findings is doubtful in terms of making a diagnosis or estimating prognosis. Ongoing studies are examining the value of MRI in the diagnosis of acute groin injuries and the results are promising. Some common MRI findings are pubic BMO, adductor tendon changes and findings around the aponeurosis anterior to the symphysis.

Pubic BMO is a common finding. Studies have shown that the percentage of athletes without groin pain found to have BMO on MRI is high (31–61%).<sup>34, 40, 41</sup> To date, no studies have examined the effect of the presence/absence or grade of BMO on the time to recovery.

Changes in MRI signal of the adductor tendon around the proximal insertion have been referred to as 'enthesopathy',<sup>42</sup> 'tendinopathy'<sup>34</sup> and 'pubic aponeurosis defect'.<sup>43</sup> This demonstrates the confusion with regard to describing these virtually identical radiological findings of increased signal intensity in the proximal adductor tendon. Some have found the reliability of determining if adductor tendon signal changes are present to be poor,<sup>44</sup> while others found it to be good.<sup>35</sup>

The differing terminology may explain why some studies found changes in the tendon to be present in more than 70% of asymptomatic players,<sup>34</sup> while others in only 11%.<sup>41</sup> As with pubic BMO, there have been no studies to date examining whether athletes who have adductor tendon signal changes take longer to recover than those without. In other tendons, only weak associations have been found between structure and symptoms, and a normalisation of tendon structure after treatment was not associated with better outcome.<sup>45</sup>

The secondary cleft sign (Fig. 32.5c) was first described as being present when contrast medium injected into the pubic symphysis extended beyond the midline or inferior to the joint.<sup>46</sup> Other groups used a high signal intensity line extending laterally and inferiorly from the

(d)

**Figure 32.5 (cont.)** (d) CT scans demonstrating stress-related changes at the pubis: (A) Cystic changes; (B) Asymmetrical irregularities and cystic changes; and (C) Unilateral widening of the pubic apophysis

inferior part of the symphysis of fluid sensitive sequences, without the use of contrast, to define the secondary cleft.<sup>34</sup> The secondary cleft was initially found to be present in two-thirds of athletes with groin pain and absent in 70 control subjects who were rowers.<sup>46</sup> Later studies found it to be present at similar prevalences in soccer players with and without groin pain,<sup>34</sup> and in a prospective study of young asymptomatic soccer players it did not predict the onset of groin pain.<sup>35</sup> Again there is a lack of data on how the presence of a secondary cleft on MRI may affect the prognosis.

#### PRACTICE PEARL

In summary, the common MRI findings of pubic BMO, adductor tendon changes and secondary cleft are found frequently in healthy players, and in general do not discriminate well between those with and those without pain.

There is a lack of data on how these findings should influence treatment decisions and their meaning for helping make a more accurate prognostic prediction.

Stress fractures, neoplasms and other occult bony injuries are rare and when suspected, but not visible on radiography, MRI is the best investigation. Even in seemingly healthy athletes, these should be considered as a possible cause of unexplained groin pain.

### Ultrasonography

Ultrasonography (US) has gained increasing popularity in recent years (Chapter 15). Scientific evidence for its use in groin injuries is very limited.<sup>33</sup> It has shown promise with other muscle and tendon injuries.<sup>47, 48</sup> There is a significant discrepancy between the widespread clinical use and experience gained in many countries, and the amount of data available in the literature to help clinicians improve interpretation of findings.

### Computed tomography scan

Computed tomography (CT) scan offers excellent visualisation of the pubic symphysis joint, but requires high doses of radiation. Its general use in the young athletic population cannot be advised due to the significant radiation risk and a lack of data on normal findings in the athletic population. An interesting recent paper which examined CT scans of young males who had undergone CT scans for reasons other than groin pain showed that the pubic apophysis closes in the late teens and early twenties (Fig. 32.5d).<sup>49</sup> While the apophysis can be visualised well on CT, it can also be clearly seen on MRI, which is safer and therefore the preferable modality.

### Radioisotopic bone scan

Given the high radiation dose of bone scans, and the fact that MRI allows good visualisation of both bony and soft tissue structures in the pelvis, the use of bone scan as a routine investigation for groin pain in athletes cannot be recommended.

## ACUTE GROIN INJURIES

An acute groin injury usually involves one or more musculotendinous structures.<sup>5</sup> The lesion can be in the musculotendinous junction, but in some cases the tendon itself or the entheses where the tendon inserts into the bone is the site of the injury. These injuries usually happen during explosive actions such as kicking, reaching with the leg, sudden change of direction or other movements where the muscle is being stretched during forceful contraction.<sup>5</sup>

### Diagnosis

The most common acute injury in the groin is to the adductors, especially the adductor longus, which has been verified both clinically and with diagnostic imaging.<sup>5</sup> Good agreement between clinical diagnosis and diagnostic imaging seems to exist for acute adductor longus injuries.<sup>5</sup>

However, acute injuries to other musculotendinous structures such as the iliopsoas, proximal rectus femoris or the inguinal canal/conjoined tendon are more difficult to localise clinically in the acute stage. Acute injuries to iliopsoas and rectus femoris are not infrequent and should be considered relevant differential diagnoses that may need imaging to be correctly identified.

In the acute stage, ultrasound has shown clinical promise as a simple method for localising specific structures in the groin, due to the visualisation of oedema or structural derangement. MRI has advantages when considering the underlying symphysis joint and adjacent bone, thus allowing for more complete assessment, and may be less operator dependant. Diagnostic imaging may therefore play an important differential diagnostic role when examining acute groin injuries, but may also have a role in guiding treatment choices from a very early stage in relation to which structures and what kind of tissue should be targeted in the rehabilitation of the particular injury. At the present time, however, there is no evidence that the use of imaging does lead to better clinical outcomes or more accurate prediction of the duration of injury.

If the initial injury is not treated appropriately in the first place or if a player is returned to sport too quickly, it may develop into a more longstanding injury. If the athlete does not get appropriate treatment and continues to participate, the injury pattern may start to resemble the more overuse type where more and more sport-specific activities become problematic. This type of injury can then take months to recover from and what started out as minor acute injury can develop into a longstanding problem.

The actual percentage of acute groin injuries that progress to longstanding groin pain in athletes is unknown. There is currently limited data on the recovery times for acute groin injuries.

## LONGSTANDING GROIN PAIN

The Doha agreement confirms our approach to the classification of longstanding groin pain into the four clinical entities: adductor-related groin pain, iliopsoas-related groin pain, inguinal-related groin pain and pubic-related groin pain.<sup>22</sup> As demonstrated in the 'Epidemiology' section an athlete can have more than one entity, in which case multiple entities can be diagnosed. The criteria for the diagnosis of each clinical entity are highlighted in each of the following sections in *italics*.<sup>22</sup>

### Adductor-related groin pain

Adductor-related groin pain is the most common acute and longstanding groin injury.<sup>3-5</sup> Acute groin injuries are described elsewhere in this chapter and this section focuses on longstanding groin pain.

The patient with longstanding adductor-related groin pain usually complains of pain medially in the groin, most pronounced around the insertion of the adductor longus tendon at the pubic bone. The pain may radiate distally along the medial thigh. Pain during sprinting, cutting changes of direction and kicking the ball are common complaints.

### Diagnostic criteria

The diagnostic criteria for adductor-related groin pain are *adductor tenderness* (Fig. 32.3h) AND *pain on resisted adduction testing* (Fig. 32.3d).<sup>22</sup>

## Evidence for treatment of groin pain in athletes

A systematic review from 2015 on the treatment of groin pain in athletes identified 72 studies.<sup>13</sup> All studies were assessed for their methodological quality with a scoring system. The majority of studies (90%) were case series, of which 80% were retrospective. Only four studies were high quality. Twenty-five per cent reported on conservative treatment and 75% on surgical treatment for groin pain. A significant association was found with methodologically weaker studies reporting higher treatment success percentages. There has been no significant improvement in the quality of studies published over the last 30 years. A level-of-evidence approach was used to synthesise the results.

### There is moderate evidence that for longstanding adductor-related groin pain:

- supervised active physical training results in a higher success and percentage of athletes returning to play than passive physical therapy modalities
- multi-modal treatment including manual adductor manipulation can result in a faster return to play, but not a higher treatment success, than a partially supervised active physical training program
- partial release of the adductor longus tendon seems effective for return to sport over time.

Additionally, there is moderate evidence that, for athletes with inguinal-related groin pain, laparoscopic hernia repair results in lower pain and a higher percentage returning to play than conservative treatment.

## Treatment

The treatment of both acute and longstanding adductor-related groin pain will be considered together. The basis of the treatment of these conditions is exercise therapy and is based on Professor Per Hölmich's seminal paper published in *The Lancet* in 1999 which was the first randomised controlled trial (RCT) to examine treatment regimes in adductor-related groin pain.<sup>50</sup> The original exercise program is shown in full in the box below.

The exercise program comprises two modules. The first module consists of specific isometric and dynamic exercises to reactivate the adductor muscles and probably also modulates the pain.<sup>51</sup> The athlete can have difficulties activating these muscles, probably as a result of negative feedback caused by the pain. The second module includes heavier resistance training as well as challenging balance and coordination exercises. The exercise program is performed three times a week, alternating with the exercises from module 1 on the days in between.<sup>50</sup>

The total length of the exercise training period is between 8 and 12 weeks. Absence from training is

necessary as the functionality and strength of the adductor muscle group has to be re-established and pain brought under control without provocation by sport. Stationary cycling and general fitness training not involving the adductors can be allowed if pain-free.

Jogging is allowed after 6 weeks as long as it does not provoke any groin pain. When the patient is able to jog and undergo his or her regular treatment without pain, the treatment program is completed and the athlete is allowed to gradually progress to demanding sports-specific training followed by sports participation. No stretching of the adductor muscles should be done during this 2-3 month exercise training period.<sup>50</sup>

Injection of corticosteroids at the adductor enthesis is not recommended, as there is no documented long-term beneficial effect and it might make it more difficult to monitor the training program needed to cure the groin pain. It is the experience of the authors that adductor tenotomy is extremely rarely indicated.

Many rehabilitation programs for adductor-related groin pain have used the Hölmich exercises as their basis.

### Professor Per Hölmich's 1999 exercise program: an evidence-based foundation for contemporary rehabilitation programs

This program consists of static and dynamic exercises aimed at improving the muscles stabilising the pelvis and the hip joints, in particular the adductor muscles. The program consists of two parts.

- Module 1: Two-week familiarisation program—adductor activation.
- Module 2: More demanding exercises with heavier resistance training and balance and coordination. The training program is performed three times a week and the exercises from module 1 are performed on the days in between the treatment days. The total length of the training period is 8–12 weeks. Sport activities are not allowed in the treatment period. Pain-free bike riding is allowed. After 6 weeks, pain-free jogging is allowed. Return to sport is allowed when neither treatment nor jogging causes any pain.

Stretching of the adductor muscles is not advised, but stretching of the other lower extremity muscles, particularly the iliopsoas, is recommended.

#### Module 1: Static and dynamic exercises (2-week base training program)

##### Static

1. a. Adduction for 30 seconds against a soccer ball placed between the feet when lying in the supine position with the knees fully extended and the first toe pointing straight upwards.

1. b. Adduction for 30 seconds against a soccer ball placed between the knees when lying in the supine position with the knees and the hips flexed at 45° and the feet flat on the floor pointing straight ahead (Fig. 32.6a).

Exercises 1a and b should be repeated 10 times with 15-second recovery periods between each contraction. The force of the adduction should be just sufficient to reach the point where pain begins.

##### Dynamic

1. c. Sit-ups from the supine position with the hip and knee joints flexed at 45° and the feet against the floor. The sit-ups are performed as a straight abdominal curl and also with a quarter twist towards the opposite knee: five sets of 10 with 15-second recovery periods.
1. d. In the same starting position as for the sit-ups but clamping a soccer ball between the knees, the player does a combination of a sit-up while pulling the ball towards the head (Fig. 32.6b and c). The exercise is performed rhythmically and with accuracy to gain balance and coordination: five sets of 10 with 15-second recovery periods.
1. e. Wobble board training for 5 minutes.
1. f. Adductor lateral slide. Using a sliding board with an extremely smooth surface (or a very smooth floor) and wearing a low-friction sock on the sliding foot, one foot is positioned next to the sliding board and the other foot on

the board parallel to the first one. The foot on the board slides out laterally and is then pulled back to the starting position. The foot should be pressed against the surface through the whole exercise with as much force as can be tolerated within the patient's threshold of pain (Fig. 32.6d).

1. g. Forward slide. The same procedure is also done with the foot on the board placed in a 90° angle to the foot outside the board. Both exercises 1f and g are performed continuously for 1 minute with each leg in turn.

All the above exercises should be commenced carefully and the number of sets and range of motion gradually increased respecting pain and exhaustion.

#### Module 2: Dynamic exercises

This entire module is done twice at each training session for three training sessions per week with a day in between. *Note:* Module 1 is done on alternate days, so players are training a total of 6 days per week. Exercises 2a to e are done as five sets of 10 repetitions.

2. a. Lying on one side with the lower leg stretched and the upper leg bent and placed in front of the lower leg, the lower leg is moved up and down, pointing the heel upwards.
2. b. Lying on one side with the lower leg bent and the upper leg stretched, the upper leg is moved up and down, pointing the heel upwards.
2. c. Begin by standing at the end of a high couch and then lie prone so that the torso is supported by the couch. The hips are at the edge of the couch at 90° of flexion and the feet are on the floor. From this position, both hips are slowly extended so both legs are lifted to the greatest possible extension of hips and spine; legs are then lowered together.
2. d. Standing abduction/adduction using ankle pulleys/elastic bands. Begin with a low weight and gradually increase the weight but keep it submaximal (Fig. 32.7).
2. e. Standing on one leg, the knee of the supporting leg is flexed and extended rhythmically and in the same rhythm swinging both arms back and forth independently ('cross-country skiing on one leg') (Fig. 32.8). The non weight-bearing leg is not moved.

*continued*

**Figure 32.7** Standing hip adductor strengthening with elastic band. Dynamic strength and coordination exercise with emphasis on maximal concentric, isometric and eccentric strength of adductor muscles, with co-activation from contralateral

The balance and position is kept accurately and the exercise is stopped when this is no longer possible. Progression of the exercise is obtained by holding a 1 kg weight in each hand.

2. f. 'Fitter' training for 5 minutes.
2. g. Standing on the sliding board, side-to-side skating movements on the sliding board are done as five sets of 1-minute training periods with 15-second recovery.

#### Practical tips

- Supervision is important—the patient should be instructed by a physiotherapist, a clinician, an athletic trainer or another qualified person who has been trained in the details of the program.
- Exercises such as 1d and 2e are very important, especially at the end of the training period, but they are technically difficult.
- The athletes can do the program at home or at the gym or fitness club, but we recommend physiotherapist supervision for three to four times within the first 2 weeks

(a)

(b)

**Figure 32.8** (a-c) Cross-country skiing. Dynamic hip flexion on one leg with coordinated arm swing

(c)

**Figure 32.8 (cont.)**

and after that a visit every 10–14 days to check the technique and ensure progression.

- Patience is the key to success.
- Patients often make good progress in the first few weeks, but symptoms can plateau from that period until the 6–9 week period, when there is a positive 'breakthrough'.
- It is important to use pain as a guide to how much to do. Muscle soreness similar to that after a regular practice in the sports field is not a problem, but if the patient experiences pain from the injury, the intensity of the exercises should be adjusted.
- Pain medication including NSAIDs should be avoided.
- Athletes should continue with some of the exercises on a regular basis (1–2 times a week) for at least a year after total recovery and return to sport.
- The athlete must appreciate that successful rehabilitation of longstanding groin pain takes a minimum of 8–12 weeks.

**PRACTICE PEARL**

An advance in recent years has been that rehabilitation programs have evolved from time-based protocols such as that used by Hölmich, to criteria-based protocols (see Chapter 18).

Reflecting this more contemporary approach, the following rehabilitation program is divided into four phases, each with a different rehabilitation focus. In general, the rehabilitation program works from focus and isolation on the specific injured tissues towards integration of the specific structures into sports-specific function and return to sport based on individual and continuous assessment of:

- injury (structural) status
- functional status
- performance status; and finally
- sports participation status, at specific time points during the rehabilitation period.

**PRACTICE PEARL**

The rehabilitation of acute groin injuries can be divided into four main phases prior to pre-injury competitive level:

1. acute/subacute phase
2. conditioning phase
3. sports-specific phase
4. return-to-sport phase.

**1. Acute/subacute phase**

The acute and subacute phase is characterised by musculotendinous pain and/or inflammation at the musculotendinous junction (MTJ), in the tendon or at the insertional enthesis. This phase focuses on the initiation of tissue repair and/or regeneration, but also includes effects of possible disuse as a result of injury. The primary goals to be addressed during this phase are protection of the injured structure, control of pain and inflammation, normalisation of flexibility within restrictions and preventing excessive muscular inhibition using isometric contractions with no or minimal pain provocation.

**Criteria for progression to conditioning phase**

The criteria for progression to the conditioning phase are:

- no or minimal pain with all exercises and clear muscle activation during isometric contractions
- active hip abduction range of movement (ROM) of at least 50% of the non-injured side.

**2. Conditioning phase**

This phase focuses on tissue repair and/or regeneration. In this phase gradual and progressive loading of adductor, hip flexor and abdominal muscles is commenced while still respecting the structural injury and underlying healing processes depending on the location of the injury (MTJ, tendon, aponeurosis or insertion) at this early stage.

Gentle dynamic muscle exercises are commenced starting off with a low load from 20–30 repetitions maximum (RM). Strength training machines, side-lying using the weight of the leg and standing exercises with elastic bands (Fig. 32.7) can be used for targeting the adductor longus muscle and at least two different exercise types should be used with  $3 \times 20$  repetitions of each.

The musculotendinous conditioning should focus on concentric, isometric and eccentric contractions during these exercises of the specific injured tissues structure. For the abdominals, abdominal crunches in supine, frontal rolling exercises with Swiss ball, modified planks or training in a machine should also be performed using the same principles as applied for the adductors. For the hip flexors, isometric hip flexion in various degrees of range of motion, hip flexor training with elastic bands, and hip flexion work in a machine or with free weights should also be performed using the same principles as applied for the adductors and the abdominals. All these exercises should be performed 3 times a week with at least one day of rest in between sessions.

Pain during exercises must not be neglected, but some discomfort and pulling may be felt during early initiation of these exercises. A general rule of thumb is that pain and discomfort should be less than 3/ on a numerical rating scale (NRS) during exercise and that initial pain levels before exercise are reached shortly after exercises are finished. Increasing morning pain and stiffness, compared to the initial state, is also a good indicator that the exercises have been progressed too quickly. Once the patient is pain-free, pain-free walking can begin and be gradually increased in speed and distance.

The criteria for when the patient may return to running are when:

- brisk walking is pain-free
- resisted hip adduction testing and squeeze testing is pain-free
- there is minimal adductor guarding.

### **Criteria for progression to sports-specific phase**

The criteria for progression to the sports-specific phase are:

- no or minimal pain with all phase 2 exercises and normal execution (no compensation strategies to avoid loading injured structures) of dynamic exercises of adductor, hip flexor and abdominal muscles
- active ROM at least 80% of the non-injured side and adductor strength of at least 60% of the non-injured side; which means that the athlete will be able to do (i) 20 repetitions maximum using the same resistance based on 20 repetitions maximum from the uninjured side, and/or able to do 20 repetitions of exercises for adductors (side-lying adductor lifts), (ii) 20 repetitions for abdominals (abdominal crunches lying supine) and

(iii) 20 repetitions for hip flexors (hip flexions against your own hand lying supine) on the floor with proper form, and with no or minimal pain.

### **3. Sport-specific phase**

The primary goals to be addressed during this phase are restoration of musculotendinous endurance and strength, aerobic and anaerobic capacity, and neuromuscular control/balance/coordination. Dynamic muscle strengthening exercises for the adductor and hip flexor muscles in standing, using elastic band resistance, are continued starting off with a load of 20 RM progressing towards 10 RM. The same principle is applied for abdominal exercises where a Swiss ball is used.

The musculotendinous conditioning should focus on slow heavy concentric, isometric and eccentric contractions during these exercises. Exercises on a sliding board (Fig. 32.6d) are commenced by introducing 5 to 10 sets of 1 minute of skating from side to side. All these exercises should be performed three times a week with at least one day of rest in between. Pain during exercises must not be neglected and the same guidelines accepting pain 0–2 on an NRS as stated earlier apply.

Various progressive running and kicking regimens can be used. An example is described below.

- The regime starts with 50–100 m run-throughs with 5–10 m acceleration and deceleration phases with walk recovery, depending on running demands of the specific sport. Patient should commence with 6–8 repetitions on alternate days. Key criteria (adductor guarding, squeeze test) should be assessed immediately after each session and again the next morning. The running program can be progressed further by replacing walk recovery with jog recovery. The aim should be to build up to 20 run-throughs and jog back.
- Lateral running (gradual change of direction such as figure of eight) can be commenced when the above running program is completed pain-free, the hip flexion test is still pain-free with no crossover sign, there is no adductor guarding and, in addition, the squeeze test is pain-free. Figure-of-eight running should commence slowly with very gradual change of direction, then gradually increase both speed and sharpness of changes of direction.
- Finally, Copenhagen hip adductor exercises (Fig. 32.9) should be incorporated starting at level 1 with 3–5 repetitions on each side (change top leg). Then progress to intermediate level 2 with 7–10 repetitions on each side and then level 3 with 12–15 repetitions on each side. All exercises above should be performed 2–3 times a week, with a day of rest from these exercises in between.

Initial agility drills should be performed with proper form, with no clear and visible compensation strategies

(a)

(b)

**Figure 32.9** (a) Copenhagen adductor exercise  
(b) A partner exercise where the player is lying on the side of the non-dominant leg with one forearm as support on the floor and the other arm placed along the body. The dominant leg is held at approximately the height of the hip of the partner, who is holding the leg with one hand supporting the ankle and the other supporting the knee. (Fig. 32.9a) The player then raises the body from the floor and the non-dominant leg is adducted so that the feet touch each other and the body is in a straight line (Fig. 32.9b)

during maximal and forceful actions such as accelerating, decelerating, twisting turning and kicking.

In kicking sports, short stationary kicking can be commenced when adduction and squeeze tests are pain-free without crossover. The player may gradually increase the kicking distance and then start shorter kicking on the run. The last stage in the kicking program is long kicks at full pace and kicking around the body.

#### **Criteria for progression to return-to-sport phase**

The criteria for progression to the return-to-sport phase are:

- no or minimal pain with all exercises and normal execution (no compensation strategies to avoid loading

injured structures) of dynamic exercises of adductor, hip flexor and abdominal muscles

- active ROM of nearly 100% of the non-injured side and adductor strength of at least 80% of the non-injured side, able to do  $3 \times 10$  RM, by using the same resistance based on 10 RM from the uninjured side for hip adductors or flexors, or able to do  $3 \times 10$  side-lying adductor lifts with external load of at least 5 kg, and able to do  $3 \times 10$  hip flexor exercises lying supine using the weight of the leg as the external weight and  $3 \times 10$  abdominal crunches lying over Swiss ball with proper form, and with no or minimal pain.

#### **4. Return-to-sport phase**

The return-to-sport phase is characterised by activities that focus on returning the athlete to full sporting function and participation, with successful return to previous functional and sporting level and the prevention of re-injury. The primary goals during this phase are maintenance of musculotendinous endurance and strength, aerobic and anaerobic capacity, and improving neuromuscular control/balance/coordination.

Dynamic muscle exercises using the elastic bands are continued with a load of 8–10 repetitions maximum, with focus on different and increasing speeds of eccentric contractions. Copenhagen adductors are continued at level 3 and exercises on a sliding board are continued by introducing 10–20 times 1 minute of skating from side to side. All these exercises should be performed 2–3 times a week with at least one day of rest from strength training in between.

#### **Criteria for return to pre-injury competitive level**

Participation in the specific sport, on an individual level or with the rest of the team, progressing from 30 minutes to 90 minutes of training and participating in 1–3 weeks of full training before full return to sport (match/competition activity) can be commenced, depending on the severity of the initial injury (the more severe the longer participation period before full return).

#### **Key clinical signs suggestive of 'excessive loading' during rehabilitation**

As the therapist must continually guard against the player 'overdoing' rehabilitation, we share the following signs that appear to suggest excessive loading and deterioration during rehabilitation:

- pain on passive hip abduction
- adductor muscle 'guarding' with increased muscle tone on passive combined hip external rotation and abduction
- pain and weakness with resisted adduction and squeeze testing.

Other non-surgical treatments for adductor-related groin pain

### Compression shorts

Compression shorts can be used in cases where athletes continue to train and play despite ongoing symptoms. This can be either in cases where therapy does not result in a complete resolution of symptoms or where, for whatever reasons, athletes return to the field without having completed rehabilitation. They can also be useful when athletes are not fully confident after longstanding injuries.

Compression shorts reduce pain during athletic activities without a significant effect on performance. A study of 29 healthy athletes wearing two types of shorts used surface electromyography (EMG) of the adductor muscles during a 45° cutting movement. When wearing compression shorts with directional reinforcement properties, athletes had reduced adductor muscle activity during cutting.<sup>52</sup> The reduced muscle activity may be one mechanism by which compression shorts reduce pain. The reductions in pain are only small and to what extent this may postpone recovery has not been studied.

### Manual therapy

A case series followed by an RCT have studied the effects of a multimodal treatment program, including an adductor muscle manipulation, stretching and a graded running program, in longstanding adductor-related groin pain.<sup>53, 54</sup> The RCT was evaluated as being high quality in a recent systematic review which concluded that multimodal treatment including manual adductor manipulation can result in a faster return to play, but not a higher treatment success, than a partially supervised active physical training program.<sup>13</sup>

There are a number of clinical scenarios in which manual therapy including adductor manipulation (Fig. 32.10a and b) or soft tissue therapy (Fig. 32.10c) can be considered. It can be offered as a standalone treatment, but should be considered more as an adjunct to active exercises in cases where:

- exercise therapy has not given a satisfactory result.
  - 'weekend warriors' are not motivated or able to perform exercise therapy for the required intensity and duration
- manual therapy might be of help.

### Iliopsoas-related groin pain

Iliopsoas-related groin pain is the second most common injury in the groin region.<sup>3-5</sup> It is characterised by pain in the anterior part of the proximal thigh, more laterally than adductor-related groin pain. Iliopsoas-related groin pain can present in isolation, but may also be part of the disturbed muscle balance in the region when other structures are injured. It is an important differential diagnosis for

hip-related groin pain; not only because of the pain location, but also since the iliopsoas with its close relation to the hip joint as an anterior stabiliser tends to get involved whenever there is a hip or groin problem. It seems to be a muscle that frequently gets involved in compensating for the overload.

### Diagnostic criteria

The diagnostic criteria for iliopsoas-related groin pain are *iliopsoas tenderness* (Fig. 32.3i and j) and *iliopsoas-related groin pain is more likely if there is pain on resisted hip flexion AND/OR pain on stretching the hip flexors* (Fig. 32.3f).<sup>22</sup>

### Treatment

Most of the literature regarding the iliopsoas is related to the snapping hip and in recent years to hip arthroscopy. The painful iliopsoas muscle and/or tendon in athletes have not been the focus of any evidence-based research. The authors' preferred treatment of iliopsoas-related groin pain aims to strengthen the hip flexor muscles (Fig. 32.11) using isometric, concentric and eccentric contractions,<sup>55</sup> and combining this with a series of pelvic stabilisation and balance exercises.

(a)

**Figure 32.10** Manipulation of the adductors (a) Using the left hand to hold the heel, the right hand takes a hold of the muscle belly of the adductors

(b)

(c)

**Figure 32.10 (cont.)** (b) The left hand brings the hip into forced abduction and external rotation to apply the maximal tolerable stretch to the adductor group, while the right hand controls the tension; the motion is circular and flowing  
(c) Soft tissue therapy to the adductors

(a)

(b)

**Figure 32.11** Hip strengthening exercises. Standing hip flexor strengthening with elastic band from start position (a) to finish position (b). Dynamic strength and coordination exercise with emphasis on maximal concentric, isometric and eccentric strength of hip flexor muscles. With elastic band fixated from above (here) the emphasis will be on rectus femoris and adductor longus in relevant kicking position, whereas if elastic band is fixated from below then the emphasis will be on strengthening the iliopsoas by focusing on optimal resistance towards full hip flexion

Additional physiotherapy, including stretching, soft tissue therapy and trigger point stimulation for symptomatic relief, might also be helpful. In most cases, players can return to play in 4–6 weeks. If the strength training is not progressing satisfactorily because it is too painful to perform the exercises, it is often possible to decrease the pain with an ultrasound guided local corticosteroid injection along the iliopsoas tendon.

Causes for groin pain can be seen in isolation or alongside each other in the same patient and the treatment needs to be directed at all entities that are diagnosed. The general exercises aiming at the coordination and synergies of the muscles and joints related to the hip and pelvis are along the

same lines in most programs. However, it is very important that the individual entities are addressed individually with specific strengthening and endurance exercises.

In the internal coxa saltans (snapping psoas) the patient feels a snap happening during activity in the groin region when the hip is extended from the flexed position. The snap can sometimes be audible. If the snapping is very uncomfortable or painful it can, in our experience, be treated with a strengthening and stretching program in the majority of cases. On rare occasions, a partial release of the tendon at or close to the insertion may be performed with good results. The surgery can be performed as an open or arthroscopic/endoscopic procedure.<sup>56</sup>

## Inguinal-related groin pain

Inguinal-related groin pain is probably one of the areas surrounded by the most confusion when dealing with groin pain in athletes. This entity has been defined in multiple ways, been given numerous differing nomenclatures and been the subject of much debate. Differing terminology has emerged from different geographical regions and the terms 'sports hernia', 'sportsman's hernia', 'sportsman's groin', 'posterior wall weakness', 'incipient hernia', 'Gilmore's groin' and 'hockey groin' have all been used in the past.<sup>22</sup> A consensus statement from the British Hernia Society proposed the term 'inguinal disruption', which can be used when three out of five possible findings are present.<sup>57</sup> This statement was the subject of some debate as it introduced yet another term into the fray and was not part of a wider classification system.<sup>58</sup>

### Diagnostic criteria

The diagnostic criteria for inguinal-related groin pain are:

- *pain in inguinal canal region and tenderness of the inguinal canal* (Fig. 32.3k-l); *no palpable inguinal hernia is present*
- *more likely if aggravated with abdominal resistance* (Fig. 32.3g) or *Valsalva/cough/sneeze*.<sup>22</sup>

There is no attempt made to describe any possible underlying pathology, as the exact substrate is still unknown. Bulging of the posterior wall, bulging causing entrapment neuropathy, tendinopathy of the inguinal ligament, tears of the external oblique aponeurosis and tearing of the conjoint tendon have all been proposed as being 'the pathology' underlying the problem. The authors feel that at this point in time, the issue of underlying pathology has yet to be resolved.

The confusion surrounding inguinal-related groin pain probably explains some of the difficulties when diagnosing and treating this condition. The actual prevalence remains unknown and this is clearly illustrated by the variety in reporting this in the literature.

A 1995 Australian case series from a sports physician on 189 cases of groin pain in athletes defined 'incipient inguinal hernia' as chronic pain above the pubic tubercle, increased by activities such as running or kicking,<sup>17</sup> local tenderness over the conjoint tendon area and posterior inguinal wall laxity at surgical exploration. In this series, 50% of the athletes were found to have incipient inguinal hernia. This is in stark contrast to a series of 207 athletes from Hölmich in 2007, who defined 'sports hernia' to be the presence of tenderness of the external inguinal ring and conjoint tendon and close to its insertion on the pubic tubercle in the absence of a visible or palpable inguinal hernia.<sup>59</sup> In this series, 4 of the 207 athletes (2%) were classified as having 'sports hernia'.

A prospective study examining new cases of groin pain in soccer players over the course of a season in Denmark defined 'abdominal-related groin pain' as the presence of pain on palpation of the abdominal muscle insertion together with pain on abdominal flexion against resistance. Eleven of the 58 entities (19%) were abdominal-related and in 9 of the 11 cases this coexisted with the presence of adductor-related groin pain.<sup>15</sup>

### Treatment

When considering treatment options for inguinal-related groin pain, it is important to consider the available evidence. The systematic review discussed earlier in the section 'Evidence for treatment' noted that there 'were no studies focused on the conservative treatment of sport's hernia with a well-described treatment protocol'.<sup>13</sup> It should be noted that only case series with more than 10 subjects were included so some smaller previous series which report success were not included.<sup>60, 61</sup>

In practice, we recommend to commence an active exercise-based approach with similar principles as those in the program earlier described for longstanding adductor-related groin pain. This approach aims to strengthen the abdominal muscles, including isometric, concentric and eccentric contractions, in combination with a series of adductor and abductor-strengthening exercises, pelvic stabilisation and balance exercises. The abdominal exercises used in the adductor program (Fig. 32.6b and c) can be used as a starting point,<sup>50</sup> progressing into more strenuous exercises for the abdominal wall through plank exercises (Fig. 32.12a) and then into modified plank exercises with high muscle activation of both internal and external obliques.<sup>62</sup> A Swiss ball can also be used in the late stage conditioning phase before return to sport to mimic some of the external loads and forceful eccentric/concentric contractions that the abdominals go through, especially in kicking, throwing or shooting (ice hockey) (Fig. 32.12b and c).<sup>63</sup>

As with the adductor program, the total length of the exercise training period is dependent on criteria-based progression, but is generally between 8–12 weeks. Absence from training is again necessary as the functionality and strength of the abdominal muscle group has to be re-established, and pain brought under control without continued provocation by the sport that first precipitated the injury. Stationary cycling and general fitness training not involving the abdominals can be allowed if they can be done without pain. Jogging is again allowed after 6 weeks as long as it does not provoke any groin pain.

When the patient is able to jog and undergo his or her regular treatment without pain, the treatment program is completed. The athlete is allowed to gradually progress to demanding sports-specific training followed by sports

participation. No excessive stretching of the abdominal or the adductor muscles during this 2-3 month exercise training period is recommended as it can put unnecessary strain on the adductor and abdominal complex.

### Surgery

In cases where conservative treatment is not successful or surgery is considered for other reasons, it should be noted that there have been no comparative studies on the superiority of different techniques. A study comparing laparoscopic to open hernia repair is currently ongoing.<sup>64</sup>

A review identified 12 surgical studies on open hernia repair, 10 studies on laparoscopic hernia repair and 16 studies in which combined procedures (including adductor tenotomy) were performed.<sup>13</sup> Additional neurectomy was performed in 12 studies. There was only one high-quality study identified in the review.<sup>65</sup> The

(a)

(b)

**Figure 32.12** (a) Long lever planks with static maximal trunk muscle activation (b) Swiss ball curls

(c)

**Figure 32.12 (cont.)** (c) Dynamic abdominal strengthening with eccentric emphasis.

studies with the weakest methodological score reported the highest treatment success. This is important to take into consideration when using these published results to help inform patient decisions in clinical practice.

The one high-quality RCT compared laparoscopic hernia repair to conservative treatment in cases of 'sportsman's hernia (athletic pubalgia)'.<sup>65</sup> This was defined as athletes having more than 3 months history of pain above the inguinal ligament. There was pain on palpation of the deep inguinal ring and in cases where there was also pain on the pubic bone, pubic tubercle or adductors, or bone marrow oedema seen on the MRI, the athletes were also included.

The study randomised 60 athletes to treatment with either a bilateral totally extraperitoneal (TEP) laparoscopic hernia repair or conservative treatment. Unfortunately, the conservative treatment protocol is only described briefly as being total rest from their sports, active physiotherapy, steroid injections into the painful area and oral anti-inflammatory analgesics. This treatment was given 3 times a week for 90 minutes for 8 weeks and was supervised by the club physiotherapist.

This study found that 97% of those treated with surgery had returned to sport at 1 year compared to 50% of the conservative group. Until now this is the only high-quality study comparing surgery with conservative treatment. The poor description of the conservative treatment makes interpretation for clinical practice challenging, but it seems that some patients may benefit from conservative treatment and will be able to return to sport without having surgery. As complications from surgery are not uncommon in this region, non-surgical treatment should be considered and exhausted first.

The consensus agreement from the British Hernia Society noted that there was no proven best surgical technique.<sup>57</sup> This means that local availability along with the experience and preference of the surgeon are likely to be important when decisions are made as to which type of surgery to perform.

### Inguinal hernia

Inguinal hernias occur in athletes as in the general population. They can be either direct or indirect. Small hernias may become painful as a result of exertion. Symptoms may include a characteristic dragging sensation to one side of the lower abdomen aggravated by increased intra-abdominal pressure, such as coughing. On examination, there is occasionally an obvious swelling and the hernia can be palpated. In cases of a symptomatic inguinal hernia, the treatment consists of surgical correction of the defect.<sup>66</sup>

### Pubic-related groin pain

No epidemiological data are available in the literature regarding how common pubic-related groin pain is.

### Diagnostic criteria

The diagnostic criteria for pubic-related groin pain are:

- *local tenderness of the pubic symphysis and the immediately adjacent bone* (Fig. 32.3m)
- *no particular resistance tests to test specifically for pubic-related groin pain could be identified.*<sup>22</sup>

Verrall et al. described clinical signs including pubic symphysis and superior pubic ramus tenderness as part of a bone stress-related problem.<sup>67</sup> The presence of BMO on MRI in the pubic bone was also a part of the diagnosis. The clinical criteria included the presence of at least 6 weeks of groin pain, located in the adductor and/or pubic bone region and present during and/or after sporting activity. No particular resistance tests to test specifically for pubic-related groin pain have been identified, but squeeze testing seems to be the most relevant.<sup>68</sup>

In a study of 10 Australian rules football players with longstanding groin pain, using the criteria mentioned, biopsy was taken from the area in the superior pubic rami where MRI showed BMO. Histologically new woven bone was found and this was considered to represent a repair process that was the pathological stress reaction that was causing the groin pain. No controls with BMO but without symptoms were included and as such it is not known if the woven bone is a normal reaction to the stress the bone is receiving playing football or it is a sign of pathology.<sup>39</sup>

### Treatment

The treatment for this condition as described by Verrall et al. consists of mainly unloading the lower extremities and gradually increasing load again over a period of 3–4 months moving from rest from all weight-bearing running activities for 12 weeks over a period with stationary cycling, a stepping device and a gradual return to running activity.<sup>69</sup> The athletes were allowed to return to football training when 30 minutes of pain-free interval running was tolerated. There is no evidence-based treatment available.

### COMPLETE ADDUCTOR AVULSIONS

Complete proximal adductor avulsions (Fig. 32.13) are not common, but in American football (National Football League) the mean time for return to play in players treated conservatively for an acute adductor longus rupture was reported to be 6  $\pm$  3 weeks (range, 3–12 weeks).<sup>70</sup> A recent study of two different adductor ruptures in a soccer player suggests that adductor longus ruptures can have very different recovery times. In this study, normal hip adductor strength was obtained after 52 weeks for the first injury, but after 10 weeks for the second injury.<sup>71</sup> This highlights the importance of measuring hip adductor strength by using a hand-held dynamometer, as this gives important information on the actual recovery process of the adductors, which cannot be obtained from diagnostic imaging.

### LESS COMMON INJURIES

#### Obturator neuropathy

Obturator neuropathy is a fascial entrapment of the obturator nerve as it enters the adductor compartment

**Figure 32.13** MRI coronal short tau inversion recovery (STIR) view of adductor avulsion. Images display acute rupture and retraction of adductor longus tendon on right side (arrow), with acute oedema (high intensity) and haemorrhage in surrounding muscle tissues

**Figure 32.14** Obturator neuropathy—fascial arrangement

(Fig. 32.14). Obturator neuropathies have been reported to occur in Australian rules football and rugby. It has distinct clinical features that separate it from other causes of groin pain.<sup>72, 73</sup>

Obturator neuropathy presents as exercise-related groin pain, which initially is located in the proximal groin but with increasing exercise radiates towards the distal medial thigh. There may be associated weakness or a feeling of a lack of propulsion of the limb during running but numbness is very rarely reported. At rest, examination findings can be non-specific, with pain on passive abduction of the hip, and pain and weakness on resisted hip adduction. The ipsilateral pubic tubercle is often tender. The essential component of the physical examination is to exercise the patient to a level that reproduces the symptoms followed by immediate examination of the patient. This examination will reveal weakness of resisted adduction and numbness over the distal medial thigh. The diagnosis is confirmed by needle EMG, which shows chronic denervation patterns of the adductor muscle group.

Conservative treatment of this condition, including sustained myofascial tension over the adductor compartment, neural stretches, spinal mobilisation and ilio-psoas soft tissue techniques, is generally unsuccessful.

The definitive treatment of this condition is surgical. An oblique incision is made in the proximal groin. The plane between the adductor longus and pectineus is identified and dissected, revealing the obturator nerve under the fascia over the adductor brevis. This fascia is divided and the nerve is freed up to the level of the obturator foramen. The fascial anatomy here is important, with the fascia of the adductor longus curving around the muscle medially and passing back deep to the muscle to become the fascia over the adductor brevis, which is thought to be responsible for the fascial entrapment of the obturator nerve. Post-surgical management includes wound management, soft tissue techniques and a graduated return to full activity over a period of 4–6 weeks.

### Other nerve entrapments

A number of superficial nerves in the groin may become entrapped and should be considered as possible causes of

groin pain. The ilioinguinal nerve supplies the skin around the genitalia and the inside of the thigh and may produce pain as a result of entrapment. The genitofemoral nerve innervates an area of skin just above the groin fold. The lateral cutaneous nerve of the thigh is the most common nerve affected. This nerve supplies the outside of the thigh. This condition is known as 'meralgia paraesthetica' and is described in Chapter 33.

Pudendal nerve entrapment requires the presence of the following criteria: pain in the territory of the pudendal nerve (from the anus to the penis or clitoris); pain that is predominantly experienced while sitting; pain that does not wake the patient at night; pain with no objective sensory impairment; and pain relieved by diagnostic pudendal nerve block.<sup>74</sup>

Treatment of these conditions is usually not necessary as they often spontaneously resolve. Meralgia paraesthetica is sometimes treated with a corticosteroid injection at the site where the nerve exits the pelvis, 1 cm medial to the anterior superior iliac spine. Occasionally, the nerve needs to be explored surgically and the area of entrapment released.

### Stress fractures of the neck of the femur

Stress fracture of the neck of the femur is another cause of groin pain. The usual history is one of gradual onset of groin pain, poorly localised and aggravated by activity. Examination may show some localised tenderness but often there is relatively little to find other than pain at the extremes of hip joint movement, especially internal rotation. Plain radiograph may demonstrate the fracture if it has been present for a number of weeks but this investigation should not be relied on to rule out the condition; isotopic bone scan and MRI (Fig. 32.15) are the most sensitive tests.

Stress fractures of the neck of the femur occur on either the superior or tension side of the bone or on the inferior or compression side (Fig. 32.16). Stress fractures of the superior aspect of the femoral neck should be regarded as a surgical emergency and treated with either urgent internal fixation or strict rest. The concern is that such stress fractures have a tendency to go on to full fracture, which compromises the blood supply to the femoral head.

Stress fractures of the inferior surface of the femoral neck are more benign and can be treated with an initial period of non weight-bearing rest followed by a period of weight-bearing without running. They require at least 6 weeks of rest and usually considerably longer. Following the period of rest, a further 6 weeks of progressive loading will take the patient back to full training. Biomechanical (Chapter 8), nutritional and endocrine risk factors (Chapter 4) should be assessed and treated as appropriate.

**Figure 32.17** MRI stress fracture of the inferior pubic ramus. Images show subcortical hypointense line (arrow) representing bony stress fracture parallel to the symphyseal joint surface in the inferior pubic ramus

### Stress fracture of the inferior pubic ramus

Stress fracture of the inferior pubic ramus, especially in distance runners, is an important differential diagnosis of adductor tendinopathy. There is usually a history of overuse and localised tenderness, which is not aggravated by passive abduction or resisted adduction. In this condition, pain is often referred to the buttock.

A stress fracture may not be visible on plain radiograph for several weeks, whereas a radionuclide bone scan will

**Figure 32.16** Stress fractures of the neck of femur—superior or tension fracture on the superior aspect of the femoral neck, and inferior or compression fracture on the inferior side

demonstrate a focal area of increased activity within hours and an MRI (Fig. 32.17) will show a focal area of bone oedema. As with any stress fracture, aetiological factors must be considered. Stress fractures of the inferior pubic ramus in females may be associated with reduced bone density, low initial aerobic fitness and nutritional insufficiency. Prolonged amenorrhoea is also linked with this stress fracture (Chapter 4).

Treatment consists of relative rest from aggravating activities such as running until there is no longer any local tenderness. Fitness should be maintained with swimming or cycling with gradual return to weight-bearing over a number of weeks. Predisposing factors such as a negative energy intake, muscular imbalance or biomechanical abnormality also require assessment and intervention.

Preventative strategies can be incorporated, especially in the female military/elite athlete population. Strategies may include pre-training interventions focusing on improving aerobic fitness to reduce fatigue fractures, and calcium and vitamin D supplementation.<sup>75, 76</sup> Female recruits who report no menses during the year previous to recruitment should also be observed closely.<sup>76</sup>

### Referred pain to the groin

The possibility of referred pain to the groin should always be considered, especially when there is little to find on local examination. A common site of referral to the groin is the sacroiliac joint (SIJ) and this should always be assessed in any examination of a patient with groin pain. The SIJ may also refer pain to the scrotum in males

and labia in females. The assessment and treatment of sacroiliac problems are discussed in Chapter 30.

The lumbar spine may refer pain to the groin. The lumbar spine and thoracolumbar junction should always be examined in a patient with groin pain. Neurodynamic tests, such as the slump and neural Thomas tests, should be performed as part of the assessment (Chapter 15). Variations such as the addition of adduction or hip rotation may reproduce the patient's pain.

A positive neurodynamic test result requires further evaluation to determine the site of the abnormality. The position of reproduction of pain can be used to correct neural tightness by stretching. Active trigger points may also refer to the groin and should be treated with soft tissue therapy.

As mentioned in the section 'Terminology and definitions' there are many other conditions that can give rise to groin pain. When athletes present with groin pain that is not typical in nature, has no clear relationship with loading, nocturnal pain or pain associated with other non-musculoskeletal symptoms, one must think broadly in terms of possible differential diagnosis.

## PREVENTION OF GROIN INJURIES

By late 2016, seven RCTs had investigated prevention of sports injuries where data on groin injuries had been included. These seven studies were evaluated and analysed in a systematic review and the data was pooled in a meta-analysis.<sup>77</sup>

The studies examined the effect of different prevention interventions, predominantly looking at strengthening, coordination and balance exercises, and there were more than 2000 subjects in control and intervention groups, respectively. In total 157 injuries occurred, 68 in the intervention group and 89 in the controls. While the reduction is around 20%, this was not statistically significant. This means that at present, despite the number of trials examining groin injury prevention, there is no proven effective intervention. Due to the use of time loss definitions in the majority of studies, many overuse injuries will not have been registered, which is a limitation in the existing literature. Furthermore, compliance was not recorded in three studies and in the other four, compliance was less than intended.

Despite these limitations, including an active exercise strategy for strengthening and improving muscle function, load transfer and tolerance in the pelvic region may induce a relevant reduction of groin injuries. No reports of adverse events in relation to such a strategy have been documented. Clinicians and athletes should weigh up the time and effort that needs to be invested against the possible reduction to decide whether to implement in their setting.

## Possible prevention strategies

A number of measures can be considered in clinical practice. Given the fact that previous injury is a risk factor, athletes with a history of groin pain should be given extra attention. Research on soccer players during the start of a new season has shown that those who had groin pain in the previous season still had reduced function and residual symptoms after the summer break.<sup>78</sup> In this light, it would seem prudent for athletes with groin pain in season to use the off-season to concentrate on treatment and recovery rather than simply resting.

A careful examination should be done at the end of the season, as described in the 'Clinical overview' section. Any deficits found can be used to target improvements in the off-season and should be combined with sports-specific training. A study from elite ice hockey showed that those players who performed the least sports-specific training in the off-season had triple the risk for a groin injury in the next season.<sup>79</sup>

Little is known about the specific relationship between training load and groin pain. Recent literature from other fields has highlighted that athletes who have a rapid rise in training load, without sufficiently accumulating training to have ensured readiness are prone to injury. As such, careful consideration of training load can be part of groin injury prevention, but is likely to be part of a more general prevention strategy than only aimed at the hip or groin.

Monitoring players for changes in hip muscle strength in an attempt to predict the onset of groin pain was performed in a study on Australian rules football players.<sup>80</sup> Elite junior players ( $n = 86$ , 16–18 years old), were measured using squeeze tests on a weekly basis. They were also monitored for the presence of groin pain in the previous week. When they reported having groin pain 2 weeks in a row, this was considered to be the start of a groin injury.

The variation of the squeeze strength scores across the season was 2–3%. Twelve players developed groin pain and their strength in the week before the onset of the pain was reduced by  $12 \pm 3\%$  from their own baseline. As such, monitoring of strength and the onset of groin pain can be used to allow early detection and hopefully aid prevention. Furthermore, in those footballers where groin pain is encountered through continuous screening and examination, early detection and management seem to be highly relevant as a groin pain duration of only 1–2 weeks is associated with a much better HAGOS score at the beginning of the pre-season/new season, compared to individuals with longer durations of groin pain in the previous season.<sup>78</sup>

# Anterior thigh pain

with ZUZANA MACHOTKA

*It was the quad in my right leg, the tendon just kept tearing. I couldn't get back to the point of playing and obviously after having a really good start last season, and not playing again, it was frustrating.*

Joel Paris, promising Australian cricket fast bowler

The anterior thigh region (Fig. 33.1) is a common site of sporting injuries. Quadriceps muscle strains and contusions constitute the majority of these injuries; however, referred pain from the hip, sacroiliac joint (SIJ) or lumbar spine may also cause anterior thigh pain.<sup>1</sup> Stress fracture of the shaft of the femur is a less common but important diagnosis. A summary of the causes of anterior thigh pain is shown in Table 33.1.

(a)

(b)

**Figure 33.1** Anatomy of the anterior thigh (a) Surface anatomy (b) Muscles of the anterior thigh

(c)

**Figure 33.1 (cont.)** (c) Central tendon of the rectus femoris

## EPIDEMIOLOGY

Lower limb injuries, particularly thigh muscle injuries, are common in sport. In athletics, thigh muscle strains account for up to 13.5% of all injuries.<sup>1</sup> In professional soccer, up to a third of injuries involve lower limb muscles and 19% of all muscle injuries involve the quadriceps.<sup>2, 3</sup> Recurrent quadriceps muscle injuries are associated with a significantly longer period of rehabilitation and time to return to sport. Therefore, an accurate initial diagnosis and a structured rehabilitation program are essential to ensure a safe return to sport.

## FUNCTIONAL ANATOMY AND BIOMECHANICS

The thigh musculature is divided into anterior, medial and posterior compartments by intermuscular septa. The anterior compartment is the largest of the three, and includes the femur, quadriceps femoris and sartorius muscles. The quadriceps include the rectus femoris, vastus lateralis, vastus medialis and vastus intermedius muscles (Fig. 33.1b). Concentric contraction of the quadriceps muscles extends the knee against gravity, which is important in such activities as rising from sitting and climbing up stairs. Eccentrically, the quadriceps muscles have an important role in lowering body weight, for example during walking/running down hills and down stairs. The quadriceps muscles contribute enormously to acceleration and power during jumping and running. As a consequence, the quadriceps can be up to three times stronger than their antagonist muscle group, the hamstrings.<sup>4</sup>

The rectus femoris is the only quadriceps muscle to cross the hip joint and has two heads at its origin (Fig. 33.1c). Proximally, the direct head of the rectus femoris originates from the anterior inferior iliac spine and the indirect head originates from above the acetabulum. The two heads form a conjoint tendon just beneath their origin. The direct head is more superficial and has connections with the deep fascia of the thigh (fascia lata). The indirect head contributes to a deep

**Table 33.1** Causes of anterior thigh pain

Common	Less common	Not to be missed
Quadriceps muscle contusion ('cork thigh', 'charley horse') Quadriceps muscle strain <ul style="list-style-type: none"> <li>• distal rectus femoris</li> <li>• proximal rectus femoris</li> </ul> Myositis ossificans	Referred pain <ul style="list-style-type: none"> <li>• upper lumbar spine</li> <li>• sacroiliac joint</li> <li>• hip joint</li> </ul> Stress fracture of the femur Sartorius muscle strain Avulsion of the apophysis of rectus femoris Nerve entrapment <ul style="list-style-type: none"> <li>• lateral cutaneous nerve</li> <li>• femoral cutaneous nerve</li> </ul>	Slipped capital femoral epiphysis Perthes' disease (Chapter 44) Tumour (e.g. osteosarcoma of the femur) Acute compartment syndrome of the thigh

musculotendinous junction or 'central tendon', which can travel up to two-thirds of the muscle belly (Fig. 33.1c).<sup>5-7</sup> This complex anatomy and its biarthrodial (i.e. two joint) nature, may be why the rectus femoris is the most commonly strained quadriceps muscle.<sup>8</sup>

Distally, all four quadriceps muscles insert into the superior pole of the patella and continue to form the patellar tendon which, in turn, attaches to the tibial tuberosity. Overlying the quadriceps muscles is the sartorius muscle. The sartorius muscle passes medially from the anterior superior iliac spine to the superior/medial surface of the tibia in an arrangement called the pes anserinus (Chapter 37). The sartorius flexes, abducts, and laterally rotates the hip joint, flexes the knee joint and provides restraint to knee valgus forces. Despite its functional importance, the sartorius is less prone to strain injury because it works synergistically with other hip and thigh muscles.

The adductor canal is located deep to the sartorius muscle and extends from the apex of the femoral triangle (Chapter 32) to the adductor hiatus—the gateway to the popliteal fossa. The femoral artery and vein, saphenous nerve, and the nerve to vastus medialis are bundled together within the adductor canal. This site is commonly used to administer anaesthesia (femoral nerve block). Quadriceps weakness can occur following a femoral nerve block and should be monitored postoperatively because the quadriceps can atrophy rapidly following periods of immobilisation or decreased activation.<sup>9, 10</sup>

## CLINICAL APPROACH

In the anterior thigh, primary diagnoses frequently include contusions and strains. However, it is important that clinicians consider important factors that may influence the diagnosis and subsequent rehabilitation. These can include:

- details of previous injuries, including rehabilitation methods, time frames and outcomes
- the magnitude of any impairments in quadriceps strength, control and activation
- any hypermobility or hypomobility, particularly of the hip, knee and ankle joints
- psychological factors such as motivation, pain tolerance and readiness to return to sport.

## History

The two most important aspects of the history of a patient with anterior thigh pain are the exact site of the pain and the mechanism of injury. The site of the pain is usually well localised in cases of contusion or muscle strain. Contusions can occur anywhere in the quadriceps muscle but they are most common anterolaterally or in the vastus medialis obliquus. Muscle strains generally occur in the midline of the thigh anteriorly.

The mechanism of injury may help differentiate between muscle strains and contusions. A contusion is likely to be the result of a direct blow, whereas a muscle strain usually occurs when an athlete is striving for extra speed when running or extra distance when kicking. In contact sports, however, the athlete may have difficulty recalling the exact mechanism of injury.

Whether or not the athlete was able to continue activity, the present level of function and range of motion, night pain and the degree of swelling are all guides to the severity of the condition. Determine whether the POLICE regimen was implemented initially (see Chapter 17) and whether there were any aggravating factors (such as continued activity).

Gradual onset of poorly localised anterior thigh pain in a distance runner worsening with activity may indicate a stress fracture of the femur. Burning pain and associated paraesthesia suggest nerve involvement, and poor location of pain can suggest a referred pain from other areas such as the SIJ, hip joint and upper lumbar spine. Bilateral pain suggests the pain is referred from the lumbar spine.

## Physical examination

In anterior thigh pain of acute onset, the diagnosis is usually straightforward and examination can focus on local structures. In anterior thigh pain of insidious onset, diagnosis is more difficult and examination should include sites that refer pain to the thigh—the lumbar spine, SIJ and hip.

Muscle tightness and altered muscle activation around the pelvis and thigh can lead to asymmetries further down the kinetic chain. These asymmetries can alter how ground reaction forces are absorbed, particularly during high impact activities such as jumping and sprinting, thus predisposing athletes to further injury. In the patient with anterior thigh pain, assessing and treating muscle imbalances is often necessary to optimise movement patterns and address risk factors for further injury.

The aim of the examination is to determine the exact site of the abnormality and to assess range of motion and muscle strength. Functional testing may be necessary to reproduce the symptoms.

1. Observation (look for muscle bulk, wasting, swelling and position of patella. During activity, observe muscle activation, pelvic control, patella tracking and any signs of a limp)
  - a. standing
  - b. walking
  - c. supine
2. Active movements (are there any asymmetries?)
  - a. hip flexion
  - b. knee flexion
  - c. knee extension
  - d. active straight leg raise<sup>11</sup>

(a)

(b)

(c)

**Figure 33.2** Examination of the patient with anterior thigh pain (a) Passive movement—quadriceps stretch. A passive stretch of the quadriceps muscles is performed to end of range. Passive hip extension may be added to increase the stretch on the rectus femoris, which may reproduce the patient's pain (b) Resisted movement—knee extension. With the hip and knee flexed to 90°, the knee is extended against resistance (c) Resisted movement—hip flexion

3. Passive movements (consider what determines the end feel e.g. muscle spasm)
  - a. hip and knee (e.g. hip quadrant, knee hyper-extension)
  - b. muscle stretch (e.g. quadriceps) (Fig. 33.2a)
  - c. patella glides (Chapter 36)
  - d. Thomas test (Chapter 32)

4. Resisted movements (isometric or concentric. Graded using a 0-5 scale or with a hand-held dynamometer)
  - a. knee extension (Fig. 33.2b)
  - b. straight-leg raise
  - c. hip flexion (Fig. 33.2c)
5. Functional tests
  - a. squat (Fig. 33.2d) (single leg, ¼ squat vs full)
  - b. jump (vertical jumps, box jumps)
  - c. hop (on the spot, hop for distance)<sup>12, 13</sup>
  - d. kick (short vs long distance)
  - e. lunge (forward vs reverse eccentric lunges)
6. Palpation (consider firmness and if able, map out area of tenderness)
  - a. sartorius and quadriceps muscles (Fig. 33.2e)
  - b. femoral artery (the proximal two-thirds of a line drawn from the mid-inguinal ligament point to the adductor tubercle with the thigh flexed, abducted, and laterally rotated represents the course of the femoral artery and nerve)

(d)

(f)

(e)

(g)

**Figure 33.2 (cont.)** (d) Functional movements—squat. If the previous activities have failed to reproduce the patient's pain, functional movements should be used to reproduce the pain. These may include squat, hop or jump (e) Palpation—the anterior thigh is palpated for tenderness, swelling and areas of focal muscle thickening. A focal defect in the muscle belly may be palpated, especially with active muscle contraction (f) Special tests—the fulcrum test for the presence of a femoral stress fracture. This is performed with pressure over the distal end of the femur. Reproduction of the patient's pain may be indicative of a femoral stress fracture (g) Special tests—neurodynamic test (modified Thomas test). The patient is placed in the psoas stretch position. Cervical and upper thoracic flexion is added and then the clinician passively bends the patient's knee (using his or her own leg). Reproduction of the patient's symptoms indicates a neural contribution

(h)

**Figure 33.2 (cont.)** (h) The side-lying slump test—an extension of the standard prone knee bend test and focuses on the neural-sensitive structures of the anterior thigh (e.g. femoral nerve). Test starts with the subject in a side-lying position. Subject holds lower leg for stability in a comfortable, not fully flexed, position with head in cervical flexion. The assessor/therapist stands behind subject supporting the upper leg in a neutral hip position, maintaining neutral hip abduction/adduction throughout the test. With one hand over hip, the other hand is used to support the lower limb in approximately 90 degree knee flexion. Resting symptoms should be recorded (e.g. stretch through anterior thigh). The subject's hip is then extended, noting any changes in resting symptoms and/or position of thigh with onset of symptoms. If no symptoms are evoked, the leg is extended to the point of firm hip resistance. The subject is then asked to extend their neck and report any change in symptoms. The assessor should monitor for any changes in hip resistance before returning to starting position. Test should be repeated on the other side

#### 7. Special tests

- fulcrum test (Fig. 33.2f) (this test is reported to have excellent sensitivity and specificity for mid-shaft femoral stress fractures)<sup>14, 15</sup>
- neurodynamic testing (modified Thomas test Fig. 33.2g, femoral nerve test,<sup>16</sup> prone knee bend<sup>17</sup>, side-lying slump Fig. 33.2h)
- lumbar spine (Chapter 29)
- SIJ (Chapter 30)
- knee jerk reflex (present, strong, endurance)

### Key outcome measures

There are currently no patient-reported outcome measures that are specific to anterior thigh pain that can be used to monitor treatment progression. However, the lower

extremity functional scale (LEFS) is a reliable (ICC=0.92) and valid questionnaire that can be used to evaluate function for a variety of musculoskeletal conditions, including anterior thigh pain.<sup>18, 19</sup> The LEFS involves rating the difficulty of performing 20 functional activities from 0 (extremely difficult) to 4 (no difficulty). The highest possible score of 80 indicates a high level of function. The LEFS has a minimum detectable change of  $\pm 9$  points, a standard error of measurement of 4 points and a minimal clinically important difference of  $\pm 9$  points.<sup>18, 19</sup>

It is important to achieve symmetrical quadriceps strength following an anterior thigh injury. The gold standard measure of quadriceps strength is isokinetic dynamometry; however, few clinicians have access to this equipment. Hand-held dynamometers offer a clinically feasible alternative. Isometric quadriceps strength testing with a hand-held dynamometer has been found to be reliable (ICC=0.96) and to correlate moderately with isokinetic testing ( $r=0.62$ ).<sup>20</sup> However, due to variability in quadriceps strength between individuals, the minimum detectable change and minimal clinically important difference in quadriceps strength for patients with anterior thigh pain is not known.

### Investigations

Investigations are usually not required in athletes with anterior thigh pain, although magnetic resonance imaging (MRI) may have a role in the evaluation of the severity of rectus femoris strains, especially where injuries to the central tendon are suspected.<sup>5, 6</sup>

If a quadriceps contusion fails to respond to treatment, plain radiographs may demonstrate myositis ossificans. This is usually not evident until at least 3 weeks after the injury. Ultrasound examination or MRI will confirm the presence of a haematoma and may demonstrate early evidence of calcification.

If a stress fracture of the femur is suspected, plain radiograph is indicated. If this is normal, an isotopic bone scan or MRI can be ordered to further rule out the condition.

Although hip pathology most often refers to the groin (Chapter 32), it can refer to the anterior and occasionally lateral, thigh. In adults, hip impingement or osteoarthritis are likely diagnoses; in adolescents, consider a slipped capital femoral epiphysis (Chapter 44) or avulsion fracture, particularly when coupled clinically with an abnormal gait pattern. When thigh pain is associated with restricted or painful hip motion, imaging may be indicated.

### QUADRICEPS CONTUSION

Quadriceps contusion, known colloquially as 'charley horse' or 'cork thigh', is an extremely common injury caused by blunt trauma to the thigh. The injury affects both the connective tissue and muscle fibres. As the fibres are disrupted during blunt trauma, the intervening space fills up with blood, which later forms clots.

**Table 33.2 Distinguishing features of minor quadriceps contusion and grade I quadriceps muscle strain**

Diagnostic features	Quadriceps contusion	Grade I rectus femoris muscle strain
Mechanism	Contact injury	Non-contact
Pain onset	Immediate or soon after	After cool down (next day)
Behaviour of pain (24 hours post-trauma)	Improves with gentle activity	Painful with use
Location	Usually lateral or distal	Rectus femoris muscle belly (proximal or middle-third)
Bruising/swelling	May be obvious early	May be absent or delayed
Palpation findings	Tenderness more obvious, lump may feel ovoid or spherical, becomes progressively harder	May be difficult to find or may be a small area of focal tenderness with a characteristic ring of inflammation surrounding it Muscle spasm in adjacent fibres proximally and distally
Effect of gentle stretch	May initially aggravate pain	Not associated with pain
Strength testing	No loss of strength except pain inhibition	Loss of strength (may need eccentric or functional testing to reproduce pain)

It can sometimes be difficult to distinguish clinically between a contusion and a muscle strain (Table 33.2).

Quadriceps contusion is common in contact sports such as soccer and basketball. In sports such as hockey, lacrosse, and cricket, sporting equipment, such as a hockey stick, ball or puck travelling at high speed may cause a contusion.

Examination confirms an area of tenderness and swelling with worsening pain on active contraction and passive stretch. In severe cases with extensive swelling, pain may be severe enough to interfere with sleep. Assessing the severity of the contusion during the initial assessment is important when planning rehabilitation and return to sport.

Severity can be divided into mild, moderate and severe<sup>21</sup> and an appropriate time to return to sport can vary from several days to a number of weeks.<sup>21-23</sup> The degree of passive knee flexion after 24 hours can be used as a clinical indicator of the severity of the haematoma (Table 33.3).<sup>22</sup>

In severe cases it is important to identify the exact muscle(s) involved. MRI together with ultrasound are the most appropriate investigations.<sup>24</sup> Ultrasonography is useful in determining the precise location of the haematoma.<sup>25, 26</sup> MRI can provide greater insight into the extent and location of the haematoma and may provide greater prognostic value than ultrasound. An example of an MRI of a severe haematoma is shown in Figure 33.3.

**Table 33.3 Grading of quadriceps contusion**

Severity	Clinical features	Active knee flexion (°)
Mild	May or may not remember incident Usually can continue activity Sore after cooling down or next morning Normal gait, tender on palpation Minimal loss of strength	>90°
Moderate	Usually remembers incident but can continue activity, although may stiffen up with rest (e.g. half-time or full-time) Some pain on contraction Antalgic gait, tender on palpation May have associated knee effusion	45–90°
Severe	Usually remembers incident May not be able to control rapid onset of swelling/bleeding Difficulty with full weight-bearing Tender over large area (tracking) Obvious bleeding Loss of strength and function	<45°

**Figure 33.3** MRI appearance of severe haematoma (arrow) of the vastus intermedius muscle

It is important to appreciate that blood from contusions of the lower third of the thigh may track down to the knee joint and irritate the patellofemoral joint. This has been demonstrated in a study of quadriceps contusion in rugby players.<sup>27</sup> Quadriceps circumference and the knee brush/swipe test, used to detect swelling around the knee, were associated with greater recovery time, more missed games and a greater number of treatments sought.

### Treatment of quadriceps contusion

The most important period in the treatment of a thigh contusion is the first 24 hours following the injury. A player who suffers a thigh contusion should be removed from the field of play and receive the POLICE regimen (Chapter 17). If full weight-bearing is painful, crutches can help unload the muscle and can emphasise the serious nature of the condition to the athlete, team mates and coaches.<sup>22</sup> Generally the treatment of a thigh contusion can be divided into four stages:

- stage 1—control of haemorrhage
- stage 2—restoration of pain-free range of motion
- stage 3—functional rehabilitation
- stage 4—graduated return to activity.

A summary of the types of treatment appropriate for each stage is shown in Table 33.4. Progression within each stage, and from one stage to the next, depends on the severity of the contusion and the rate of recovery. For severe contusions, regular ice and compression over 2–3 days should be commenced straightaway. Massage, electrotherapy and stretching should be avoided in the first 3 days. After the initial period, electrotherapy with non-thermal effects (e.g. pulsed ultrasound) may be considered; however, evidence of the effectiveness of such interventions continues to be limited.<sup>28, 29</sup>

**Figure 33.4** Ice and compression treatment of an acute thigh contusion in a position of maximal pain-free stretch

#### PRACTICE PEARL

In the acute management of a thigh contusion, ice should be applied in a position of maximal pain-free quadriceps stretch (Fig. 33.4). Immobilising the knee in 120° of flexion immediately after injury and for the first 24 hours may be beneficial.<sup>30</sup> This is done by bandaging the entire lower limb. The patient then mobilises with crutches.

In the first 7–10 days after a moderate-to-severe contusion there is a considerable risk of re-bleed. The athlete must be careful not to aggravate the bleeding by excessive activity, alcohol ingestion or the application of heat. Care should also be taken with stretching and it should be pain-free in the initial stages. The aim of soft tissue therapy in the first few days after a thigh contusion is to promote lymphatic drainage. Excessively painful soft tissue therapy will cause bleeding to recur and is contraindicated for 48 hours following contusion.

Loss of range of motion is the most significant finding after thigh contusion and range of movement must be regained in a gradual, pain-free progression before return to athletic activity is considered. In a study of military cadets, Ryan et al. found average disability times of 13 days for mild contusions, 19 days for moderate contusions and 21 days for severe contusions.<sup>22</sup>

Protective padding, such as thigh pads and athletic pants with removable pads, may help attenuate direct contact forces to the anterior thigh. It has been suggested that athletes in high-risk sports should consider wearing thigh-protective padding routinely.<sup>31</sup> Players such as ruckmen in Australian rules football, forwards in

**Table 33.4 Treatment of moderate quadriceps contusion or grade II muscle strain**

Stage	Weight-bearing	Acute management	Soft tissue therapy	Stretching	Strengthening
1. Control haemorrhage	Crutches if FWB	POLICE, compression to include knee joint. If lower-third of thigh (Fig. 33.4)	Contraindicated	Gentle active stretch to onset of pain (no hold of stretch) (Fig. 33.5a)	Static muscle contraction if pain-free
2. Restore pain-free range of motion	Progress to WB and FWB as tolerated	Maintain compression bandage when limb is dependent. Ice after exercise	Grade I–II longitudinal gliding away from site of injury Grade II transverse gliding away from site of injury	Increase active stretches to passive stretches to regain ROM	Static muscle contraction, inner-range to through-range (Fig. 33.6a) Stationary exercise: bike Pool: pain-free (walk/swim/kick) Concentric and eccentric exercises (Fig. 33.6b), reverse Nordics (Fig. 33.6c)
3. Functional rehabilitation	FWB	NA	Longitudinal gliding Transverse gliding	Maintain stretch (Fig. 33.5b)	All stage 2 exercises gradually increasing repetitions, speed and resistance Include pulleys, rebounder, proffitter, wall squats, step-downs (Fig. 33.6d) Hopping/jumping, running. Increase eccentric exercises
4. Graduated return to sport	FWB	NA	Myofascial release techniques in knee flexion (Fig. 33.7)		Kicking action with pulleys Multidirectional activities Figure of eight Jumping Plyometrics Graduated specific sporting activities Must complete full training before return to sport Heat-retaining brace may be helpful

ROM = range of motion; PWB = partial weight-bearing; FWB = full weight-bearing

(b)

**Figure 33.5** Quadriceps stretching exercises (a) Standard quadriceps stretch while standing. It is important to have good pelvic control and not to lean forward while performing the stretch (b) Passive stretch. The tension of the stretch can be altered by adding hip extension

(a)

(b)

**Figure 33.6** Quadriceps strengthening exercises (a) Active quadriceps exercises. Initially inner-range quadriceps strengthening is performed with a rolled towel under the knee as shown. The range is slowly increased, depending on symptoms, until through-range quadriceps contraction can be performed without pain (b) Resisted quadriceps. Concentric and eccentric exercises are performed against gradually increased resistance. Knee extension involves concentric contraction of the quadriceps muscle, while lowering the foot from extension involves eccentric quadriceps contraction

(c-i)

(c-ii)

(d)

**Figure 33.6 (cont.)** (c) (i) and (ii) Reverse Nordics. Similar to the hamstring Nordic curl exercise but in the opposite direction. Subject/athlete starts in a kneeling upright position (i). The subject/athlete goes as far as they can (ii) until feeling a stretch in anterior thigh or until they cannot maintain neutral trunk position. Focus is placed on the knee being the pivot point while maintaining neutral trunk position throughout exercise (i.e. not breaking at the hips or increasing lumbar lordosis). Exercise can be performed either with ankles in full plantar flexion or on toes. Progressions include arms outstretched with hand weights or arms over head with a medicine ball (d) Functional exercises. A variety of functional exercises can be performed in the late stage of rehabilitation: squats, wall squats, stepdowns (shown), shuttle. Most of these involve both eccentric and concentric contraction of the quadriceps

basketball, and running backs in American football may sustain a series of minor contusions during the course of a game, which may have a cumulative effect and impair performance. Protective padding may help to reduce the severity of contusions; however, evidence for its effectiveness is currently limited.

**Figure 33.7** Soft tissue therapy—sustained myofascial tension in the position of maximal hip extension and knee flexion

## Complications related to contusion

### Compartment syndrome of the thigh

Intramuscular haematoma of the thigh after a blunt contusion may result in high intra-compartmental pressures and a diagnosis of compartment syndrome of the thigh. Symptoms often include pain and paraesthesia, and occur with intra-compartmental pressures greater than approximately 20 mmHg.<sup>32</sup> Pressures of greater than 30 mmHg over a duration of more than 6 hours can lead to irreversible damage.<sup>32, 33</sup> Unlike other compartment syndromes, there is no evidence that this condition needs to be treated by surgical decompression unless it occurs in conjunction with other significant injuries or medical conditions, for example fractured femur, coagulation defects.<sup>33</sup> A number of cases of surgery have been reported, but none described necrotic muscle or subsequent clinical evidence of muscle fibrosis, restriction of knee motion or loss of function.<sup>34</sup>

A case study detailing conservative management of an amateur soccer player who sustained a high-impact injury from an opposing player has been published.<sup>32</sup>

Conservative treatment included rest from any lower limb activity for the first 48 hours followed by gentle range of motion exercises of the hip and knee. This routine was slowly progressed over the following months and the athlete returned to soccer after 6 months. Success with conservative treatment can be achievable, but often requires a prolonged rehabilitation period.<sup>32</sup>

### Myositis ossificans

Occasionally, after a thigh contusion, the haematoma calcifies; that is, osteoblasts replace some of the fibroblasts in the healing haematoma and bone tissue is deposited within the muscle. This condition is known as myositis ossificans. The estimated incidence of myositis ossificans following a thigh contusion ranges from 9% to 20%.<sup>35</sup> It is unclear why some contusions develop calcification and others do not; however, the more severe the contusion, the more likely that an athlete will develop myositis ossificans.<sup>35</sup> Intramuscular contusions appear to be more susceptible to the development of myositis ossificans than intermuscular contusions.

In the acute phase, that is, the first week following the injury, there is a proliferation of fibroblasts into the area of injury.<sup>36</sup> The following 10 days, the sub-acute phase, are characterised by the infiltration of osteoblasts. In the final stage, bone is deposited within the muscle. By approximately 6–7 weeks, this bone growth ceases. At this stage a lump is often palpable and a plain radiograph (Chapter 3, Fig. 3.7a) can help to confirm the diagnosis. Ultrasound can demonstrate the myositis ossificans (Fig. 33.8a) however, MRI (Fig. 33.8b) is more sensitive in detecting the inflammatory oedema that precedes myositis ossificans and therefore may be more useful in the early stages.<sup>36</sup>

Symptoms of myositis ossificans include ongoing pain in the injured area, morning or night pain, decreased range of motion, local tenderness, stiffness and a palpable mass.<sup>37</sup> On palpation, the developing myositis ossificans has a characteristic 'woody' feel. If there is no convincing history of recent trauma, the practitioner must rule out differential diagnoses such as tumours (Chapter 7).<sup>38</sup>

The risk of myositis ossificans is especially high if the contusion results in prone knee flexion of less than 45° 2–3 days after the injury. Thus, particular care should be taken when managing a severe thigh contusion, as a significant re-bleed may result in the development of myositis ossificans. Inappropriate treatment after muscle injury, such as heat, massage and forced stretching, may increase the risk of developing myositis ossificans.<sup>39</sup> The incidence of myositis ossificans appears to be increased when a knee effusion is present.

Once myositis ossificans is established, there is very little that can be done to accelerate the resorption process. Treatment may include local electrotherapy to

reduce muscle spasm and gentle, painless range of motion exercises. Shock wave therapy has been suggested to improve function for patients with myositis ossificans; however, evidence for its effectiveness is limited.<sup>40, 41</sup> Acetic acid iontophoresis has been shown to be helpful in two case studies,<sup>42, 43</sup> while one case study described the intravenous use of bisphosphonate pamidronate.<sup>44</sup> However, neither method is widely used.

Indomethacin, which reduces new bone formation, has been prescribed as a preventative measure in

high-risk presentations such as severe contusions or those close to bone.<sup>35</sup> A corticosteroid injection is absolutely contraindicated in this condition. Surgery is contraindicated in the early stages and only considered when the margins of the ectopic bone are smooth on investigation, suggesting bone maturity. It must be noted that surgery can lead to recurrence post-surgery.<sup>35</sup>

## QUADRICEPS STRAIN

Strains of the quadriceps muscles are common and usually occur during sprinting, jumping or kicking. Fatigue, weakness, muscle imbalance and sprinting/kicking sports are proposed risk factors for quadriceps strains.

In soccer, quadriceps strains are often associated with over-striding when decelerating during running or under-striding during the deceleration phase of the kicking leg when kicking a ball on the run.<sup>45</sup> Among professional soccer players, quadriceps muscle injuries cause more missed games than hamstring and groin muscle injuries, and re-injury rates are high.<sup>3</sup> Strains are most common in the rectus femoris muscle, which is more vulnerable to strain than the other quadriceps muscles, because it passes over two joints—the hip and the knee.

### PRACTICE PEARL

The most common site of strain is the distal musculotendinous junction of the rectus femoris (see below). Management of this type of rectus femoris strain and of strains of the vasti muscles is relatively straightforward; rehabilitation time is short. Strains of the proximal rectus femoris are not as straightforward and are considered in a separate section later in the chapter.

## Distal quadriceps muscle strain

The grading of muscle strains such as distal quadriceps strains (Fig. 33.9a) has recently been reviewed and is discussed in Chapter 3. The athlete feels the injury as a sudden pain in the anterior thigh during an activity requiring explosive muscle contraction. There is local pain and tenderness, pain on stretching and resisted knee extension, and, if the strain is severe, swelling and bruising. If the athlete reports burning or paraesthesia, assessment should rule out femoral nerve injury and neural mechanosensitivity.

Pain on resisted active contraction and on passive stretching are typical signs in quadriceps strains. An area of local spasm is palpable at the site of pain.

Complete tears of the rectus femoris occur with sudden onset of pain and disability during intense

(a)

(b)

**Figure 33.9** Two types of quadriceps strains (a) The more common occurs at the distal musculotendinous junction of rectus femoris and has a better prognosis (b) The less common occurs in the proximal rectus femoris and takes longer to repair

ADAPTED FROM HASSELMAN ET AL. P.495

activity. A muscle fibre defect is usually palpable when the muscle is contracted. In the long term, they resolve with conservative management, often with surprisingly little disability.<sup>46</sup>

### Treatment

The principles of treatment of a quadriceps muscle strain are similar to those of a thigh contusion. The various treatment techniques shown in Table 33.4 are appropriate for the treatment of quadriceps strain; however, progression through the various stages may be slower for more severe injuries.

Although loss of range of motion may be less obvious for quadriceps strains compared to contusions, it is important that the athlete regains pain-free range of movement as soon as possible. Loss of strength may be more marked than with a thigh contusion and strength retraining should be emphasised in the rehabilitation program, with respect to the stage of healing. As with the general principles of muscle rehabilitation, the program should commence with low-resistance, high-repetition concentric strengthening exercises, and progress to higher resistance and eccentric strengthening exercises.

General fitness can be maintained by activities such as swimming (initially with a pool buoy) and upper body training. Functional retraining such as running and kicking should be incorporated as soon as it is safe to do so. Full training must be completed prior to return to sport. Unfortunately, quadriceps strains often recur; therefore, it is important to maintain an ongoing preventative program.<sup>47</sup> Prevention should focus on general flexibility of muscles of the thigh and leg, adequate balance of concentric and eccentric strength of the hip flexors and knee extensors and adequate core stability. Exercises based on deceleration under specific sport situations should be included in prevention programs for rectus femoris muscle injuries.

### Proximal rectus femoris strain

Strains of the proximal rectus femoris (Fig. 33.9b) can occur either at the conjoint tendon or at the deep musculotendinous junction of the indirect head.<sup>5, 7, 48</sup> A strain occurring at this musculotendinous junction has a worse prognosis than one occurring peripherally in the muscle belly.

Diagnosis of these deeper injuries is difficult because the physical assessment findings are often inconclusive. MRI can help diagnosis in this instance and demonstrates what is termed a 'bull's eye lesion'<sup>49</sup> (Fig. 33.10). A bull's eye lesion is present when a disruption is seen around the deep part of the proximal tendon.

Management of proximal rectus femoris strains is influenced by the location and severity of the injury, and the age and athletic demands of the individual. Most proximal rectus femoris strains are managed conservatively and surgical intervention is typically reserved for injuries that involve significant damage to the central tendon (Fig. 33.9). Conservative management aimed at symptom relief and avoidance of re-injury is recommended for most strains.

A study involving 10 professional soccer players reported that players took an average of 3.8 months to return to full training and playing after surgery.<sup>50</sup> Another study reported that professional Australian rules footballers took an average of 27 days to return to full training following central tendon lesions compared to 9 days for peripheral rectus femoris strains and 4.5 days for strains of the vasti muscles.<sup>51</sup>

The use of platelet-rich plasma (PRP) injections has been suggested for these recalcitrant injuries. This treatment is discussed more fully in Chapter 17. There is little evidence for its efficacy in the treatment of muscle injuries.

### Complete rectus femoris tear

Complete tears of the rectus femoris muscle are uncommon due to the length of the musculotendinous junction (approximately two-thirds of the muscle belly).<sup>5</sup> In three case studies of complete rectus femoris tears the time from injury to when the athlete sought treatment ranged from 5–7 months.<sup>51</sup>

The initial injury may be described as a deep tearing sensation. Patients complain of a tender anterior thigh mass, and weakness and/or pain with activities such as running and kicking. The anterior thigh mass may be associated with muscle retraction.<sup>5</sup> These signs and symptoms are likely due to the indirect (central tendon) and direct heads of the proximal tendon acting independently, creating a shearing phenomenon in contrast to what occurs in the normal rectus femoris.<sup>8</sup> Unlike typical strains, which present as focal lesions on MRI, rectus femoris proximal musculotendinous junction injuries have a longitudinal distribution of increased signal along the tendon (Fig. 33.10).<sup>5</sup>

### Avulsion injury

Adolescent athletes participating in sports that involve sprinting may sustain an avulsion injury of the anterior inferior iliac spine (AIIS)—the proximal attachment of the direct head of the rectus femoris muscle. These injuries are uncommon in skeletally mature athletes. Patients with greater than 2 cm displacement of the fragment from the AIIS, as determined by X-ray, may require surgery. However, most patients do not require surgery and return to sport after 10–12 weeks.<sup>52</sup>

(a)

(b)

**Figure 33.10** MRI of the proximal rectus femoris musculotendinous junction (a) MRI of a proximal rectus femoris tear in a 19-year-old man shows the characteristic 'bull's-eye' sign; this is made up of a halo of increased signal (white signal highlighted by white arrows) around the deep tendon (black tendon highlighted with a black arrow) (b) A comparable MRI of a similar injury, which differs only in the tendon having a low-signal intensity inside the bright halo (arrow). This is consistent with fatty atrophy in the tendon—the results of the injury having occurred a reasonable time in the past (chronic)

Injury to the indirect head of rectus femoris may be associated with concomitant injury to the hip joint labrum; or a HALTAR lesion (Hip Anterosuperior Labral Tear with Avulsion of Rectus femoris).<sup>52</sup> This injury has been described in both skeletally mature and skeletally immature athletes and is analogous with the SLAP lesion of the shoulder (Chapter 24). Athletes with rectus femoris injuries who do not progress as expected through rehabilitation may have sustained a concomitant hip labral injury and may require further investigation.

## Prevention

Warming up to reduce the risk of injury is common practice in sport. Stretching is commonly performed as part of the warm-up by athletes; however, recent evidence suggests that static stretching does *not* reduce the incidence of exercise-related injury.<sup>53-56</sup>

Furthermore, static stretching has been associated with impairments in muscular performance, particularly in the quadriceps and hamstring muscle groups.<sup>54, 57, 58</sup> On the other hand, studies have shown that dynamic stretching can enhance muscular performance, but as yet, no consensus exists on the most appropriate exercise parameters (e.g. duration and frequency).<sup>57, 59-61</sup> Dynamic stretches for the anterior thigh muscles can include walking quadriceps stretches, high knee pulls, forward leg swings, walking lunges and various running drills.

In addition to integrating dynamic stretching into the athlete's warm up, stretching and mobility exercises may also need to be addressed after and between training sessions and games. Prevention strategies for rectus femoris injuries include improving general flexibility of muscles of the thigh and leg, and a focus on both concentric and eccentric strength of the hip flexors and knee extensors.

The iliopsoas muscle has a mechanical relationship with the femoral nerve. If the iliopsoas muscle becomes restricted, the mobility of the femoral nerve may also be affected, in the same way that hamstring muscle restrictions can affect the mobility of the sciatic nerve (Chapter 34). Similarly, because the iliopsoas muscle functions synergistically with the rectus femoris in sprinting and kicking, iliopsoas weakness may increase the demand placed on the rectus femoris muscle.<sup>7</sup>

### PRACTICE PEARL

Flexibility and strengthening programs should address both the rectus femoris and the iliopsoas muscles, rather than considering these muscles in isolation.<sup>7</sup>

In sprinting, the risk for rectus femoris injuries may be highest during the acceleration (eccentric muscle actions in the early swing phase) and deceleration phases. Exercises that simulate this eccentric loading should therefore be included in prevention programs for rectus femoris muscle injuries. Exercises such as the reverse Nordic curl (Fig. 33.6c), forward deceleration and reverse lunge (with/without overhead medicine ball, Fig. 33.11) may improve the capacity of the rectus femoris to tolerate eccentric loads during sport.<sup>7</sup>

Adequate core strength and activation is necessary to counteract torsional forces of the spine, pelvis, and lower limb, particularly during kicking and changing direction. Preventative programs should therefore emphasise strength and activation of the trunk and gluteal muscles, using both isolated and functional tasks.

## LESS COMMON CAUSES

### Stress fracture of the femur

Stress fractures are common in the athletic population and are categorised as overuse injuries (Chapter 4). Femoral stress fractures can occur around the femoral neck, intertrochanteric and subtrochanteric regions (Chapter 32), and the femoral shaft.<sup>62</sup> Stress fractures in the distal femur can occur following anterior cruciate ligament (ACL) reconstruction surgery using transfemoral fixation and may be more common in athletes using accelerated rehabilitation programs.<sup>63, 64</sup> Stress fracture of the shaft of the femur should be suspected in an athlete, especially a long distance runner, who complains of a dull and poorly localised ache in the anterior thigh.<sup>14</sup>

Risk factors for developing femoral stress fractures include training errors, hard training surfaces (e.g. concrete), and poor footwear (ill-fitting, worn and inflexible such as military boots).<sup>62, 65</sup> Intrinsic risk factors include leg length discrepancies and excessive foot pronation or supination.<sup>65</sup>

Pain may be referred to the groin or knee and the athlete may present with an antalgic gait (especially in the case of femoral neck stress fractures).<sup>66</sup> Clinical assessment should include an assessment of lower limb alignment, particularly leg length and foot posture. Local tenderness, warmth and swelling may be present. The fulcrum test is a pain-provocation test that can be used to confirm the diagnosis (Fig. 33.2f).

Plain radiography may not be sensitive enough to detect changes in bone structure in the initial stages of a femoral stress fracture; however, MRI (Fig. 33.12) has excellent specificity (100%) and sensitivity (86-100%) for identifying femoral stress fractures.<sup>65</sup> Isotopic bone scans have excellent sensitivity (74-84%) but poor specificity (33%).<sup>65, 67</sup>

(a)

(b)

**Figure 33.11** Reverse lunge with overhead medicine ball: Subject starts in a comfortable split lunge position (a), medicine ball over head. Subject then performs a backwards lunge (b), focusing on placing weight through the behind leg until thigh is vertical. The knee should remain behind the toes of the forward leg

**Figure 33.12** MRI of a stress fracture of the shaft of the femur

False positives associated with bone scans include bone infections and tumours. Differentiating between a bone stress reaction and a stress fracture on a bone scan can be challenging because the size of the uptake on the scan may not correlate with the magnitude of the pathology.

Stress fractures are more prevalent among female athletes. The 'female athlete triad', discussed in Chapter 4, is a specific risk factor for stress fractures in females (low energy availability with or without disordered eating, menstrual dysfunction and low bone mineral density).<sup>68, 69</sup>

#### PRACTICE PEARL

There may be tenderness over the shaft of the femur that can be aggravated if the patient sits with the leg hanging over the edge of a bench, particularly if there is downward pressure placed on the distal femur, the so-called 'hang test' or 'fulcrum test' (Fig. 33.2f).

Treatment of femoral stress fractures depends on the location and type of fracture, but all treatment should initially involve rest from painful activities and maintenance of aerobic fitness with cycling, deep water running or swimming. Weight-bearing as tolerated is often permitted; however, cam boots and crutches may be considered for athletes who are unable to weight bear without pain. Underwater and anti-gravity treadmills may be beneficial for these athletes.<sup>70</sup> Surgery is indicated where a fracture has become displaced.

When the fulcrum test is completely negative, on average after 7 weeks, it is thought to be safe to initiate return-to-sport progressions in rehabilitation.<sup>15</sup> To avoid associated complications, such as a complete fracture, bone healing must be confirmed before the athlete returns to play.<sup>9</sup>

In females with stress fractures, menstrual disturbance information should be sought and corrected where possible through the aid of bone mineral density tests and endocrine function tests. Nutritional input may be considered for those identified with eating disorders.

### **Lateral femoral cutaneous nerve injury ('meralgia paraesthetica')**

Lateral cutaneous nerve of thigh (LFCN) injury, also known as 'meralgia paraesthetica', can be a cause of anterolateral thigh pain.

#### **Anatomy**

The LFCN is a sensory nerve that originates from the lumbar plexus (L2, L3 spinal nerves) and runs along the lateral border of the psoas major muscle, across the iliacus muscle, and exits the abdomen under the inguinal ligament close to the anterior superior iliac spine (ASIS). From here it crosses the sartorius muscle and divides into anterior and posterior branches.

The posterior branch pierces the fascia lata and runs distally supplying the skin of the lateral thigh from the greater trochanter to mid-thigh region. The anterior branch supplies the skin approximately 10 cm below the inguinal ligament and distally to the proximal knee. It should be noted that the anatomical course can have many variations between individuals and is susceptible to compression injury where it exits the pelvis.<sup>71</sup>

#### **Clinical biomechanics**

Repeated hip flexion and extension during sporting activity (e.g. gymnastics) can irritate the nerve, and entrapment can occur around the ASIS between the ilium and the inguinal ligament.<sup>72</sup> Obesity and pregnancy increase intra-abdominal pressure and can compress the nerve via the distended abdomen where the nerve leaves the pelvis.<sup>73</sup> Tight-fitting garments and athletic

compression garments can lead to symptoms. Entrapment as a result of wearing weight belts in scuba divers has also been reported.<sup>74</sup>

The LFCN is susceptible to injury via blunt trauma around the ASIS and the anterior thigh, especially in contact sports such as rugby.<sup>72</sup> Repeated falls from a balance beam in gymnastics may also cause injury.<sup>74</sup> Surgical procedures are a risk factor for LFCN injury, irritation and entrapment.<sup>32, 75, 76</sup> Injury to the LFCN has been reported following hip arthroscopy because this nerve lies approximately 3 mm from the anterior portal.

#### **Clinical features**

Symptoms include pain, burning, numbness, and paraesthesia of the anterolateral thigh without loss of reflex or motor control.<sup>74, 75</sup> Sporting activity can aggravate symptoms, while sitting may alleviate symptoms by altering the length and tension within the nerve and associated tissues.<sup>71, 72, 77</sup> Differential diagnoses include femoral nerve injury and referred pain (discussed below). Sensory changes and symptoms exacerbated by hip extension can help to confirm the diagnosis.<sup>71</sup>

#### **Management**

Treatment is often conservative, with a period of rest and manual therapy until symptoms have resolved. One case series has suggested that Kinesio taping is beneficial, but evidence continues to be limited.<sup>78</sup> Anti-inflammatory medications can be beneficial in the early phases.<sup>75</sup> If symptoms do not settle quickly, other interventions such as a local injection of corticosteroid and surgical interventions (either nerve decompression or neurectomy) can be considered, but these interventions currently have limited evidence.<sup>73</sup> Thigh and hip pads can be used as preventative strategy in high-contact sports.<sup>72</sup>

#### **Femoral nerve injury**

The femoral nerve passes between the psoas major and the iliacus muscles and exits the abdomen deep to the inguinal ligament through the femoral canal. In the upper thigh, the nerve gives off motor branches to the quadriceps, sartorius and pectineus muscles. The sensory branches supply the skin of the anterior thigh. The femoral nerve then continues distally as the saphenous nerve.

Injury to the nerve can occur secondary to hyperextension of the hip, such as seen in gymnasts, dancers, soccer players, basketball players and long jumpers.<sup>72, 74</sup> Gymnasts and dancers performing manoeuvres that involve extreme hip extension coupled with knee flexion are susceptible to femoral nerve injury.<sup>74</sup>

Previously, injury was thought to be due to traction placed on the nerve. However, it is now thought to be secondary to muscle strain of the iliopsoas muscle, where

the local haematoma causes compression of the nerve.<sup>72, 74</sup> Psoas bursitis can also lead to compression and irritation.<sup>74</sup>

Pain is often located around the inguinal region. Reduced power of the knee extensors and/or reduced knee jerk may also be present.<sup>72, 74</sup> Sometimes, despite motor changes, sensation can be normal.<sup>74</sup>

Conservative treatment is normally trialled first until symptoms settle. Return to sport is possible when strength in the lower limb is regained.

### Referred pain

Referred pain may arise from the hip joint, SIJ, lumbar spine (especially upper lumbar) and neural structures. Patients with referred pain may not have a history of injury and may have few signs suggesting local abnormalities. An increase in neural mechanosensitivity may suggest that referred pain is contributing to thigh pain. The modified Thomas' test (Fig. 33.2g) is the most specific neurodynamic tension test for a patient with anterior thigh pain.

If the modified Thomas' test reproduces anterior thigh pain and altering the neural mechanosensitivity (e.g. passive knee flexion/extension) affects the pain, the lumbar spine and psoas muscle should be examined carefully. Any areas of abnormality should be treated and both the local signs (e.g. reproduction of pain with functional testing) and neurodynamic tests should be repeated to assess any changes. The slump knee bend test (side-lying slump) (Fig. 33.2h) has good reliability, excellent sensitivity and specificity, and can be used in patients with suspected lumbosacral radicular pain.<sup>16, 79</sup> The test is considered positive if the symptoms can be reproduced and if the intensity of the symptoms can be influenced by changing the nerve tension.<sup>16</sup>

As with any soft tissue injury, local and referred factors may contribute to the patient's symptoms. Commonly there is hypomobility of the upper lumbar intervertebral

**Figure 33.13** Deep soft tissue treatment to the psoas muscle

segments on the affected side associated with a tight psoas muscle. Mobilisation of the hypomobile segments and/or deep soft tissue treatment to the psoas muscle will often reduce symptoms (Fig. 33.13).

# Posterior thigh pain

with CARL ASKLING and ANTHONY SCHACHE

*You know, this is a different hamstring—I did my left hamstring, I've done the right side of my back, I've just done my right hammy . . . obviously I've got injury concerns at the moment, now I have to go back and do what the experts tell me to give myself the best chance of being fully fit.*

Michael Clarke, Australian cricket captain, December 2014

Pain in the 'hamstring region' can prove very frustrating for recreational and amateur athletes and may be career threatening for professional athletes. Hamstring muscle strains are the most common cause of posterior thigh pain, but referred pain to this area is also common. The average number of days until return to play (RTP) for hamstring injuries depends on the severity of the injury, but has been found to range between 18–60 days in elite level soccer players.<sup>1</sup>

The incidence of recurrence is high. Up to one-third of hamstring injuries will recur, with the greatest risk being during the initial 2 weeks following return to sport.<sup>2</sup>

In this chapter, we focus on:

- relevant anatomy which is critical to diagnosis, prognosis and management
- clinical distinction between the major pathologies in the patient with posterior thigh pain
- the role of diagnostic imaging for this injury
- treatment approaches for the two types of acute hamstring injuries and for referred pain
- the indications for considering early or late surgical treatment
- how to make the often difficult return-to-play decision
- preventing the rightfully feared setback—hamstring strain recurrence.

### FUNCTIONAL ANATOMY

The hamstring muscle group (Fig. 34.1) consists of three main muscles: biceps femoris, semimembranosus and semitendinosus. Biceps femoris has two heads: a long head and a short head. The long head is innervated by

the tibial portion of the sciatic nerve (L5, S1–3), whereas the short head is innervated by the common peroneal portion (L5, S1–2).

The proximal hamstring complex (Fig. 34.1c) is a common site for pathology and has a complex anatomical arrangement.<sup>3</sup>

(a)

**Figure 34.1** Anatomy of the posterior thigh (a) Surface anatomy

(b)

(c)

(d)

**Figure 34.1 (cont.)** (b) Muscles of the posterior thigh  
(c) Proximal hamstring origin (d) Anatomical arrangement of the long and short heads of biceps femoris

The long head of biceps femoris and semitendinosus share a common proximal tendon that arises from the medial facet of the ischial tuberosity. Semitendinosus muscle fibres originate from the ischial tuberosity and the medial aspect of the common tendon; the biceps femoris long head muscle fibres originate from the lateral aspect of the common tendon approximately 6 cm below the ischial tuberosity (Fig. 34.1d). The proximal free tendon of semimembranosus arises from the lateral facet of the ischial tuberosity and has a length of more than 10 cm. Moving distally, it extends medially passing ventral (deep)

to the semitendinosus/biceps femoris long head common proximal tendon.

The short head of biceps femoris arises from the linea aspera and thus only acts about the knee joint. Semitendinosus inserts onto the anteromedial surface of the proximal tibia (as part of the pes anserine muscle group), whereas semimembranosus inserts onto the medial tibial condyle. Biceps femoris long head and short head form a common distal tendon that has several insertions, including the lateral femoral condyle, fibula head, popliteus tendon and arcuate popliteal ligament.<sup>4</sup>

Both the proximal and distal tendons of the biceps femoris extend approximately 60% of the length of the muscle (Fig. 34.1d).<sup>5</sup> As such, the biceps femoris muscle-tendon junction (a common site of injury) has a relatively unique arrangement that comprises two parts: the proximal muscle-tendon junction extending along the medial border and the distal muscle-tendon junction extending along the lateral border, with an area of overlap in the mid-zone of the muscle belly.

The ischiocondylar portion of the adductor magnus functions as if it was a 'hamstring' due to its anatomical alignment and innervation. Adductor magnus is a strong hip extensor muscle, especially when the hip is flexed. The ischiocondylar portion is innervated by the tibial portion of the sciatic nerve, like the majority of the hamstring group.

## CLINICAL APPROACH

The key to effective management of posterior thigh pain is correct diagnosis. The clinician must determine whether the injury to the posterior thigh is an acute muscle injury (e.g. strain or contusion) or pain referred from elsewhere (e.g. lumbar spine). This differentiation can sometimes be challenging.

In healthy individuals, a strain to a large muscle group such as the hamstrings is the result of substantial force. The athlete will typically recall a particular point in time that the incident occurred and whether a significant force was applied to the muscle. The incident may be related to an eccentric contraction (e.g. sprinting) or it may be associated with an excessive stretch (e.g. ballet dancing).

Tethering of neural structures or fascial strains in the posterior thigh can also occur as an incident; however,

appropriate examination will reveal whether the injury has a neuromechanical or fascial component. Although the clinical examination may not present differently to a low-grade strain, the absence of evidence of muscle injury on magnetic resonance imaging (MRI) (10–20% of posterior thigh pain presentations) should make the clinician highly suspicious of a referred cause of pain.<sup>6–9</sup>

The causes of posterior thigh pain are shown in Table 34.1.

## History

Because there are different causes of posterior thigh pain, the clinician should use the history to develop a differential diagnosis that can then be refined further with a physical examination that is then appropriately structured.

Clinicians consider a wide range of factors in the history of the patient with posterior thigh pain. Some of these include the following.

1. Level of activity
  - a. Has a change in training coincided with injury?
  - b. Is there an adequate base of training?
2. Occupation/lifestyle
  - a. What factors outside of sport could be aggravating the condition (e.g. prolonged sitting at work, repetitive bending over with young children)?
3. Incident
  - a. Yes: consider strain, fascial/neural trauma.  
If there was an incident, then what was the mechanism of injury? This information will help determine optimal rehabilitation exercises. Also, what was the severity of the pain experienced at the time of the injury? This information is important because a greater maximum pain score (visual analogue scale [VAS] 0–10) is associated with a longer time to RTP. For example, a VAS pain score of greater than 6 out of 10 has been shown to be significantly associated with an RTP time of >40 days.<sup>8, 10, 11</sup>
  - b. No: consider overuse, referred pain, alternative abnormality.
4. Immediate impact on function
  - a. Being forced to stop participating in sport within 5 minutes of the initial incident is associated with an increased time to RTP.<sup>11</sup>
5. Progress following injury
  - a. Slow: indicates a more severe injury
  - b. Erratic: strain is being aggravated by activity or injury is not a strain.
6. Ability to walk pain-free within one day following injury.  
A study involving Australian rules football players found that those who could not walk pain-free within 1 day

### PRACTICE PEARL

Clinicians should be reticent to diagnose an acute muscle strain in the absence of a convincing history of injury. Without a strong history of injury, consider referred pain.

**Table 34.1 Causes of posterior thigh pain**

Common	Less common	Not to be missed
Hamstring muscle strains <ul style="list-style-type: none"> <li>• Type I</li> <li>• Type II</li> <li>• Recurrent</li> </ul> Hamstring muscle contusion Referred pain <ul style="list-style-type: none"> <li>• Lumbar spine</li> <li>• Neural structures</li> <li>• Gluteal trigger points</li> </ul>	Referred pain <ul style="list-style-type: none"> <li>• Sacroiliac joint</li> </ul> Tendinopathy <ul style="list-style-type: none"> <li>• Biceps femoris</li> <li>• Semimembranosus/semitendinosus</li> </ul> Bursitis <ul style="list-style-type: none"> <li>• Semimembranosus</li> <li>• Ischiogluteal</li> </ul> Fibrous adhesions 'Hamstring syndrome' (Chapter 30) Chronic compartment syndrome of the posterior thigh Apophysitis/avulsion fracture of the ischial tuberosity (in adolescents) Nerve entrapments <ul style="list-style-type: none"> <li>• Posterior cutaneous thigh</li> <li>• Sciatic</li> </ul> Adductor magnus strains Myositis ossificans, hamstring muscle	Tumours <ul style="list-style-type: none"> <li>• Bone tumours</li> </ul> Vascular <ul style="list-style-type: none"> <li>• Iliac artery endofibrosis</li> </ul>

were four times more likely to require >3 weeks to RTP compared to those who could.<sup>12</sup> Note, however, that a more recent study involving athletes from a variety of sports did not confirm this relationship.<sup>13</sup>

#### 7. Aggravating factors

- Incident related: useful for specificity of rehabilitation (e.g. acceleration injuries require acceleration in the rehabilitation program)
- Non-incident related: eradication or modification for recovery and prevention (e.g. sitting at a computer causing back/hamstring pain requires ergonomic modification).

#### 8. Behaviour with sport

- Warms up with activity, worse after: inflammatory pathology
- Starts with minimal or no pain, builds up with activity but not as severe after: claudicant, either neurological or vascular
- Sudden onset: mechanical (e.g. strain).

#### 9. Night pain

- Sinister pathology
- Inflammatory condition.

#### 10. Site of pain

- Posterior thigh and/or lower back: lumbar referral or neuromotor/biomechanical mediator
- Buttock, sacroiliac joint (SIJ) without lower back symptoms: gluteal trigger points
- Ischial: tendinopathy/bursitis/apophysitis/avulsion.

#### 11. Presence of neurological symptoms

- Nerve involvement

#### 12. Recurrent problem

- Extensive examination and rehabilitation required
- History of hamstring injury in the previous season is a strong predictor of risk of recurrence. For example, Australian Football players with a recent history of hamstring injury are 20 times more likely to suffer a recurrence within 3 weeks of RTP than those without a history.<sup>12</sup>

#### PRACTICE PEARL

Two items in the above list are particularly important:

- **3-the severity of the pain at the time of injury**
- **12-whether it is a recurrent problem.**

#### Physical examination

The examination further refines the distinction between local injury (i.e. acute muscle strain), referred pain or other unusual causes. A practical approach to assess various factors that commonly cause posterior thigh pain is outlined below.

##### 1. Observation

- standing (Fig.34.2a)
- walking
- lying prone

##### 2. Active movements

- lumbar movements
- hip extension
- standing leg swing
- supine active knee extension (Fig.34.2b)

3. Passive movements
  - a. hamstring muscle stretch (Fig.34.2c)
4. Resisted movements
  - a. knee flexion in isolation
  - b. hip extension in isolation
  - c. combined contraction—single leg bridge (Fig.34.2d)
5. Functional tests
  - a. running
  - b. kicking
  - c. sprint starts
6. Palpation
  - a. hamstring muscles (Fig.34.2e)
  - b. ischial tuberosity
  - c. gluteal muscles (Fig.34.2f)

(a)

(b)

(c)

(d)

**Figure 34.2** Examination of the patient with posterior thigh pain (a) Observation. Look for wasting, bruising or swelling of the posterior thigh. Observation of gait is also important. Observation of the lumbar spine may show the presence of an excessive lordosis or relative asymmetry. A lateral view may demonstrate excessive lumbar lordosis or anterior pelvic tilt (b) Active movement—active knee extension. The hip is actively flexed to  $90^\circ$  with the knee initially at  $90^\circ$  also. The knee is then slowly extended until pain is felt and then to the end of range (c) Passive movement—hamstring muscle stretch. The leg is raised to the point where pain is first felt and then to the end of range, pain permitting. Movement should be compared with the uninjured side (d) Combined contraction—single-leg bridge. A widely used ‘quick’ clinical assessment of resisted hamstring contraction is the single-leg bridge. This can be done with the knee fully extended or flexed to  $90^\circ$  (or any angle in between these two positions)

(e)

(g)

(f)

**Figure 34.2 (cont.)** (e) Palpation. Palpate carefully bearing the underlying anatomy in mind to determine the location of an acute muscle strain (e.g. medial versus lateral hamstring, proximal versus distal etc.) (f) Palpation—gluteal muscles. Palpate the gluteal muscles for trigger points that are taut bands, which are usually exquisitely tender locally and may refer pain into the hamstring muscle (g) Special tests—slump test. The slump test (Chapter 15) is an essential part of the examination of the patient with posterior thigh pain. It helps the clinician differentiate between hamstring muscle injuries and referred pain to the hamstring region from the lumbar spine

## 7. Special tests

- a. neuromechanical tests: slump test (Fig.34.2g)
- b. lumbar spine examination (Chapter 29)
- c. sacroiliac joint (Chapter 30)
- d. assessment of lumbopelvic stability (Chapter 11)
- e. biomechanical analysis (Chapter 8).

## Investigations

Investigations of posterior thigh pain can be very useful but clinicians must interpret these findings together with the rest of the examination. Appropriate imaging may include ultrasound (Fig. 34.3a), MRI (Fig. 34.3b) and at times, computed tomography (CT). MRI is the most

(a)

(b)

**Figure 34.3** Imaging of hamstring injuries (a) Ultrasound showing hypoechoic area (between electronic callipers, +) (b) MRI demonstrating area of oedema in hamstring consistent with biceps femoris muscle tear

popular option (especially for the elite-level athlete) because it is non-invasive and capable of providing high-resolution images.<sup>13–16</sup>

#### PRACTICE PEARL

MRI can help identify the presence and location of pathology, contribute to determining the likely prognosis in certain instances, and monitor healing over time.

### Integrating the clinical assessment and investigation to make a diagnosis

Table 34.2 summarises elements of the history, physical examination and investigations that point to whether the diagnosis is likely to be an acute hamstring muscle injury or referred pain to the posterior thigh.

### ACUTE HAMSTRING MUSCLE STRAINS

Before outlining type I and type II hamstring injuries, we briefly outline the epidemiology of these injuries

**Table 34.2** Clinical features of hamstring muscle tear and referred hamstring pain

Acute hamstring strain (type I or II)	Referred pain to posterior thigh
Sudden onset	May be sudden onset or gradual feeling of tightness
Moderate to severe pain	Usually less severe, may be cramping or 'twinge'
Disabling—difficulty walking, unable to run	Often able to walk/jog pain-free
Markedly reduced stretch	Minimal reduction in stretch
Markedly reduced contraction with pain against resistance	Full or near to full muscle strength against resistance
Local haematoma, bruising	No local signs
Marked focal tenderness	Variable tenderness, usually non-specific
Slump test negative	Slump test frequently positive
May have gluteal trigger points	Gluteal trigger points that reproduce hamstring pain on palpation or needling
May have abnormal lumbar spine/SIJ signs	Frequently have abnormal lumbar spine/SIJ signs

together. As the differentiation of acute hamstring injuries into two types has only recently been recommended, it is not possible to confidently separate epidemiological data.

#### PRACTICE PEARL

In the large majority of hamstring strains, the injured muscle is biceps femoris (83% of all hamstring injuries). Semimembranosus injuries are uncommon (12%) and semitendinosus injuries are rare (5%).<sup>1</sup>

### Epidemiology

Acute hamstring strains are common in many popular sports, including the various football codes, field hockey, cricket and athletics. For example, hamstring strains are the most common injury in Australian rules football, constituting 15% of all injuries, with an incidence rate of six injuries per club (approximately 40 players) per season and a cost of 21 missed matches per club per season.<sup>17</sup> Similarly, in English soccer, hamstring strains make up 12% of all injuries, with an incidence rate averaging five injuries per club per season, resulting in 15 matches and 90 days missed.<sup>18, 19</sup>

Approximately 180 hamstring injuries occur in the 30 teams in the American National Football League (NFL) each year, so the incidence of approximately six injuries per team per season is similar to the AFL. Mean days lost per injury has been found to be 13.2.<sup>20</sup> Twelve per cent of all injuries in European elite-level soccer are hamstring injuries. A typical 25-player squad

experiences 4–6 hamstring injuries during a season with a mean of 14.3 days lost per injury (standard deviation 14.9).<sup>21</sup> A study of American collegiate soccer players noted that men were 64% more likely than women to sustain a hamstring strain.<sup>22</sup>

The average injury severity has been reported to be between three to four missed matches per injury.<sup>17, 23</sup> Hamstring injuries in ballet have not been captured as well as in football codes but estimates of lifetime prevalence of hamstring injury are as high as 51% (34% acute, 17% overuse).<sup>24</sup>

With respect to epidemiology of recurrence, acute hamstring strains have the highest recurrence rate of any injury, with a rate of 20% in AFL,<sup>25</sup> 16.5% in American NFL<sup>20</sup> and 16% in European soccer.<sup>21</sup> It has also been shown in collegiate soccer that recurrence is more common for men than women.<sup>22</sup>

### Type I and type II acute hamstring strains— not all acute hamstring injuries are the same!

There are at least two distinctly different types of acute hamstring strains (types I and II), distinguished by different injury situations. The more common, type I, hamstring strains occur during high-speed running (Fig. 34.4a).<sup>26–32</sup> Type II hamstring strains occur during movements leading to extensive lengthening of the hamstrings in hip flexion combined with knee extension, such as high kicking, sliding tackle and forward split (Fig. 34.4b), and may occur at slow speeds.<sup>26–29, 31</sup>

Type I strains (the high-speed running type) usually involve the long head of biceps femoris, most commonly at

(a)

(b)

**Figure 34.4** (a) Sprinting is the classic activity that causes type I hamstring strains (b) Type II hamstring strains occur with maximal stretching (e.g. dancer's forward split shown with right hamstring under tension)

(A AND B) ISTOCKPHOTO

**Figure 34.5** (a) Type I strains (the high-speed running type) are mainly located to the long head of biceps femoris and typically involve the proximal muscle–tendon junction (b) Type II injuries (the stretching type) are typically located close to the ischial tuberosity and involve the proximal free tendon of semimembranosus<sup>31</sup>

the proximal muscle-tendon junction (Fig. 34.5a).<sup>26, 27, 30–32</sup> In contrast, type II injuries (the stretching type) are typically located close to the ischial tuberosity and involve the proximal free tendon of semimembranosus (Fig. 34.5b)<sup>27, 31</sup> thus the stretching type of hamstring strain can in fact be considered a primary tendon injury.<sup>33</sup>

Type I strains (e.g. high-speed running) generally cause a more marked acute decline in function, but typically require a shorter rehabilitation period than type II stretching-type hamstring strains (Fig. 34.6).<sup>34</sup> The injury mechanism and location can give us important information about the prognosis of the injury.<sup>26–28, 30, 34</sup> The injury location can be determined both by maximal pain palpation and by MRI during the first 2 weeks after injury occurrence. The closer the site of maximum pain palpation to the ischial tuberosity, the longer the rehabilitation period. An injury site closer to the ischial tuberosity has been reported to be associated with a longer rehabilitation period,<sup>26, 27, 31, 32, 35</sup> however, a recent study by Moen did not confirm this relationship.<sup>13</sup> MRI should always be performed when a total rupture is suspected.

**(a)** **Figure 34.6** Comparison of hamstring injuries in sprinters (type I) and dancers (type II) (a) Hip flexibility (range of motion) of the injured leg expressed as a percentage of the uninjured leg in the sprinters (n=18) and dancers (n=15). The sprinters' injuries (type I) resulted in more reduction in flexibility, but similar times to return to near pre-injury flexibility levels<sup>34</sup> REPRODUCED WITH PERMISSION OF BRITISH JOURNAL OF SPORTS MEDICINE

(b)

(c)

REPRODUCED WITH PERMISSION OF BRITISH JOURNAL OF SPORTS MEDICINE

### Type I acute hamstring strain: sprinting-related

Although there are a variety of sports skills that can potentially heavily load the hamstrings (e.g. kicking, twisting, jumping, hurdling), sprinting is the most commonly reported mechanism of type I acute hamstring muscle strain.<sup>8, 23, 36, 37</sup>

Why do hamstrings fail during sprinting? Biomechanical studies suggest that hamstrings are most vulnerable to injury during the terminal swing phase of sprinting,<sup>38, 39</sup> a time in the stride cycle where they are highly activated as they work eccentrically to decelerate the swinging tibia and control knee extension in preparation for foot strike.<sup>40</sup>

Patients who present with type I acute hamstring strain typically complain of sudden onset pain in the hamstring region that usually stops them. On examination, careful palpation and testing will usually locate the injury in the long head of biceps femoris, often the proximal muscle-tendon junction.<sup>26, 27, 31, 32</sup> Type I strains are generally associated with a more marked acute decline in function than type II strains.

If imaging is deemed necessary (e.g. if presence of type I acute hamstring strain is unclear on clinical grounds), then MRI (Fig. 34.7) would be the current recommended imaging modality because it is non-invasive and of high resolution. The only disadvantage is cost (rarely an issue for the elite athlete). MRI can be helpful in accurately identifying the location of the injury (semimembranosus versus biceps femoris long head versus semitendinosus;

**Figure 34.7** MRI showing type I hamstring injury

distal versus proximal; tendon versus muscle-tendon junction versus epimysium).

For two reasons, the role of MRI in predicting prognosis following type I acute hamstring muscle strains is currently uncertain. First, simple clinical parameters (Table 34.2) are just as good if not better predictors of prognosis than MRI-based parameters.<sup>11, 13</sup> Second, most of the studies investigating the prognostic value of MRI-based parameters are considered to have a high risk of bias and thus findings must be interpreted cautiously,<sup>15</sup> although a recent high-quality study has found increased cranio-caudal length of lesion on MRI to be positively correlated with longer time to RTP.<sup>41</sup> If there is a clinical suspicion of total tendon rupture, then MRI should always be performed.

## Type II acute hamstring strain: stretch-related (dancers)

Type II acute hamstring strains more commonly occur in sports that necessitate large amplitude movements and ballistic limb actions, such as ballet dancing and gymnastics. The common mechanism of injury in these instances is an excessive stretch into hip flexion.

In contrast to type I injuries, the stretching-type injuries typically are located close to the ischial tuberosity and involve the proximal free tendon of semimembranosus.<sup>26, 27, 35, 42</sup> MRI shows the site of the type II injury close to the ischial tuberosity (Fig. 34.8).

Although type II hamstring strains can cause a less dramatic acute limitation than type I strains, their rehabilitation period is often longer than that of type I strains.<sup>26, 27, 34</sup> It is important to directly inform the athlete that the rehabilitation is likely to be prolonged. Unrealistically optimistic information will only reinforce the disappointment and frustration of the injured athlete. The athlete can often do quite demanding rehabilitation training early on, as long as pain-provoking exercises are avoided. Passive stretching and heavy load exercises seem to aggravate the stretch-type of hamstring injuries by increasing pain.

## Prognosis of hamstring injuries

The following factors have been shown to be associated with increased length of time to RTP, although in some instances the evidence is conflicting.

- Time (days) to walk normal pace pain-free has been shown to be significantly associated with RTP time (>1 day = 4 times more likely to take >3 weeks). Combining this with a past history of hamstring injury

**Figure 34.8** MRI shows the site of the type II injury close to the ischial tuberosity

within 12 months resulted in a 93% chance of taking longer than 3 weeks to return in elite AFL players.<sup>12</sup> However, note that a more recent study involving athletes from a variety of sports has failed to confirm this relationship.<sup>13</sup>

- Days to jog pain-free has been found to be a strong predictor of time to RTP.<sup>8</sup>
  - 1-2 days  $\leq$  2 weeks to RTP
  - 3-5 days  $\geq$  2 weeks to RTP
  - >5 days  $\geq$  4 weeks to RTP
- MRI-negative 'hamstring strains' are associated with relatively rapid time to RTP and are relatively common (10-20%).<sup>6, 8, 9, 43</sup>
- Several studies have found the more proximal the site of injury, the more prolonged the time to RTP,<sup>26, 27, 31</sup> although this relationship was not confirmed in a recent study.<sup>13</sup>
- Injury to the intramuscular ('conjoint' or 'central') tendon of biceps femoris long head is associated with a long time to RTP (e.g. around 3-4 months), much longer than an injury only involving the muscle-tendon junction or epimysium.<sup>35, 44-46</sup> (See below.)
- A 'kicking' or 'slow-stretching' mechanism of injury is associated with a longer rehabilitation period than a high-speed running mechanism, even though initial signs and symptoms may actually present as far less severe.<sup>26, 27, 34</sup>
- Greater self-predicted time to RTP.<sup>13</sup>
- Forced to stop training/playing within 5 minutes following onset of pain.<sup>11</sup>
- Greater maximum pain intensity experienced at the time of injury.<sup>10, 11</sup>
- Longer length of hamstring tenderness with palpation (cm).<sup>11</sup>
- Passive range of motion deficit (injured versus uninjured side) recorded within a few days of injury occurrence using the passive straight leg raise test<sup>13</sup> or the active knee extension test.<sup>47</sup>
- Longer craniocaudal length of lesion on MRI.<sup>6, 41</sup>

### PRACTICE PEARL

Clinicians need to watch out for the type I acute hamstring muscle strain of the proximal biceps femoris long head that is associated with a longitudinal split or partial rupture of the proximal conjoint tendon (as visualised on MRI). These particular injuries require a prolonged rehabilitation period.

### Intramuscular tendon injuries

Injuries to the musculotendinous junction of the proximal or distal intramuscular tendons (Fig. 34.1d) are common. Occasionally the tendon itself is injured. On MRI scanning, the disrupted intramuscular tendon has a wavy retracted appearance as opposed to its normal taut cord-like appearance (Fig. 34.9a). Sometimes the tendon failure occurs like a piece of string, with disrupted tendon strands overlapping each other and offering some scaffold for healing to occur (Fig. 34.9b). In some cases, there is longitudinal delamination and splitting of the intramuscular tendon (Fig. 34.9c), which otherwise appears continuous. In other cases, the tendon may retract and create a gap (Fig. 34.9d).

These injuries have particular clinical significance due to prolonged healing rates and possible increased risk of recurrence.<sup>44, 46</sup> It is increasingly thought that surgical intervention for this latter pathology offers a predictable and steadfast pathway for healing. An example of a split proximal intramuscular tendon is shown on MRI (Fig. 34.9e) and surgical appearance (Fig. 34.9f). Regardless, of whether conservative or surgical treatment is employed, studies have shown that the RTP time frame is typically 8-10 weeks. High resolution MR scans can help in making the distinction as to whether strands of the disrupted intramuscular tendon rachis remain in broad continuity or are separated and retracted.

### Management of hamstring injuries

Six RCTs evaluated the efficacy of a particular intervention for the rehabilitation of acute hamstring

strains.<sup>26, 27, 41, 48–50</sup> While these studies have provided clinicians with some important information, more research is required to fully elucidate the best treatment

**PRACTICE PEARL**

Progression through phases of rehab program must NOT be time-dependent. Sometimes what initially appears to be a rather minor injury can take an extended period to fully recover and vice versa. Progression must be based on successfully achieving key functional and/or clinical criteria (see Table 34.3).

options, particularly with regards to avoiding recurrence following RTP. Hence, the approach below remains largely based on clinical experience. Management of acute hamstring strains is summarised in Table 34.3.

Rehabilitation programs require a basic structure, but should never be a 'recipe'. Treat each case on its merits. The following is a suggested structure, which is similar to that recommended by other experienced clinicians.<sup>43, 51</sup>

### Acute management phase

Acute injuries should always be assessed thoroughly before any treatment is administered. The fundamental objective of the acute management phase is to facilitate myofibre regeneration and minimise fibrosis. If strategies aimed at minimising scar tissue formation are instituted immediately, then such strategies may reduce the chances of injury recurrence.

#### Rest, ice, compression, elevation

Traditionally, the most common treatment in the first few days or thereabouts following type I acute hamstring strain is the rest, ice, compression, elevation (RICE) program. For example, applying ice for 10-15 minutes using a cold pack, every 3-4 hours, for the first few days until acute symptoms settle. Compression can be achieved in-between times via an elastic bandage or Tubigrip™ stocking.

#### Muscle activation

Although RICE would still be the recommended initial approach, recent research in cell therapy and tissue engineering is indicating an additional role for controlled and monitored exercise (or muscle contraction) regimens. Muscle contraction promotes angiogenesis (i.e. the formation of new blood vessels and the expansion of existing vascular trees) and in doing so increases the likelihood of delivering muscle-derived stem cells to the injured region. These cells are likely derived from the vascular endothelium and offer great potential for providing long-term myofibre regeneration.<sup>52</sup> Another aim of early pain-free muscle contractions is to prevent neuromuscular inhibition around the injured area. Note that this recommended

approach to muscle healing is consistent with the concept of 'mechanotherapy'.<sup>53</sup>

The commencement of frequent (e.g. 3-4 times per day), low-grade, pain-free muscle contractions (e.g. simple isometric hamstring contractions or active prone knee bends) immediately following injury would appear advantageous (Fig. 34.10). Such exercises should be biased as much as possible towards selective activation of the injured muscle.

### Medical therapies

A number of different medical therapies have been used in the management of acute hamstring muscle injuries. There is little evidence to support their use.<sup>54</sup>

Despite the widespread use of nonsteroidal anti-inflammatory drugs (NSAIDs) in the treatment of hamstring injuries, the two randomised controlled studies

(a)

(b)

**Figure 34.10** Early pain-free muscle contraction (a) Single-leg hip extension exercise with whole leg a few centimetres off the plinth (b) Active prone knee bends

failed to show beneficial or superior effects of NSAIDs compared to analgesics or placebo on acute muscle strain injuries.<sup>12, 55</sup> It is likely that simple analgesics are just as effective without the long-term risks on skeletal muscle and the gastrointestinal system associated with NSAIDs.

One study showed favourable results with intramuscular corticosteroid injection in American football players with acute hamstring injuries.<sup>56</sup> Previously, the use of corticosteroids in acute muscle strains had been clearly contraindicated because they were thought to delay elimination of haematoma and necrotic tissue, as well as retard muscle regeneration. There are concerns regarding the retrospective nature of the NFL study and lack of control group, so we caution against the use of corticosteroids in this situation in light of the fact that there have been no further studies confirming these results.

The pros and cons of delivering growth factors via autologous blood or platelet-rich plasma (PRP) injections are discussed in Chapter 17. A number of studies have investigated the effect of PRP administration specifically in hamstring muscle injuries.

One study suggested that a single autologous PRP injection combined with a rehabilitation program was significantly more effective in treating hamstring injuries than a rehabilitation program alone;<sup>57</sup> however, a number of subsequent studies of higher quality have shown no significant benefit.<sup>58–60</sup> At this stage, there is insufficient evidence to recommend the use of PRP in acute hamstring muscle injuries.

The combined injection of Traumeel® S and Actovegin®, a deproteinised calf-blood haemodialysate, immediately after a hamstring muscle injury and again at days 2 and 4 post-injury to the area of the muscle strain and the lumbar spine is common practice in sports medicine in Germany, and has been used elsewhere in some instances, despite the lack of any controlled trials supporting its use.<sup>61, 62</sup> A pilot study with limited subjects and a poor methodology reported a significant difference in subjective recovery and the RTP time in athletes following the intramuscular administration of Actovegin into grade I muscle tears, but there is no further evidence available.<sup>63</sup>

In summary, there is currently no good scientific evidence to support the use of any medication in the management of hamstring muscle injuries.

### Criteria for progression to subacute phase

Once the athlete is pain-free with walking and adequate/sufficient force can be generated without pain on resisted hamstrings contraction, then jogging can commence and gradually increased.

In some instances, the athlete can experience considerable improvement in clinical signs and symptoms within 4–6 days post-injury. However, the clinician must remember that the healing process is still in its initial stages and the risk for re-injury is high, as the injured tissue is unlikely to be able to tolerate maximal loads. The criteria for progression to the subacute phase are shown in Table 34.3.

**Table 34.3 Criterion-related rehabilitation of hamstring muscle strains**

Phase	Key criteria
1. Begin running/active rehabilitation (i.e. begin subacute phase)	Pain-free walking Adequate force with resisted muscle contraction
2. Return to full training (i.e. begin functional phase)	Complete resolution of <b>any</b> symptoms with maximal resisted muscle contraction Equivalent tenderness upon palpation (left = right) Full and symptom free range of movement/flexibility (left = right) Successful completion of a structured running program (i.e. maximum sprinting speed achieved at the end of the running program is comparable to the athlete's previously recorded benchmark when uninjured) Successful completion of appropriate rehabilitation exercises Successful completion of controlled functional (sports-specific) tasks simulating the original injury mechanism
3. Return to play (RTP)	Successful completion of <b>at least one</b> full week of normal training load with no adverse reaction in any clinical and/or functional signs and symptoms Additional quantitative tests of hamstring function (e.g. hand-held dynamometry, isokinetic dynamometry, Askling H-test (below), the single-leg bridge capacity test, performance on Nordic eccentric hamstring exercise); compare data for injured limb to uninjured limb or to data collected prior to injury No adverse psychological characteristics, such as apprehension regarding RTP or fear of re-injury

### Subacute/conditioning phase

#### Stretching

The role of targeted hamstring stretching in the rehabilitation of hamstring strain injury should be considered on an individual basis (Fig. 34.11). There is some limited evidence to suggest that rate of recovery can be increased with an increased daily frequency of hamstring-stretching exercises.<sup>49</sup> Consequently, to prevent long-term loss of range of motion (e.g. perhaps from significant scar tissue), a controlled stretching program can be instituted. However,

(a)

(b)

**Figure 34.11** Hamstring stretches (a) Hamstring stretch with contralateral knee flexion. The lower leg can be placed in different degrees of external and internal rotation to maximise the effectiveness of the stretch (b) Hamstring stretch with bent knee results in maximal stretch to the upper hamstrings

in our clinical experience, most athletes regain their normal range of motion without the need for excessive or aggressive hamstring-stretching regimens.

It may be more important to focus on stretching of other structures. For example, tight hip flexor muscles, if present, may place the athlete at greater risk of hamstring strain.<sup>64, 65</sup>

#### Manual therapy

A comprehensive clinical examination of the lumbar spine, sacroiliac and buttock regions should be instituted at an early stage to assess whether or not these regions have any contribution to the presenting injury. For example, Cibulka et al. reported that mobilisation of the sacroiliac joint was of some benefit in the treatment of acute hamstring strains.<sup>48</sup>

Neural mobility restriction is frequently present in hamstring injuries secondary to bleeding around the sciatic nerve. Neural mobilising exercises should be performed to reduce adhesions. Neural mobilising can be performed in the hamstring stretch position (Fig. 34.11) by adding gentle cervical flexion.

Soft tissue techniques can be used in the treatment of hamstring strains. Sustained compression (Fig. 34.12a) and sustained myofascial tension (Fig. 34.12b) are used, gently at

(a)

**Figure 34.12** Soft tissue techniques in the treatment of hamstring injuries (a) Sustained compression force to hamstring

(b)

**Figure 34.12 (cont.)** (b) Sustained myofascial tension combined with passive knee extension. The hand or the elbow (illustrated) is kept stationary and the release is performed by passively extending the knee (arrow)

first and then more vigorously. Longitudinal massage along the muscle may assist in optimising scar reorganisation. Abnormalities of the gluteal muscles may be associated with hamstring strains. These regions may be treated in a side-lying position using elbow ischaemic pressure with the tissue on stretch (Fig. 34.13).

#### Strengthening for hamstring muscles

Strengthening is an essential component of the rehabilitation and prevention of hamstring injuries. When designing a strengthening program, the clinician needs to consider the following parameters: the type of contraction (i.e. eccentric/isometric/concentric), the length of the muscle-tendon unit (i.e. lengthened/optimal/shortened) and the speed of contraction (i.e. slow/fast rate of force development). A further consideration is selective recruitment (i.e. medial versus lateral), as different exercises tend to preferentially activate different parts of the hamstring muscle group.<sup>66–68</sup> A comprehensive strengthening program will therefore require a variety of exercises.

**Figure 34.13** Treatment of the gluteal region in a side-lying position using elbow ischaemic pressure

Most hamstring strain researchers probably agree that the strains occur when the hamstring muscle group is extensively lengthened, especially in the stretching-type<sup>35, 42</sup> injury, but also in the sprinting type of injury.<sup>40, 69</sup>

It is also generally accepted that retraining needs to be specific to muscle function and as much as possible to the specific hamstring muscle injured (i.e. most commonly biceps femoris long head).<sup>70–73</sup>

Based on this concept, training programs for the rehabilitation of hamstring injuries should include exercises emphasising eccentric muscle contractions and extensive lengthening. It is also recommended to use exercises that load the hamstrings about the hip and the knee simultaneously, since three of the four hamstring muscles are bi-articular.

Recent clinical trials have shown that a rehabilitation program emphasising lengthening-type exercises (L-protocol) is more effective after acute hamstring injuries in elite footballers/sprinters/jumpers than a program

containing inner range exercises such as supine single leg bridging and standing hip extension against a pulley.<sup>26, 27</sup>

The L-protocol (lengthening) consists of three exercises (the extender, the diver and the glider) specifically aimed at loading the hamstrings during extensive lengthening, shown and explained in detail in Figures 34.14. The extender is aimed mainly at increasing flexibility, the diver is a combined exercise for hamstring strength and trunk/pelvis stabilisation, and the glider is more of a specific eccentric hamstring exercise. The L-protocol could be started 3–5 days after injury occurrence and no pain should be provoked.<sup>26, 27</sup>

Another recent clinical trial<sup>41</sup> compared a rehabilitation program containing progressive running and eccentric strengthening to a program containing progressive agility and trunk stabilisation exercises. The time taken to RTP was similar for both programs.

There are a wide variety of strengthening exercises that load the hamstrings eccentrically and involve simultaneous hip and knee joint motions. Figure 34.15 illustrates some of the more popular exercises:

(a)

(b)

(c)

**Figure 34.14** The L-lengthening protocol recommended by Askling (a) The Extender (aimed mainly at increasing flexibility) The subject should hold and stabilise the thigh of the injured leg with the hip flexed approximately 90° and then perform slow knee extensions to a point just before pain is felt. Perform twice every day, 3 sets with 12 repetitions (b) The Diver (combined exercise for hamstring strength and trunk/pelvis stabilisation) The exercise should be performed as a simulated dive, that is, as a hip flexion (from an upright trunk position) of the injured, standing leg and simultaneous stretching of the arms forwards and attempting maximal hip extension of the lifted leg while keeping the pelvis horizontal; angles at the knee should be maintained at 10–20° in the standing leg and at 90° in the lifted leg. Due to its complexity, this exercise should be performed very slowly in the beginning. Perform once every other day, 3 sets with 6 repetitions (c) The Glider (a specific eccentric strength exercise). The exercise is started from a position with upright trunk, one hand holding onto a support and legs slightly split. All the body weight should be on the heel of the injured (here left) leg with approximately 10–20° flexion in the knee. The motion is started by gliding backwards on the other leg (note low-friction sock) and stopped before pain is reached. The movement back to the starting position should be performed with the help of both arms, not using the injured leg. Progression is achieved by increasing the gliding distance and performing the exercise faster. Perform once every third day, 3 sets with 4 repetitions

(f)

One study has confirmed the efficacy of the Nordic drops in developing hamstring strength.<sup>74</sup> Other studies have shown that Nordic exercises are effective in preventing both new and recurrent hamstring injuries (see below).<sup>75–77</sup>

The Nordic strengthening program shown in Table 34.4 is based on the Mjolsnes and Arnason studies.<sup>74, 75</sup> It is designed for a 5–10 week pre-season training program. Because of the eccentric load, it is important to ensure that there is at least one day between sessions and that the loads are adjusted if excessive delayed onset muscle soreness (DOMS) results, as this may affect compliance. If the program is continued in-season, then one session per week is adequate.

Generally, low grade/minor hamstring injuries or first-time injuries will progress quickly; therefore, functional strength may be adequate to allow return to sport. In this situation, an exercise such as the single-leg bridge catch (Fig. 34.15b) is probably sufficient.

(g)

**Figure 34.15 (cont.)** (f) The single-leg reverse dead lift. The athlete holds a kettle bell in one hand and flexes forward at the hip while maintaining the lumbar spine in a neutral position. Note that in this instance the non weight-bearing limb is NOT used as a counter lever to specifically increase the load on the hamstrings of the weight-bearing limb. The exercise can be progressed by increasing the weight of the kettle bell, the depth of movement (i.e. the amount of hip flexion) and the speed of movement (i.e. drop/catch) (g) Yo-Yo machine

More severe or recurrent injuries require more advanced strength exercises and high-level eccentric loading (e.g. Nordic eccentric hamstring exercise, single-leg reverse dead lift, L-protocol). Eccentric muscle training results in muscle damage and DOMS in those unaccustomed to it. Therefore, any eccentric strengthening program should allow adequate time for recovery, especially in the first few weeks.

#### Strengthening for hamstring synergists

Rehabilitation must not be restricted to the hamstring muscles alone—it must also include exercises to target muscles that assist the hip extensor function of the hamstrings, such as the gluteus maximus and adductor magnus muscles. Thus, if gluteal and adductor magnus strength is inadequate in a sprinting athlete, it is possible that the hamstrings will be overloaded.

The gluteus maximus acts during running to control trunk flexion of the stance leg, decelerate the swing

**Table 34.4** Pre-season training protocol for Nordic hamstring exercises

Week	Sessions per week	Sets and repetitions	Load
1	1	2 × 5	Load is increased as subject can withstand the forward fall longer. When managing to withstand the whole range of motion for 12 repetitions, increase load by adding speed to the starting phase of the motion. The partner can also increase loading further by pushing at the back of the shoulders
2	2	2 × 6	
3	3	3 × 6–8	
4	3	3 × 8–10	
5–10	3	3 × 12/10/8	

leg and extend the hip.<sup>78</sup> Therefore, any alteration in gluteus maximus activation, strength or endurance may place greater demand on the hamstrings to control hip extension of the stance leg and decelerate the leg during the swing phase. Overall, the gluteus maximus provides powerful hip extension when sprinting.<sup>79</sup>

The hip extensor moment arm of the gluteus maximus is largest when the hip is in extended, whereas the hip extensor moment arm of the adductor magnus is largest when the hip is flexed.<sup>80</sup> Thus, the gluteus maximus is a strong hip extensor of the extended hip, whereas the adductor magnus is a strong hip extensor of the flexed hip.

To improve gluteus maximus activation, strength and endurance, initially teach good motor patterns and isolate the gluteus maximus from hamstrings, commencing bridges with both legs then progressing to one leg, and finally progress to high load hip extension exercises such as the barbell hip thrust (Fig. 34.16a).<sup>81</sup> Other hip extensor strength exercises that load both the gluteus maximus and adductor magnus in addition to the proximal hamstrings include squats (Fig. 34.16c) and deep lunges (Fig. 34.16d).<sup>66, 79, 82</sup>

#### Neuromuscular control exercises

Neuromuscular control of the lumbopelvic region, including anterior and posterior pelvic tilt, may be required to promote optimal function of the hamstrings in sprinting and high-speed skilled movement. For example, a rehabilitation program focusing on progressive agility, neuromuscular control and lumbopelvic stability exercises has been shown to be more effective in preventing injury recurrence than a more traditional stretching and simple strengthening exercise program.<sup>50</sup> Furthermore, the time taken to RTP appears to be similar for progressive agility and trunk stabilisation exercises compared to progressive running

and eccentric strengthening.<sup>41</sup> Progressive agility and trunk stabilisation exercises include fast feet drills, side-stepping, karaoke side-stepping, single-leg balance

(a)

(b)

**Figure 34.16** Gluteus maximus and adductor magnus strengthening exercises: barbell hip thrust (a) starting with hips flexed and (b) moving hips into extension

(c)

(d)

**Figure 34.16 (cont.)** (c) squat (d) deep lunge

(Fig. 34.17), single-leg stand windmill touches (moving in and out of a body weight arabesque position) and supine single-leg bridging.<sup>41, 50</sup>

It may also be important to consider motor control exercises for the deep lumbar spine stabilisers (e.g. multifidus). Such exercises can involve isolated activations in prone lying, and then progress to functional postural control exercises against gravity (e.g. sit-to-stand action, inclining the trunk forwards by flexing at the hip while maintaining an extended posture at the lower lumbar spine, performed against resistance). Recent studies have found motor control training to be effective in reducing lower-limb injuries in Australian rules football players.<sup>83, 84</sup>

Other examples of advanced neuromuscular control exercises for the lumbopelvic region and entire lower extremity are discussed in Chapter 11.

#### Functional progression

Early commencement of a structured running program is an important part of the rehabilitation

**Figure 34.17** Lumbopelvic stability exercises—single-leg balance. A quarter squat can be added

### Key principles to consider when designing a running program following hamstring muscle strains

1. Running sessions may be completed 5–6 times per week in the initial stages of the rehabilitation process when volume and intensity is low (if so desired). However, once the sessions become more advanced, a day on/day off approach is recommended (i.e. 3 times per week). Running on a day on/day off basis allows the athlete sufficient time to recover and adapt between sessions. The clinician can assess key clinical signs the following day and make a judgment as to whether or not the athlete has tolerated or reacted adversely to the load. The structure of the next running session can then be planned accordingly.
2. Running can commence once the athlete is capable of producing adequate force with resisted muscle contraction and has no pain with walking or other everyday activities. Begin with slow jogging intervals and then progress to fartlek-type running as tolerated (e.g. 15–20 repetitions of a 10-second walk followed by a 20-second jog followed by a 30-second run).
3. Once the athlete is capable of achieving approximately 50% pace without symptoms or apprehension, then running may be progressed to a structured running program that involves repeated strides over a distance of 60–90 m at a prescribed intensity. In order to increase the dose of high-speed running in the latter stages of the rehabilitation process, extra interval running at a safe intensity can be completed in addition to the structured running program (e.g. 150 m or 200 m repetitions).
4. Load on the hamstrings increases with faster running.<sup>40</sup> Therefore, running speed both within a session and from one session to the next should always be progressed in a graduated manner. Rapid increments in running intensity must be avoided, especially during the early stages of the rehabilitation process.
5. The warm-up prior to running should consist of jogging as well as footwork and agility drills.<sup>41, 50</sup>
6. Sprinting technique drills should also be integrated into the running program (e.g. as part of the warm-up). Sprinting technique drills have been shown to be effective in improving an athlete's lower-limb joint position sense (or proprioception).<sup>85</sup> Furthermore, poor lower-limb joint position sense has been linked with greater risk of hamstring strains in Australian rules football players.<sup>86</sup>
7. Sport-specific training drills should be included in the final stages of the rehabilitation process.<sup>87</sup> Ideally, these drills should simulate as closely as possible the original mechanism of injury.

B

process following a hamstring muscle strain. The basic principles of the running program are outlined in the box above. Once the athlete has successfully completed all running progressions as well as relevant sport-specific activities, and all strength and neuromuscular control exercises have been advanced to a sufficient level, then the athlete can progress to the next stage—the RTP phase.

#### PRACTICE PEARL

**Progression of hamstring strain rehabilitation is NOT time dependent, but rather progressed on the basis of clinical signs (key outcome measures).**

#### RTP phase

It is extremely difficult to decide when the athlete is ready to RTP after a hamstring strain.<sup>2, 43, 50, 88</sup> These difficulties may be reflected in a conspicuously high injury recurrence rate, particularly within a few weeks after the return.<sup>36, 89</sup> This vulnerability to strain persists, though gradually reduces, for many weeks following RTP.<sup>17</sup>

RTP rehabilitation programs that rely solely on subjective measures such as 'pain-free movements' may result in deficits in neuromuscular control, strength, flexibility, ground reaction force attenuation and production, and lead to asymmetries between legs during normal athletic movements.<sup>79</sup> These deficits and deficiencies could persist into sport practice and competition, and ultimately increase the risk of re-injury and limit athletic performance.

A criteria-based approach to rehabilitation that includes objective and quantitative tests has the potential to identify deficits and address them in a systematic progression (i.e. algorithm) during the stages of returning to sport. While validated criteria to assess whether an athlete can safely RTP are still lacking, criteria that should be considered by the clinician when making this assessment include:

- no difference in tenderness with palpation for the injured versus uninjured hamstring<sup>14</sup>
- full range of movement (equal to uninjured leg) measured via:
  - active/passive straight leg raise test<sup>90, 91</sup>
  - active knee extension test<sup>14</sup>
- pain-free maximal isometric contraction

- objective strength assessments measured via:
  - hand-held dynamometer<sup>92</sup> or isokinetic dynamometer<sup>93, 94</sup>
  - performance with the Nordic eccentric hamstring exercise (e.g. using the NordBord<sup>88</sup> to measure the force from each lower limb independently during the exercise—see below)
  - performance with the single-leg bridge capacity test<sup>95</sup>
- Asklings's H-test<sup>96</sup> (see box below)
- completion of structured running program:
  - maximum sprinting speed achieved at the end of the running program is comparable to the athlete's previously recorded benchmark when uninjured
- functional tests:
  - repeat maximum accelerations from a standing start over a variety of distances (e.g. 5 m, 10 m, 15 m, 20 m)
  - high-intensity weaving/cutting and random (unanticipated) agility activities
  - successful execution of sport-specific activities (e.g. bending over to gather a ground ball while running at speed for Australian rules football players)
- successful completion of a sufficient amount of standard training sessions (e.g. 1 to 2 weeks)
- evaluation of an athlete's psychological status regarding readiness for RTP and fear of re-injury.

While it is recommended that athletes do not RTP following hamstring strains until all clinical signs and

### Asklings's H-test

Asklings's H-test is a complement to the clinical examination before return to sport.<sup>96</sup> Notably, this active test must not be performed before all clinical tests, including those of passive flexibility, indicate complete recovery. During the test, the subject should be positioned on a bench in a supine position with the contralateral leg and the upper body stabilised with straps (Fig. 34.18). A knee brace ensures full knee extension of the tested leg and the foot of the tested leg should be kept in a slightly plantar-flexed position. No warm-up exercises are to be performed before the test. The uninjured leg is tested before the injured leg.

The instruction to the subject is to perform a straight leg raise as fast as possible to the highest point without taking any risk of injury. A set of three consecutive trials are performed, preceded by one practice trial with submaximal effort. After the three active test trials, the subject is to estimate his or her experience of insecurity and pain on a VAS scale, from 0 to 100. In the study by Asklings, Nilsson and Thorstensson, the athletes noted an average insecurity estimation of 52 for the injured leg and 0 for the uninjured leg, respectively.<sup>96</sup>

The active test seems to be sensitive enough to detect differences both in active flexibility and in insecurity after acute hamstring strains at a point in time when the commonly used clinical examination fails to reveal injury signs. If insecurity persists, the test should be repeated until no insecurity is reported. The athlete is then allowed to return to sport.

(a)

(b)

**Figure 34.18** Asklings's hamstring apprehension test (a) Starting position (b) Maximal hip flexion

symptoms have fully resolved,<sup>14</sup> clinicians should recognise that many athletes are capable of coping with advanced functional progressions and making a successful RTP despite in some instances having residual strength deficits of 10% of more<sup>94, 97</sup> and persisting increased signal intensity on MRI.<sup>6, 97, 98</sup> These characteristics may take up to 6 months to fully resolve.<sup>97</sup> Hence, MRI appearance does not seem to be a valid indicator of readiness to RTP.

MRI can monitor tissue healing, but the extent of healing on MRI that is sufficient for an athlete to RTP with minimal risk for recurrence is presently not known. It is therefore evident that RTP following hamstring muscle strains rarely coincides with complete healing from the injury, making the timing of RTP a very challenging management decision for the clinician. The issue of RTP has been suggested to be one of risk minimisation (not risk elimination), as there appears to be trade-off between quick RTP and likelihood for recurrence.<sup>99</sup> This trade-off must be acknowledged and carefully considered by the clinician on a case-by-case basis.

The length of time until RTP depends on the severity of the injury. In most cases, an athlete with a mild hamstring strain who is optimally managed will be able to successfully RTP within approximately 18 days.<sup>1</sup>

A practical tip to reduce the incidence of recurrence is to restrict game time when first returning from hamstring injury to minimise fatigue and reduce overall exposure to high-risk activities. In this way, RTP can be gradually progressed over several weeks.

#### PRACTICE PEARL

It is important to persist with a well-structured strength and neuromuscular control exercise program after RTP to lessen the likelihood of recurrence. All elements of the program should be continued until all impairments have been resolved. These strength sessions must be carefully scheduled to allow recovery time before exposing the athlete to high-risk activities again.

## RISK FACTORS FOR ACUTE HAMSTRING STRAIN

We discuss risk factors here because patients rarely present for 'primary prevention'—to avoid hamstring injuries before they have one. We review risk factors for acute hamstring strain to identify those which may be mitigated. As with all injuries (Chapters 3 and 4),

risk factors for acute hamstring strains may be intrinsic (person-related) or extrinsic (environment-related) factors. Two systematic reviews were published on this topic in 2013.<sup>100, 101</sup>

Factors that appear to predict risk of hamstring strain are discussed in the following section. Other factors have been evaluated, but do not appear to be risk factors. Such factors include:

- body mass index<sup>36, 102, 103</sup>
- height<sup>36, 37, 102, 103, 105</sup>
- weight<sup>36, 102, 103, 105</sup>
- functional performance tests (e.g. countermovement jump, 40 m sprint tests, gross performance with the Nordic eccentric hamstring exercise, hamstring length measurement).<sup>103</sup>

## Intrinsic risk factors

### Age

A number of studies have shown that athletes of an older age are at increased risk of acute hamstring strain, even when the confounding factor of previous injury is removed.<sup>37, 102–105</sup> Australian rules football players aged 23 years or more were almost four times as likely to sustain an acute hamstring strain before their younger counterparts during the season.<sup>37</sup>

Older athletes may be at heightened risk due to increased body weight and reduced hip flexor flexibility.<sup>65</sup> It has also been speculated that the high risk of older athletes to acute hamstring strain is related to degenerative changes at the lumbosacral junction.<sup>106</sup>

## Past history of injury—a critical factor

Past history of injury is a critical factor for the development of another hamstring injury. It has been well demonstrated that a prior history of acute hamstring strain is a strong risk factor for future injury.<sup>100, 101</sup> In comparison to athletes without a history of hamstring strain, recent studies have found that those with a history do not appear to display appreciable differences in running mechanics;<sup>107–109</sup> however, they do display evidence of neuromuscular inhibition,<sup>110–112</sup> specific strength deficits,<sup>110, 112</sup> as well as altered muscle-tendon morphology (muscle atrophy, reduced muscle fascicle length, presence of scar tissue)<sup>97, 113, 114</sup> and contraction mechanics.<sup>115</sup>

It may be that future risk of re-injury in athletes who have suffered a hamstring strain is explained by the presence of one or more of these characteristics. Clinical interventions (e.g. exercise, manual therapy) aimed at addressing or minimising the impact of such characteristics are therefore of great importance.

Athletes with a history of injury to other areas of the lower limb also have an increased likelihood of acute hamstring strain. These include:

- knee—major knee injury (anterior cruciate reconstruction, patellar dislocation)<sup>105, 116</sup>
- groin—history of groin pain (bone oedema MRI)<sup>105</sup>
- calf muscle strain<sup>104</sup>
- lumbar spine—major injury (i.e. episode which required radiological investigation with a specific recorded clinical diagnosis).<sup>105</sup>

## Strength

Numerous studies have evaluated whether strength quantified via an isokinetic dynamometer is a risk factor for hamstring strain. While intuitively reduced muscle strength would appear to predispose to hamstring strain, the evidence is mixed. Such conflicting findings may relate to the difficulty in quantifying muscle strength in a systematic manner; that is, what type of contraction (isometric, concentric, eccentric), what strength parameter or index to measure (peak torque, knee angle at which peak torque occurs, hamstring/quadriceps ratio, hamstring to hip flexor ratio, strength asymmetry), as well as the level of motivation of the athletes.

A recent systematic review and meta-analysis evaluating the existing evidence regarding risk factors for hamstring strain reported a somewhat counterintuitive outcome concerning strength; specifically, that increased quadriceps strength is a risk factor for hamstring strain but reduced hamstring strength is not.<sup>100</sup> This result might be a consequence of some of the previously outlined issues with measuring strength, but it might also be a consequence of previous risk factor studies not taking the multifactorial nature of hamstring injuries into account.<sup>117</sup> Clinicians aiming to design evidence-based hamstring injury prevention programs for athletes are therefore advised to be cautious about how findings from risk factor studies are interpreted.

To further understand the role that hamstring strength has in creating injury risk, a prospective study has recently been completed investigating whether or not eccentric hamstring strength, measured during the Nordic hamstring exercise, is a risk factor for hamstring strain in elite Australian rules football players.<sup>118</sup>

In this study, a novel field-testing device, the NordBord (Fig. 34.19), was used to record eccentric strength while players performed the Nordic hamstring exercise. Force was recorded by connecting uniaxial load cells between the braces holding the ankles and the base of the testing device, allowing the force output for each lower limb to be recorded independently. Peak force during the exercise from a single lower limb averaged 330 N for

**Figure 34.19** The NordBord test

uninjured football players. Players with a peak force of less than 279 N at the end of the pre-season were found to have a 4.3 fold greater risk of sustaining a hamstring strain during the season. Similar results have also recently been reported in elite soccer players.<sup>119</sup> Taken together, these findings suggest that athletes with low levels of eccentric hamstring strength are at greater risk of injury.

## Musculotendon morphology

While the available evidence is somewhat limited at this stage, intrinsic musculotendon morphological properties may have a role in determining an individual's risk for hamstring strain. For example, the width of the proximal biceps femoris long head tendon exhibits high variability among healthy athletes,<sup>120</sup> and tissue strains in the muscle fibres immediately adjacent to the proximal musculotendinous junction have been found to be higher in individuals with a narrow proximal tendon width.<sup>121, 122</sup> Thus, it is possible that athletes with a narrow proximal tendon have an increased risk for proximal biceps femoris long head strains.

Smaller muscle fascicle length might be another morphological property associated with greater risk for injury, as it has been recently reported that athletes with a history of unilateral hamstring strain have reduced muscle fascicle length in the biceps femoris long head on the injured side compared to the contralateral uninjured side and compared to people without a history of injury.<sup>114</sup> Furthermore, a recent prospective study has found that risk of hamstring injury is significantly greater for soccer players with biceps femoris long head fascicle lengths shorter than 10.56 cm.<sup>119</sup>

## Other factors

Other intrinsic risk factors for acute hamstring strain which have only limited supporting evidence include (but are not limited to): ethnicity,<sup>23, 105</sup> reduced ankle

dorsiflexion lunge range of motion,<sup>123</sup> reduced quadriceps flexibility<sup>91, 123</sup> and poor lower-limb joint position sense.<sup>86</sup>

There is conflicting evidence regarding whether or not reduced hamstring flexibility (e.g. assessed via the active and/or passive knee extension test) is a risk factor for hamstring strain. Most studies indicate that reduced hamstring flexibility is not a risk factor;<sup>37, 102, 103, 123</sup> however, two studies have reported the contrary.<sup>91, 124</sup>

## Extrinsic risk factors

### Fatigue

It has long been speculated that fatigue is a risk factor for an acute hamstring strain, but there is very little evidence to support or refute this claim. Verrall et al. found that 85% of acute hamstring strains occurred after the first quarter of a competitive match or after the first 15 minutes of a training session.<sup>8</sup> Furthermore, Woods et al. found that 47% of their acute hamstring strains occurred towards the end (during the final third) of the first and second halves of the match.<sup>23</sup> Such observations suggest fatigue may be a factor, but further research is required.

### Player position

There is limited evidence that different playing positions are associated with a higher risk of hamstring strain. Goalkeepers have a significantly lower risk for hamstring strain than outfield players in soccer<sup>23</sup> and rugby forwards have a reduced risk of hamstring strains compared to backs.<sup>36</sup> In American football, the speed position players, such as the wide receivers and defensive secondary, as well as players on the special teams units, are most commonly injured.<sup>20</sup>

## PREVENTION OF HAMSTRING STRAINS

A systematic review published in 2010 concluded that there is insufficient evidence from randomised controlled trials to draw conclusions on the effectiveness of interventions used to prevent hamstring injuries in people participating in football or other high-risk activities for these injuries.<sup>125</sup> However, recent studies have provided strong evidence indicating that eccentric hamstring strength training with good compliance is an effective intervention for preventing hamstring strains.<sup>126</sup>

### Eccentric hamstring strength training

High-quality studies have demonstrated that eccentric strength training for the hamstring muscles can prevent hamstring strains in athletes.<sup>75–77, 127</sup>

In Petersen's study,<sup>76</sup> there was a significant reduction (approximately 3-fold) in the 'total' number of hamstring injuries (i.e. new plus recurrent injuries) and a significant

reduction (approximately 7-fold) in the number of recurrent injuries for the intervention group, which undertook a 10-week progressive pre-season eccentric training program of Nordic exercises (Table 34.4) followed by a weekly seasonal program. There was also an approximate 2.5-fold reduction in the number of new hamstring injuries in the intervention group, but this effect did not reach statistical significance.

Arnason's study also showed a reduction in hamstring injuries with a Nordic exercise program,<sup>75</sup> while a positive effect on prevention of hamstring injuries in soccer players was also found for an eccentric/concentric strengthening program using a Yo-Yo flywheel ergometer.<sup>126</sup> Most recently, van der Horst et al. investigated the preventive effect of the Nordic hamstring exercise in amateur soccer players and found a significant reduction in the incidence of hamstring strains but not the severity.<sup>77</sup>

In contrast to the aforementioned studies, two other studies have investigated the effectiveness of the Nordic hamstring exercise. Gabbe et al.<sup>128</sup> reported a minimal effect only, while Engebretsen et al.<sup>129</sup> reported no effect. However, both of these studies suffered from poor compliance, which most likely explains the less favourable results.<sup>125</sup>

### Balance exercises/proprioception training

Proprioceptive exercises or balance training may be an effective strategy for preventing hamstring injuries.<sup>130–132</sup> A positive effect was found in one study,<sup>130</sup> while two other studies failed to show any effect.<sup>131, 132</sup>

In the German study, 24 elite female soccer players of a premier league soccer team included an additional soccer-specific proprioceptive multistation training program over 3 years.<sup>130</sup> Progression in level of difficulty from easy to complex was a main feature of the exercises. The duration of each exercise was between 15 and 30 seconds.

The following exercises were implemented:

1. single-leg stand on right and left foot
2. jump forwards in single-leg stand with flexed knee at landing and balancing
3. jump backwards in single-leg stand and balancing
4. row jumping single foot
5. row jumping bipedal
6. obstacle course forwards and backwards
7. obstacle course sideways
8. bipedal jumping on forefoot
9. sideways jumping in single-leg stand
10. sitting on a wobble board with balancing torso
11. jumping forwards over a line, landing with flexed knees and balancing
12. standing on both hands and feet with diagonal balancing.

All exercises were performed with no additional weight; that is, players had to bear only their own body weight on one or two legs or all extremities depending on the exercise. In addition, balance training was implemented in soccer-specific match play training on balance boards.

At the end of the 3-year proprioceptive balance training intervention, non-contact hamstring injury rates were reduced from 22.4 to 8.2/1000 hours. Furthermore, the more minutes of balance training performed, the lower the rate of hamstring injuries.

### Sport-specific training

In seasonal sports such as Australian rules football and soccer, hamstring strains occur far more frequently during official matches/games than training sessions. Hence, sport-specific training during the pre-season is considered to be an important strategy for preventing hamstring strains during the competitive season.<sup>133</sup>

The aim of sport-specific training during the pre-season is to gradually expose the hamstring muscles to the sorts of high-risk activities that are regularly encountered during the competitive season (e.g. repetitive sprinting, maximum accelerations, kicking, running with trunk flexion), thereby improving the ability of the hamstrings to withstand these activities. For instance, Verrall et al. demonstrated a significant reduction in the incidence of hamstring strains in one Australian rules football club following the introduction of sprint training, stretching once fatigued and sport-specific training drills during the pre-season.<sup>87</sup>

### A promising clinical approach for the high-risk athlete

Another potential strategy for preventing hamstring strains, especially for the athlete with a past history of injury, is to try to identify (via clinical examination) those who have reacted adversely to a high-intensity activity (e.g. match/game or training session). In some instances, high-intensity activities may result in aberrant levels of muscle damage and/or fatigue. Athletes can be assessed 1–2 days following a match/game throughout the competitive season and high-risk activities can be modified accordingly for those who display positive clinical signs (e.g. pain and inhibition with resisted muscle contraction and overt tenderness with palpation).

Isometric maximum voluntary contractions may be most suitable for this purpose because they are quick and easy to perform for the clinician, no expensive equipment is necessarily required and they are relatively safe for the athlete. Recent research has demonstrated the potential capability of isometric maximum voluntary contractions of the hamstrings to detect the presence of

neuromuscular inhibition for up to 72 hours following a soccer match.<sup>134, 135</sup>

A simple, clinically applicable approach for measuring isometric maximum voluntary contractions has been described by Schache et al.<sup>136</sup> A digital sphygmomanometer can be used as an inexpensive way to quantify the athlete's hamstring strength. Alternatively, a portable force plate can be used to obtain data in newtons (N).<sup>135</sup> Data can be collected in different positions that change the way load is distributed on the hamstrings; for example, with the athlete positioned with their knee flexed to 90° and heel resting on a firm surface (Fig. 34.20a) or with the athlete positioned in supine with their knee extended and heel resting on a small step performing a single-leg bridge (Fig. 34.20b). Both of these positions mimic commonly used pain provocation tests for the hamstrings. Other clinically applicable and reliable methods for recording isometric maximum voluntary contractions of the hamstrings involve the use of a hand-held dynamometer or load cell and are performed in various prone or seated positions against either therapist resistance or external belt fixation.<sup>92, 137, 138</sup>

The overall objective is to identify those athletes who have painful and/or inhibited hamstring muscles. It is then up to the clinician to use these findings together with the athlete's history and other clinical examination findings to decide whether or not an intervention is required, and if so, what type of intervention (e.g. manual therapy, specific exercise therapy, activity modification). Clinically applicable tests of hamstring strength are also very useful outcome measures for monitoring healing following acute hamstring strains.<sup>34</sup>

## REFERRED PAIN TO POSTERIOR THIGH

The possibility of referred pain should always be considered in the athlete presenting with posterior thigh pain. Hamstring pain may be referred from the lumbar spine, the SIJ or from soft tissues; for example, the proximal fibres of the gluteus maximus, and especially the gluteus medius and the piriformis muscle. Often, there is a history of previous or current low back pain.

The slump test (Fig. 34.2g) should be used to detect neural tightness. The test is positive when the patient's hamstring pain is reproduced and subsequently relieved with reduction of the neural tension by neck extension. Examination may reveal reduced range of movement of the lumbar spine, tenderness and/or stiffness of lumbar intervertebral joint(s) or tenderness over the area of the SIJ.

A positive slump test is strongly suggestive of a referred component to the patient's pain. The slump test has been advocated as a method of treatment of hamstring pain in Australian rules football players.<sup>139</sup> Nevertheless, a negative slump test does not exclude the possibility of referred pain and the lumbar spine should be carefully examined to detect any intervertebral segment hypomobility. Careful palpation of the hip musculature, especially the extensors, abductors and external rotators, should also be performed.

## Trigger points

Trigger points are common sources of referred pain to both the buttock (Chapter 30) and posterior thigh. The most common trigger points that refer pain to the

**Figure 34.21** Pattern of referred pain to the hamstrings from trigger points

mid-hamstring are in the gluteus minimus, gluteus medius and piriformis muscles (Fig. 34.21).

The clinical syndrome associated with posterior thigh pain without evidence of hamstring muscle injury on MRI and reproduction of the patient's pain on palpation of gluteal trigger points is now well recognised and extremely common.<sup>140</sup>

The clinical features are described earlier in Table 34.2. The patient will often complain of a feeling of tightness, cramping, 'twinge' or a feeling that the hamstring is 'about to tear'. On examination there may be some localised tenderness in the hamstring, although it is usually not focal and there is restriction in hamstring and gluteal stretch. Firm palpation of the gluteal muscles will detect tight bands that contain active trigger points, which when firmly palpated are extremely tender, refer pain into the hamstring and may elicit a 'twitch response'.

Treatment involves deactivating the trigger point either with soft tissue massage techniques (Fig. 34.22a) or dry needling (Fig. 34.22b). Following the local treatment, the tight muscle groups (the gluteals and hamstrings) should be stretched.

(a)

(b)

**Figure 34.22** Treatment of gluteal trigger points (a) Elbow pressure (b) Dry needling

## Lumbar spine

The lumbar spine is a source of pain referral to the posterior thigh. Unfortunately, it is difficult to distinguish between sources based on the behaviour and distribution of the pain. Pain may be referred from the disc, zygapophyseal joints, muscles, ligaments or any structure that can produce pain locally in the lumbar spine.<sup>141</sup>

Nerve root compression may also be a cause of hamstring pain. Diagnostic blocks and provocation injections have been advocated to isolate sources of pain in the lumbar spine. However, in the clinical setting, this is often not possible. It is important to examine the lumbar spine carefully (Chapter 29). This will assist in the identification of the lumbar spine as a source of hamstring pain. It is also important to remember that the lumbar spine may be a cause of lumbar pain indirectly. For example, the lumbar spine may cause a biomechanical block to hip extension, resulting in overload of the SIJ and referred pain to the hamstring group.

True nerve root compression is usually more definitive in its presentation. The patient may have associated neurological symptoms, such as numbness and loss of foot

eversion. The management of these injuries usually involves an extended period of rest and, in certain cases, an epidural injection. In extreme cases, surgical decompression of the nerve root may be warranted.

Spondylolisthesis and spondylolysis (Chapter 29) have both been associated with hamstring pain and tightness.<sup>142</sup> Examination findings of positive lumbar quadrant tests or single-leg standing lumbar extension suggests either of these conditions and these spinal pathologies can be confirmed on MRI or CT scan.

Stabilisation programs are the treatment of choice as the deep abdominal muscles are deficient in people with back pain as a result of spondylolisthesis and spondylolysis.<sup>143</sup> In severe cases, clinicians have resorted to corticosteroid injection (+/- neuroablation using pulsed radiofrequency) under X-ray control into the deficient pars interarticularis.<sup>144</sup> This procedure is only supported by low-level evidence, but it may reduce pain from spondylolysis.

Not all hamstring pain associated with the lumbar spine is due to sport-related loading of the lumbar spine. The lumbar spine can cause pain as a result of prolonged sitting

or bending forwards. Athletes in sedentary occupations should be aware that poor sitting posture can aggravate lumbar-mediated posterior thigh pain.

Travel involving prolonged sitting prior to training and competition may cause injury. Prolonged sitting results in sustained lumbar flexion whereas running requires good lumbar extension. When the lumbar spine is required to suddenly 'switch' from one activity to the other, this may cause problems. Care should be taken to limit prolonged sitting and to provide adequate lumbar support.

### Sacroiliac complex

SIJ abnormalities can refer pain into the hamstring or cause indirect pain in the hamstring similar to the lumbar spine. Problems of the SIJ are discussed in Chapter 30.

## OTHER HAMSTRING INJURIES

### Avulsion of the hamstring from the ischial tuberosity

with RAJ SUBBU and FARES HADDAD

The proximal hamstring complex is frequently injured in athletes, with 12% of hamstring injuries being in the proximal complex and 9% being complete ruptures.<sup>145</sup> Traditionally, these occur in waterskiing, sprinting and hurdling; however, they are increasingly being recognised in a variety of different sports, commonly soccer and rugby.<sup>146</sup> The injuries are typically associated with a very forceful eccentric contraction of the hamstrings where the hip is rapidly flexed with the knee in full extension.

Patients present with a history of hearing a pop or snap at time of injury, complaining of acute pain at the buttock crease, an antalgic gait, and loss of hip and knee function with reduced hamstring power. Physical examination may reveal swelling and massive ecchymosis in the posterior aspect of the thigh, which may even track distally. There may also be a positive bowstring sign when the patient is assessed in the prone position with a palpable lack of tension on passive flexion of the knee to 90°. Palpation at the gluteal crease evokes pain and there is decreased power in both flexion of the knee and extension of the hip. Tenderness proximally with symptoms and signs of sciatic nerve irritation should alert the clinician to the possibility of an avulsion injury.

Once clinically assessed, radiological imaging is required to confirm the diagnosis. MRI and ultrasonography remain the imaging modalities of choice (Fig 34.23).<sup>145</sup> With greater severity of injury there is a greater amount of haemorrhage, oedema and fluid involving a larger longitudinal and cross-sectional area.<sup>145</sup> Studies have compared MRI and ultrasonography, and MRI has been shown to consistently demonstrate large areas of oedema and greater sensitivity

in picking up subtle fluid changes and exact anatomical area of injury.<sup>147</sup> A specific MRI classification for proximal avulsion injuries has been described based on the anatomical location and amount of retraction of the proximal complex (Table 34.5).<sup>147</sup> Typically, type 5 injuries are delayed presentations, indicating that the tendons may retract with time (Fig 34.23b).

Treatment has previously been based on the amount of retraction from the ischial tuberosity with less than 2 cm being treated conservatively, which may lead to decreased hamstring strength, function and prolonged rehabilitation.<sup>148</sup> A recent study of 112 proximal avulsion injuries has shown that surgical repair is indicated in all proximal avulsion injuries despite the amount of retraction.<sup>146</sup>

The timing of surgery is important regarding RTP. Subbu et al. reported that the average time to RTP for those with surgical repair within 6 weeks of initial injury was 16 weeks (range 12–32), 25 weeks (range 18–40) within 6 months and 29 weeks (24–41) after 6 months of initial injury.<sup>146</sup> Return to full pre-injury level of sport was on average 9 weeks faster for those with surgical repair within 6 weeks of injury compared with those within 6 months, and 13 weeks faster compared with those with surgical repair performed more than 6 months after injury.<sup>146</sup>

(a)

**Figure 34.23** (a) MRI showing acute complete avulsion of the conjoint tendon of semitendinosus and biceps femoris with retraction (red arrow). Semimembranosus intact (white arrow)

(b)

**Figure 34.23 (cont.)** (b) MRI showing chronic complete avulsion of the entire proximal hamstring complex with diffuse increased signal and early muscle atrophy. Ischial tuberosity fragment identified (arrow). Consistent with type 5b injury

The surgical procedure involves retrieving the retracted complex with suture anchors that have a metal peg, which are fastened into the ischial tuberosity. The synthetic sutures attached to the metal peg can then be passed through the mobilised tendon to fashion a well-tensioned bone-tendon approximation. When surgery is delayed, the procedure becomes more complex with greater retraction of the proximal complex; a larger, vertical incision is required for greater exposure and there is an increased risk of damage to the sciatic nerve, with it becoming embedded within the retracted complex. When surgery is delayed until after 6 weeks, patients inevitably require postoperative bracing which consequently delays the rehabilitation process.

A structured rehabilitation program should be centred on using the first 4 weeks as healing time while protecting the surgical repair. The next 4 weeks are used to regain range of motion and function and then a graduated return to sport-specific activity.<sup>149</sup> Each patient should be given an individualised rehabilitation program depending on the complexity of surgery and the level of activity to be achieved. A rehabilitation guide is outlined in Table 34.6.

Early diagnosis and surgical interventions are associated with less complex surgery, fewer postoperative complications, more efficient rehabilitation and a faster return to pre-injury levels of activity.

### Upper hamstring tendinopathy

Tendinopathy of the proximal hamstring tendon or 'high hamstring tendinopathy' is increasingly being recognised as an important cause for chronic pain in the active population (Chapter 30). Patients usually present with subacute onset of deep buttock or posterior thigh pain/stiffness that is exacerbated by repetitive activity (such as long-distance running) and is often aggravated by sitting, stretching and aggressive strengthening. MRI is more sensitive than ultrasound in detecting pathological abnormalities involving the proximal hamstring tendons, but note that many typical findings such as intratendinous and peritendinous signal as well as ischial tuberosity oedema can also be seen in asymptomatic individuals.

Initial treatment in clinical practice should include a graduated strengthening program, largely comprising isometric and slow isotonic exercises under high load. However, patients sometimes fail to respond to this conservative regimen. The use of ultrasound-guided injections of corticosteroid and local anaesthetic has been shown to be safe and effective in reducing pain in the short term, but is associated with a high recurrence rate when used in isolation.<sup>150</sup> This procedure should be performed in conjunction with a progressive strengthening program to achieve optimal results and avoid recurrent injury.

**Table 34.5 MRI classification of proximal avulsion injuries<sup>147</sup>**

Type	Level of injury
Type 1	Osseous avulsions (generally seen in paediatric patients)
Type 2	Avulsions at the musculotendinous junction
Type 3	Incomplete tendon avulsions
Type 4	Complete avulsions with no/minimal retraction
Type 5a	Complete avulsions with retraction but NO sciatic nerve involvement
Type 5b	Complete avulsions with retraction AND sciatic nerve involvement

**Table 34.6 Rehabilitation protocol for proximal avulsion injuries**

Weeks	Rehabilitation guide
1–2	Avoid hip flexion beyond 60° Wound care Avoid sitting on affected ischial tuberosity Calf pumps Non weight-bearing
3–4	Start passive knee flexion and hip extension
5–6	Bear toe weight if possible
7–10	Encourage to bear full weight Hydrotherapy Passive and active range of motion—avoid extremes Begin core work Begin closed chain exercises
11–14	Expect normal gait Encourage strength work Progress to fast walk/jog
15–16	Consider isokinetic testing Heavy weight training Potentially running

A rehabilitation program utilising eccentric training, lumbopelvic stabilisation and trigger point dry needling has been suggested.<sup>151</sup> Shock wave treatment has also been shown to be effective in relieving symptoms associated with high hamstring tendinopathy.<sup>152</sup>

In order to document the severity of the tendinopathy, the VISA-H questionnaire has recently been developed.<sup>153</sup>

## LESS COMMON CAUSES

### Nerve entrapments

The hamstring group is supplied by the tibial branch of the sciatic nerve except for the short head of the biceps femoris, which is supplied by the peroneal branch of the sciatic nerve. These nerves arise from the lumbosacral plexus, specifically from the roots of L5, S1 and S2.

Nerve damage can occur at a variety of sites, resulting in pain in the posterior thigh. Compression of the nerve roots of the sacral plexus will often result in pain into the hamstring group. Usually this is distinguished from other conditions by the identification of associated neurological symptoms such as alteration in sensation, loss of the Achilles reflex or weakness in muscles not in the hamstring group, such as the ankle evertors.

The sciatic nerve may be damaged or compressed at any point along its pathway as a result of direct impact or pelvic trauma. Compression of the nerve at the level of

the piriformis has been described as an alternative cause of sciatica.<sup>154</sup> However, work by McCrory et al. suggests that it is not only the piriformis, but also the other hip external rotators that may cause compression of the sciatic nerve.<sup>155</sup>

The peripheral nerves may also be a source of posterior thigh pain. The posterior cutaneous nerve of the thigh (PCNT) and the inferior cluneal nerve supply the skin over the posterior thigh. The PCNT has been described as the source of pain in piriformis syndrome as an alternative to the sciatic nerve.<sup>155</sup> If symptoms do not extend below the knee and there is no associated loss of neurological function in the structures supplied by the sciatic nerve, then the PCNT should be considered.

### Ischial bursitis

It is often difficult to distinguish between high hamstring tendinopathy and ischial bursitis. Both conditions present as pain at the origin of the hamstring muscle. An inflamed bursa is not readily palpated; however, athletes tend to complain of pain when sitting on hard surfaces where the ischium is under pressure. Ultrasound or MRI can confirm the presence of a fluid-filled bursa.

Anti-inflammatory medications combined with ice and rest are of limited benefit. Corticosteroid injections can be performed under radiographic control but the results are not always satisfactory.

### Adductor magnus strains

Adductor magnus strains are rare, but when they do occur, behave similarly to a hamstring strain. The mechanism tends to be more of a rotatory action of eccentric internal rotation on one hip or landing with sudden deep hip flexion. Prognosis tends to be far better than hamstring strains; therefore, it is important to differentiate it from strains in the hamstring. The key to differentiating this condition is careful palpation to elicit the precise location of the tissue damage. Side-lying on the affected leg allows that hamstring group to fall laterally so that ready access can be made to the adductor magnus.

### Compartment syndrome of the posterior thigh

Although nowhere near as common as lower leg compartment syndromes, the posterior thigh can be affected by a compartment syndrome. Patients present with dull pain, stiffness, cramps and weakness of the posterior thigh during and after training.<sup>156</sup> Two groups of patients with this syndrome are seen—endurance athletes without a history of trauma and those with a history of hamstring injury. Conservative management has not been successful and posterior fasciotomy of the thigh appears to be an effective treatment.<sup>156</sup>

**Vascular**

Endofibrosis of the external iliac artery usually produces pain in the lateral and anterior thigh or calf (Chapter 39). However, in some cases pain may be experienced in the posterior thigh. This condition is associated with cycling and has been observed in triathletes.<sup>157</sup> The pain is claudicant in nature. Pain may arise after 15–20 minutes of

exercise but usually stops immediately with the cessation of exercise.

On examination, a bruit is heard during the exercise that causes the pain. Diagnosis may be confirmed with echography or arteriography. If the condition is affecting performance, then surgical treatment is indicated.

# Acute knee injuries

with RICHARD FROBELL, RANDALL COOPER, HAYDEN MORRIS and  
MARK HUTCHINSON

*The thing is I have no ACL. So unless I get surgery, there's nothing really magical that I can do that's going to make it better. I just can get my leg stronger, my muscle stronger and try and support it a little more. But that has a small impact. My knee is loose and it's not stable and that's the way it's going to be from here on out.*

Lindsey Vonn, Olympic gold medal skier

For many athletes, the most fearful injury is that of the acute knee—it can spell the end of a professional career. Even for recreational athletes, an acute knee injury may be the catalyst for early arthritis. Acute knee injuries are common in all sports that require twisting movements and sudden changes of direction, especially the various types of football, basketball, netball and alpine skiing.

## FUNCTIONAL ANATOMY

The knee joint can be divided into two parts: the tibio-femoral joint with its associated collateral ligaments, cruciate

ligaments and menisci; and the patellofemoral joint, which obtains stability from the medial and lateral retinaculum and the large extensor mechanism tendons (quadriceps and patella tendons) which encase the patella distally before its insertion on the proximal tibia. Most commonly we refer to the tibiofemoral joint as the knee joint. The anatomy of the knee joint is shown in Figure 35.1.

The two cruciate ('cross') ligaments, anterior and posterior, are often referred to as the 'crucial' ligaments, because of their importance in providing knee stability. They are named anterior and posterior in relation to their

**Figure 35.1** Anatomy of the knee joint (a) The knee joint (anterior view) (b) The knee joint (posterior view)

attachment to the tibia. The anterior cruciate ligament (ACL) prevents forward movement of the tibia in relation to the femur and controls rotational movement of the tibia under the femur. The posterior cruciate ligament (PCL) prevents the femur from sliding forwards off the tibial plateau.

The ACL is essential for control in pivoting movements. If the ACL is not functional, the tibia may rotate under the femur in an anterior-lateral direction such as when an athlete attempts to land from a jump, pivot or stop suddenly. The PCL stabilises the body (femur) above the tibia. In its absence, the femur wants to shift forwards on the tibia. This shift forwards is accentuated when one tries to run down an incline plane or down stairs.

The two collateral ligaments, the medial and lateral, provide medial and lateral stability to the knee joint. The superficial medial (or tibial) collateral ligament (MCL) is extracapsular. The deep layer, or coronal ligaments, attaches to the joint margins and has an attachment from its deep layer to the medial meniscus. The MCL prevents excessive medial opening (i.e. valgus) of the tibial-femoral joint.

The lateral (or fibular) collateral ligament (LCL) is a narrow strong cord with no attachment to the lateral meniscus. It prevents lateral opening of the tibia on the femur during varus stress; it also stabilises the upright knee in single-leg stance phase of gait.

The medial and lateral menisci are intra-articular and attach to the capsule layer at the level of the joint line. The menisci buffer some of the forces placed through the knee joint and protect the otherwise exposed articular surfaces from damage. By increasing the concavity of the tibia, they contribute to stabilising the knee. As the menisci contribute to joint lubrication and nutrition, it is important to preserve as much of them as possible after injury.

## CLINICAL APPROACH

The acute knee injury of greatest concern to the athlete is the tear of the ACL. Meniscal injuries are common among

athletes, either in isolation or combined with a ligament injury (e.g. of the MCL or ACL). Importantly, the articular cartilage of the knee is often damaged in association with ligament or meniscal injuries. Cartilage damage, depending on the size and/or location, can accelerate the development of arthritis.<sup>1</sup>

A list of acute knee injuries occurring in sport is shown in Table 35.1.

## ‘Does this patient have a significant knee injury?’

To answer this critical question, consider the following elements of the patient’s story:

- the mechanism of injury (low-energy force versus high-energy force)
- the amount of pain and disability at the time of injury
- the presence and timing of onset of swelling which may be a clue to haemarthrosis (joint bleeding)
- the degree of disability on presentation to the clinician
- patient-specific vulnerabilities (previous injury, medical comorbidities that can affect bone and/or tendon health).

In the majority of cases, an acute knee injury can be diagnosed with an appropriate history and examination. The main goals of assessment are:

1. to determine which structures have been damaged
2. to determine the extent of damage to each structure
3. to determine the degree of joint/limb disability to provide safe and timely initial management.

## History

It is absolutely critical to invite the patient to tell his or her own story of the injury. Once the patient has explained what happened, the clinician may elicit additional aspects of the history.

**Table 35.1 Causes of acute knee pain**

Common	Less common	Not to be missed
Medial meniscus tear	Patellar tendon rupture	Fracture of the tibial plateau
MCL sprain	Quadriceps tendon rupture	Avulsion fracture of tibial spine
ACL sprain (rupture)	Acute patellofemoral contusion	Osteochondritis dissecans (in adolescents)
Lateral meniscus tear	LCL sprain	Complex regional pain syndrome type 1 (post injury)
Articular cartilage injury	Bursal haematoma/bursitis	Quadriceps muscle rupture
PCL sprain	Acute fat pad impingement	
Patellar dislocation	Avulsion of biceps femoris tendon	
	Superior tibiofibular joint injury	

Note: all these conditions may occur in isolation or, commonly, in association with other conditions

Important components include:

- a description of the precise mechanism of injury and the subsequent symptoms (e.g. pain and giving way)
- demonstration by the patient if possible, on the uninjured knee, of the stress applied at the time of injury
- the location of pain – pain associated with cruciate ligament injuries is often poorly localised (or emanates from the lateral tibial plateau); pain from injuries to the collateral ligaments is usually fairly well localised
- severity of pain – this does not always correlate with the severity of the injury, although most ACL injuries are usually painful immediately.

#### PRACTICE PEARL

The degree and time of onset of swelling can reflect either intra-articular or extra-articular injury and thus, provides an important clue to the injured structure (Table 35.2). Intra-articular swelling (i.e. haemarthrosis) is usually voluminous (obvious) and develops within 1 or 2 hours following injury.

The causes of haemarthrosis are:

- major ligament rupture
  - ACL
  - PCL
- patellar dislocation
- osteochondral fracture
- peripheral tear of the meniscus, more common medially
- Hoffa's syndrome (acute fat pad impingement)
- bleeding diathesis (rare).

*Note:* Lipohaemarthrosis (fat and blood in the knee) is caused by intra-articular fractures. Lipohaemarthrosis will present in a similar manner to haemarthrosis.

#### PRACTICE PEARL

An effusion that develops after a few hours or, more commonly, the following day represents reactive synovitis and is a feature of meniscal and chondral injuries. There is usually little effusion with collateral ligament injuries.

#### PRACTICE PEARL

If the patient volunteers having heard a 'pop', a 'snap' or felt a 'tear', the injury should be considered as an ACL tear until proven otherwise.

Patients presenting with a sensation of something having 'moved' or 'popped out' in the knee may be thought to have a patellar dislocation. However, this symptom is more commonly associated with an ACL rupture. There may be associated 'clicking' or 'locking' and this is often seen with meniscal injuries. Locking is classically associated with a loose body or displaced meniscal tear. Locking does not mean locked in one knee position, but is used when significant loss of passive range of motion is present, especially loss of full extension. It is helpful to ask the patient in what 'position' the knee locks. If the patient reports that the knee locks when it is straight and does not bend, this usually is a manifestation of patellofemoral pain and injury – the kneecap is unable to engage in the groove secondary to pain.

The symptom of 'giving way' can occur with instability, such as in ACL deficiency. Instability may also occur with meniscal tears, articular cartilage damage, patellofemoral pain (Chapter 36) or severe knee pain. In the latter cases of knee *pain* instability, a careful history will reveal more of a 'jackknife' (collapsing) phenomenon in flexion rather than a true 'give way' in extension. Patients with recurrent patellar dislocation and those with loose bodies in the knee can describe similar sensations. If a patient reports feeling unstable on steps, this is most often a reflection of quadriceps weakness and/or pain and rarely represents true kneecap instability.

The comprehensive history will also include:

- the initial management of the injury
- the degree of disability
- a history of previous injury to either knee or any previous surgery
- the patient's age, occupation, type of sport and leisure activities and the level of sport played.

If the patient is a good historian, the diagnosis will be obvious in most cases.

**Table 35.2 Time relationship of swelling to diagnosis**

Intermediate (0–2 hours) – haemarthrosis	Delayed (6–24 hours) – effusion	No swelling
ACL rupture Patellar dislocation Major chondral lesion MCL sprain (deep)	Meniscus Smaller chondral lesion	MCL sprain (superficial)

## Physical examination

Examination includes:

1. Observation
  - a. standing
  - b. walking
  - c. supine (Fig. 35.2a)
2. Active movements
  - a. flexion
  - b. extension
  - c. straight leg raise
3. Passive movements
  - a. flexion (Fig. 35.2b)
  - b. extension (Fig. 35.2c)
4. Palpation
  - a. patellofemoral joint (including patellar and quadriceps tendons, medial and lateral retinaculum)
  - b. MCL
  - c. LCL
  - d. medial joint line (Fig. 35.2d)
  - e. lateral joint line
  - f. posterior structures (e.g. hamstring tendons, Baker's cyst, gastrocnemius origins, best done in the prone position)

## 5. Special tests

- a. presence of effusion (Fig. 35.2e)
- b. stability tests
  - i. MCL (Fig. 35.2f)
  - ii. LCL (Fig. 35.2g)
  - iii. ACL
    1. Lachman's test (Figs 35.2h-k)
    2. anterior drawer test (Fig. 35.2l)
    3. pivot shift test (Fig. 35.2m)
- iv. PCL
  1. posterior sag (Fig. 35.2n)
  2. reverse Lachman's test
  3. posterior drawer test (Fig. 35.2o)
  4. external rotation test—active and passive
- v. patella
  1. medial and lateral patella translation (or mobility)
- c. flexion/rotation
  - i. McMurray's test (Fig. 35.2p)
  - ii. Apley's grind test
- d. patellar apprehension test (Fig. 35.2q)

(a)

(b)

**Figure 35.2** Examination of the patient with an acute knee injury (a) Observation—supine. Look for swelling, deformity and bruising (b) Passive movement—flexion. Assess range of motion, end feel and presence of pain

- e. patellofemoral joint (Chapter 36)
- f. functional tests
  - i. squat test (helps to assess functional valgus collapse of knee)
  - ii. hopping on the spot
  - iii. pelvic bridge/plank arrow (helps assess core strength)

The clinical utility of the various special tests for diagnosing acute knee injuries is shown in Table 35.3.

### Key outcome measures

Patient-reported outcome measures (PROMs) for acute knee injuries are shown in Table 35.4.

(c)

(d)

(e)

**Figure 35.2 (cont.)** (c) Passive movement—extension. Hold both legs by the toes, looking for fixed flexion deformity or hyperextension in ACL or PCL rupture. Overpressure may be applied to assess end range. This procedure may provoke pain in meniscal injuries (d) Palpation—medial joint line. The knee should be palpated in 45–90° of flexion (e) Special tests—presence of effusion. Manually drain the medial subpatellar pouch by stroking the fluid in a superior direction. Then ‘milk’ the fluid back into the knee from above on the lateral side while observing the pouch for evidence that fluid is re-accumulating. This test is more sensitive than the ‘patellar tap’. It is important to differentiate between an intra-articular effusion and an extra-articular haemorrhagic bursitis

(f)

(g)

(h)

**Figure 35.2 (cont.)** (f) Stability test—MCL. This is tested first with the knee in full extension and then also at 30° of flexion (illustrated). The examiner applies a valgus force, being careful to eliminate any femoral rotation. Assess for onset of any pain, extent of valgus movement and feel for end point. If the knee 'gaps' at full extension, there must be associated posterior cruciate injury (g) Stability test—LCL. The LCL is tested in a similar manner to the MCL except with varus stress applied (h) Stability test—Lachman's test. Lachman's test is performed with the knee in 15° of flexion, ensuring the hamstrings are relaxed. The examiner draws the tibia forwards, feeling for laxity and assessing the quality of the end point. Compare with the uninjured side (i) The ACL is slightly slack in the start position (j) When the ACL is intact, the ligament snaps tight and the examiner senses a 'firm'/'sudden' end feel (k) When the ACL is ruptured, the Lachman's test results in a 'softer'/'gradual' end feel

(i)

(j)

(k)

(l)

(m)

(n)

(o)

**Figure 35.2 (cont.)** (l) Stability test—anterior drawer test. This is performed with the knee in  $90^\circ$  of flexion and the patient's foot kept stable. Ensure the hamstrings are relaxed with the index finger on the femoral condyles. The tibia is drawn anteriorly and assessed for degree of movement and quality of end point. The test can be performed with the tibia in internal and external rotation to assess anterolateral and anteromedial instability respectively (m) Special test—pivot shift test. With the tibia internally rotated and the knee in full extension, a valgus force is applied to the knee. In a knee with ACL deficiency, the condyles will be subluxated. The knee is then flexed, looking for a 'clunk' of reduction, which renders the pivot shift test positive. Maintaining this position, the knee is extended, looking for a click into subluxation, which is called a 'positive jerk test' (n) Stability test—posterior sag. With both knees flexed at  $90^\circ$  and the patient relaxed, the position of the tibia relative to the femur is observed. This will be relatively posterior in the knee with PCL deficiency (o) Stability test—posterior drawer test. With the knee as for the anterior drawer test, the examiner grips the tibia firmly as shown and pushes it posteriorly. Feel for the extent of the posterior movement and quality of end point. The test can be repeated with the tibia in external rotation to assess posterolateral capsular integrity

(p)

(q)

**Figure 35.2 (cont.)** (p) Flexion/rotation test—McMurray's test. The knee is flexed and, at various stages of flexion, internal and external rotation of the tibia are performed. The presence of pain and a palpable 'clunk' is a positive McMurray's test and is consistent with meniscal injury. If there is no clunk but the patient's pain is reproduced, then the meniscus may be damaged or there may be a patellofemoral joint abnormality (q) Special test—patellar apprehension test. The knee may be placed on a pillow to maintain 20–30° of flexion. Gently push the patella laterally. The test is positive if the patient develops apprehension with a sensation of impending dislocation

Table 35.4 Patient-reported outcome measures for acute knee injuries

#### International Knee Documentation Committee (IKDC) Subjective Knee Evaluation Form

- Self-administered questionnaire evaluating symptoms, function and sports activities due to knee impairment
- Eighteen items (7 items for symptoms, 10 items for sport activities and 1 item for current knee function)
- Score range 0–100
- Test-retest reliability: 0.845–0.93<sup>8–10</sup> (ACL injuries) 0.95<sup>11</sup> (meniscal injuries)
- Construct validity: Lysholm score 0.62–0.89,<sup>10, 12–15</sup> SF-36 physical function 0.71,<sup>16</sup> Cincinnati Knee Rating System 0.87–0.946<sup>17</sup>
- MDC 95%: 8.8–15.6<sup>11, 18</sup>
- MCID: (Sn) 11.5,<sup>19</sup> (Sp) 20.5<sup>19</sup>
- Available online in a range of languages: American Orthopaedic Society for Sports Medicine, [www.sportsmed.org/aossmimis](http://www.sportsmed.org/aossmimis)

#### Knee Injury and Osteoarthritis Outcome Score (KOOS)

- Self-administered questionnaire evaluating a patient's opinion about their knee and associated problems<sup>20</sup>
- Five domains: Symptoms and stiffness (7 items), Pain (9 items), ADL function (17 items), Sport and recreational activity function (5 items) and Quality of life (4 items)
- Score range 0–100 (0 = extreme symptoms and 100 = no symptoms)
- Test-retest reliability: Symptoms and stiffness (cartilage lesions 0.9/ACL 0.89), Pain (cartilage lesions 0.91/ACL 0.87), ADL function (cartilage lesions 0.93/ACL 0.87), Sport and recreational activity function (cartilage lesions 0.92/ACL 0.84) and Quality of life (cartilage lesions 0.95/ACL 0.88)<sup>21</sup>
- Construct validity: SF-36-bodily pain (cartilage lesions 0.72/ACL 0.66), SF-36 physical function (cartilage lesions 0.63/ACL 0.65)<sup>21</sup>
- MDC 95%: Symptoms and stiffness (cartilage lesions 30.8/ACL 15.6), Pain (cartilage lesions 26.3/ACL 12.7), ADL function (cartilage lesions 29.7/ACL 12.9), Sport and recreational activity function (cartilage lesions 29.9/19.2) and Quality of life (cartilage lesions 20.5/ACL 16.3)<sup>21</sup>
- MCID: NA
- Available online in a range of languages: Professor Ewa Roos, Institute of Sports Science and Clinical Biomechanics, [www.koos.nu/](http://www.koos.nu/)

*continued*

Table 35.4 Cont.

**Lysholm Knee Scoring Scale**

- An eight-item knee-specific scale initially designed for the purpose of assessing knee ligament function that can be self-administered or clinician administered
- Eight items related to knee function
- Score range 0–100 (100 = no symptoms or disability)
- Test–retest reliability: 0.88–0.97<sup>15, 22–25</sup>
- Construct validity: Fulkerson Knee Instability Scale 0.93,<sup>25</sup> Kujala Anterior Knee Pain Scale 0.86,<sup>26</sup> SF-12 physical function 0.54<sup>24</sup> and SF-12 role physical 0.48<sup>24</sup>
- MDC95%: 8.9–10.1<sup>15, 22–25</sup>
- MCID: Has not been established<sup>20</sup>
- Available online in a range of languages; original scale is freely available from the paper:<sup>22</sup> [www.ncbi.nlm.nih.gov/pubmed/4028566](http://www.ncbi.nlm.nih.gov/pubmed/4028566)

**Lysholm Knee Scoring Scale**

- A standardised method to grade work and sporting activity level; the questionnaire can be self-administered or clinician administered and was developed initially to be used in combination with the Lysholm knee score
- One item
- Score range 0–16 (16 = increased frequency of participation in athletic activity)
- Test–retest reliability 0.82–0.92<sup>15, 23, 25</sup>
- Construct validity: SF-12 physical function 0.46,<sup>23</sup> Lysholm Knee Scoring Scale 0.35<sup>24</sup>
- MDC95%: 1<sup>23</sup>
- MCID: Has not been established<sup>20</sup>
- Original scale is freely available from the original paper:<sup>22</sup> [www.ncbi.nlm.nih.gov/pubmed/4028566](http://www.ncbi.nlm.nih.gov/pubmed/4028566)

**Lysholm Knee Scoring Scale**

- Self-administered, knee-specific questionnaire that evaluates activity level of various knee disorders<sup>20</sup>
- Four items related to frequency of athletic activity<sup>20</sup>
- Score range 0–16 (16 = more frequent participation in athletic activities)<sup>20</sup>
- Test–retest reliability 0.97 (mixed knee pathologies)<sup>27</sup>
- Construct validity: Tegner Activity Scale 0.66,<sup>27</sup> Cincinnati Knee Rating System 0.67<sup>27</sup>
- MDC95%: Has not been established<sup>20</sup>
- MCID: Has not been established<sup>20</sup>
- Available online: [www.aaos.org/uploadedFiles/PreProduction/Quality/Measures/pdf-MARX%20SCALE-%20english.pdf](http://www.aaos.org/uploadedFiles/PreProduction/Quality/Measures/pdf-MARX%20SCALE-%20english.pdf)

SF = Short Form Health Survey; MDC = minimal detectable change; MCID = minimal clinically important difference;

Sn = sensitivity; Sp = specificity; ADL = activities of daily living

## Investigations

### Plain radiography (AP)

Should you perform a plain radiograph in cases of an acute knee injury? More than 90% of radiographs ordered to evaluate knee injuries are normal. The Ottawa knee X-ray decision rules may be helpful (Table 35.5).<sup>28</sup>

The main aim of performing a plain radiograph in cases of moderate and severe acute knee injuries is to detect a fracture:

- tibial avulsion fracture associated with an ACL or PCL injury
- a tibial plateau fracture following a high-speed injury or knee loading injury
- an osteochondral fracture after patellar dislocation.

The classic radiograph series should include an anterior-posterior (AP) view, a lateral view and a patellar tangential view (skyline or sunrise view). Additional oblique views can assist in identifying subtle loose bodies. A notch view can image cruciate avulsions and assess notch width as a factor for ACL injury. Weight-bearing views are ideal to assess for associated arthrosis. For children, comparative images of the contralateral side may be helpful in identifying subtle physeal injuries. Finally, stress radiographs can assist in defining the severity of ligamentous injuries.

If surgery is considered, preoperative films are justified.

### Magnetic resonance imaging

Magnetic resonance imaging (MRI) is reliable, safe and accurate in the diagnostic work-up of acute knee injuries.

**Table 35.5 Criteria for knee X-ray based on Ottawa knee rule\***

A knee radiograph is indicated after trauma only when at least one of the following is present:

- patient age more than 55
- tenderness at the fibular head
- tenderness over the patella
- inability to flex the knee to 90° (this captures most haemarthrosis, fractures)
- inability to weight-bear for four steps at the time of the injury and when examined.

To these, we suggest adding a high Index of suspicion for:

- high-speed injuries
- children or adolescents (who may avulse a bony fragment instead of tearing a cruciate ligament)
- if there is clinical suspicion of loose bodies.

\* The Ottawa knee rule was designed for use in the emergency department setting

Even when a ligament disruption is diagnosed by physical exam, MRI can add value by demonstrating the extent of associated injury to cartilage and meniscus. Patellar and quadriceps tendon injury can also be assessed.

#### PRACTICE PEARL

**MRI does not substitute for a good physical examination.**

MRI should never be ordered in the absence of a thorough history and physical examination and MRI findings should be interpreted in the light of the clinical findings. For example, a relatively high proportion of asymptomatic knees, especially in athletes >35–40 years, have meniscus tears.<sup>29</sup> Thus, evidence of a meniscal tear on MRI, but not associated with pain, local tenderness and positive examination findings, might be a 'red herring' (irrelevant) not in need of treatment.

MRI can be very useful when a primary patellar dislocation is suspected clinically and can help to detect osteochondral avulsion fractures that require surgical assessment. As the avulsed fragment swells (and deteriorates), there is limited window of time for surgical fixation. Usually it needs to be identified and treated within 10–14 days of the injury.

Significant knee injuries are associated with MRI findings of oedema in the subchondral region—a bone bruise or bone marrow lesion (BML). Clinically, a BML is associated with pain, tenderness, swelling and delayed recovery. The presence of a BML indicates articular cartilage damage,<sup>30, 31</sup> but its clinical relevance is discussed later in this chapter.

### The role for diagnostic arthroscopy

The concept of 'diagnostic arthroscopy' predates knee MRI. Today, it remains a diagnostic option in settings where MRI is not available. In the developed world, arthroscopy may be performed to seek pertinent

intra-articular pathology in those rare cases when the patient has persistent pain and swelling not responding to treatment and MRI is normal.

### Ultrasound examination

As outlined in Chapter 15, ultrasound examination can detect complete and partial patellar or quadriceps tendon tears, the size and location of bursal swelling and identify intra-versus extra-articular swelling if necessary. Ultrasound is not as efficacious for intra-articular injuries such as cruciate ligament or osteochondral injury. When radiography and MRI are available, ultrasound in a clinic/hospital setting adds little value to the assessment of the acute knee. As a sideline instrument, it can help confirm the diagnosis of a complete patellar or quadriceps tendon rupture and facilitate definite transfer, referral and treatment of that patient.

### MENISCAL INJURIES

Acute meniscal tears occur when the shear stress generated within the knee in flexion and compression combined with femoral rotation exceeds the meniscal collagen's ability to resist these forces.<sup>32</sup> The medial meniscal attachment to the medial joint capsule decreases its mobility, thereby increasing its risk for injury compared with the more mobile lateral meniscus.<sup>33</sup>

Experienced clinicians consider patients with meniscal injury to be on a continuum where the two anchors of the continuum can be considered as being:

1. the young patient with the morphologically pristine articular surfaces in whom substantial forces damage the previously pristine meniscus, and
2. the older (>40 years) patient in whom an 'acute' presentation of knee pain arises from a knee that already has features of (asymptomatic) articular cartilage damage and has menisci that already had (asymptomatic) degenerative features.

Patients will fall along this continuum—and where they fall should influence management (see the section on treatment). Degenerative meniscal tears occur in the older population frequently without an inciting event and also without symptoms.<sup>29</sup> (See box below.)

The different types of meniscal tear are shown in Figure 35.3.

### Clinical features

The history can provide a mechanism and a sense of the severity of meniscal tears. The clinical features can include the following.

- The most common mechanism of meniscal injury is a twisting injury with the foot anchored on the ground; this rotational force is often caused by another player's body.
- The twisting component may be of comparatively slow speed. This type of injury is commonly seen in football and basketball players.
- The degree of pain associated with an acute meniscal injury varies considerably. Some patients may describe a tearing sensation at the time of injury.
- A small meniscal tear may cause no immediate symptoms; it may become painful and cause knee swelling over 24 hours.
- Small tears may also occur with minimal trauma in the older athlete as a result of degenerative change of the meniscus.
- Patients with more severe meniscal injuries, such as a longitudinal ('bucket handle') tear, present with more

**Figure 35.3** Meniscus tear orientation and zones of vascularity; these drawings are of a medial meniscal tear

### Degenerative meniscus lesions

**Adapted from the ESSKA Meniscus Consensus project ([www.esska.org](http://www.esska.org))**

A degenerative meniscus lesion is a slowly developing lesion, typically involving a horizontal cleavage of the meniscus, generally in a middle-aged or older person. Such meniscus lesions are frequent in the general population and often incidental findings on knee MRI. There is often no clear history of an acute knee injury.

The prevalence of meniscus lesions in the general population:

- age 50–59 years = 25%
- 60–69 years = 35%
- 70–79 years = 45%
- patients with knee osteoarthritis = 75–95%.

There is very limited evidence that pain in the degenerative knee is directly attributable to a degenerative meniscus lesion, even if the lesion is considered to be unstable. Great caution must be taken before arriving at the conclusion that the degenerative meniscus lesion is the direct cause of the patient's knee symptoms.

Knee radiographs should be used as a first-line imaging tool to support a diagnosis of osteoarthritis or to detect certain more rare pathologies of the knee. Therefore, at least anteroposterior weight-bearing semi-flexed knee radiographs including a lateral view should be included in the work-up of the middle-aged or older patient with knee pain.

Knee MRI is typically not indicated in the first-line work-up of middle-aged or older patients with knee joint symptoms. However, knee MRI may be indicated in selected patients with refractory symptoms or in the presence of 'warning flags' or localised symptoms indicating more rare disease. If a surgical indication is considered, based on history, symptoms, clinical

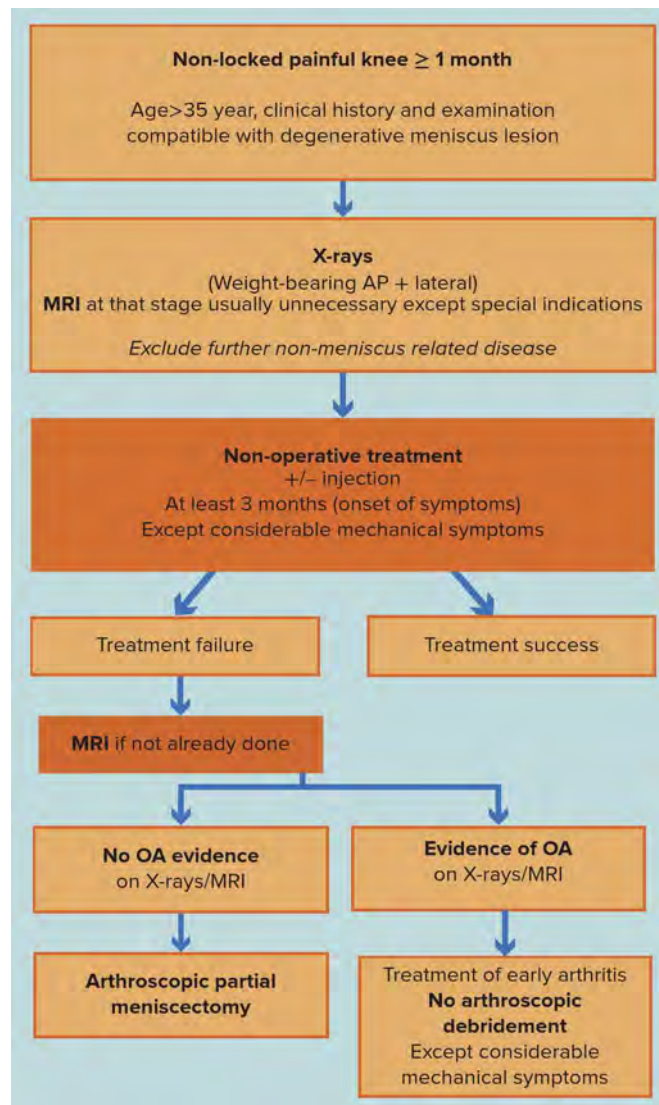

exam and knee radiographs, knee MRI may be useful to identify structural knee pathologies that may (or may not) be relevant for the symptoms.

#### When should arthroscopic partial meniscectomy (APM) be proposed?

- Surgery should not be proposed as a first line of treatment of degenerative meniscus lesions.
- After 3 months with persistent pain/mechanical symptoms despite appropriate rehabilitation: for a degenerative meniscus with normal X-rays/abnormal MRI (grade III meniscus lesion), APM may be proposed.
- Surgery can be proposed earlier for patients presenting with considerable mechanical symptoms.
- No arthroscopic surgery should be proposed for a degenerative meniscus lesion with advanced osteoarthritis on weight-bearing radiographs.

Most of the published randomised control trials (RCTs) found no difference in terms of clinical outcomes after surgery compared to non-operative treatment.

**Figure 35.4** ESSKA Meniscus Consensus algorithm

severe symptoms. Pain and restriction of range of motion occur soon after injury. Intermittent locking may occur as a result of the torn flap, the 'bucket handle', impinging between the articular surfaces. This may unlock spontaneously with a clicking sensation. This often occurs in association with ACL tears. In these patients, a history of locking may be due to either the ACL or the meniscal injury.

On examination, the signs of a meniscal tear include:

- joint line tenderness (palpated with the knee flexed at 45–90°)
- joint effusion—this is usually present, although absence of an effusion does not necessarily rule out meniscal damage
- pain—usually present with knee hyperflexion, such as squatting, especially with posterior horn tears
- restricted range of motion of the knee joint—this may be due to the torn meniscal flap or the effusion.

The flexion/rotation (McMurray's) test (Fig. 35.2p) is positive when pain is produced by the test and a clunk is heard or felt that corresponds to the torn flap being impinged in the joint. However, it is not necessary to have a positive McMurray's test (i.e. a clunk) to make a diagnosis of a torn meniscus. The hyperflexion portion of the McMurray's test provokes pain in most meniscal injuries. Pain produced by flexion and external rotation suggests medial meniscal damage, whereas pain on internal rotation indicates lateral meniscal pain. Asking patients where they feel pain during hyperflexion manoeuvres gives a suggestion of the location of the tear, medial or lateral. MRI is the investigation of choice. This can aid management if the MRI shows either a complex tear versus minimal damage or, more rarely, a peripheral meniscus tear.

## Treatment

The management of meniscal tears varies depending on the severity of the condition, the age of the patient and the presence of mechanical pathology. At one end of the

spectrum, a small tear or a degenerative meniscus tear, presenting with pain but not with mechanical symptoms such as locking or range of motion (ROM) restriction, should initially be treated conservatively.<sup>34</sup>

In a highly publicised paper published in the *New England Journal of Medicine* in 2013, the outcomes after arthroscopic partial meniscectomy in patients without knee osteoarthritis but with symptoms of a degenerative medial meniscus tear, were no better than those after a sham surgical procedure.<sup>35</sup> A recent trial compared exercise therapy with arthroscopic partial meniscectomy in middle-aged patients with degenerative meniscal tears and found no clinically relevant difference between the two groups in Knee injury and Osteoarthritis Outcome Score (KOOS) at 2 years. At 3 months, muscle strength had improved in the exercise group.<sup>36</sup>

An algorithm for the management of degenerative meniscal lesions is shown in the box above.

On the other hand, a large painful 'bucket handle' tear, causing a locked knee, requires urgent arthroscopic surgery. The majority of meniscal injuries fall somewhere between these two extremes and the decision on whether to proceed immediately to arthroscopy must be made on the basis of the severity of the symptoms and signs, as well as the demands of the athlete. Table 35.6 provides some clinical guidance for choosing either conservative or surgical treatment.

### PRACTICE PEARL

Physical examination features and MRI can predict those patients with early osteoarthritis and a meniscus tear who might benefit from arthroscopic surgery.<sup>37</sup> The highest likelihood of benefit from arthroscopic partial meniscectomy came in patients with clinical findings of increasing pain (as distinct from stable pain) as well as locking when these were complemented by MRI findings of a displaced meniscal tear but no marrow lesions.<sup>37</sup>

**Table 35.6 Clinical features of meniscal injuries that may affect prognosis**

Factors that may indicate non-surgical treatment is likely to be successful	Factors that may indicate surgery will be required
Symptoms develop over 24–48 hours following the injury	Severe twisting injury, athlete is unable to continue playing
Minimal injury or no recall of specific injury	Locked knee or severely restricted ROM
Able to weight-bear	Positive McMurray's test (palpable clunk)
Minimal swelling	Pain on McMurray's test with minimal knee flexion
Full range of movement with pain only at end of ROM	Presence of associated ACL tear
Pain on McMurray's test only in inner range of flexion	Little improvement of clinical features after 3–6 weeks of non-surgical treatment
Previous history of rapid recovery from similar injury	
Early degenerative changes on plain radiographs	

ROM = range of motion

### Non-surgical management of meniscal injuries

Non-surgical management of relatively minor meniscal injuries will often be successful, particularly in the athlete whose sporting activity does not involve twisting activities. The principles of non-surgical management are the same as those following partial meniscectomy (Table 35.7), although the rate of progress may vary depending on the clinical features.

The criteria for return to sport following meniscal injury, treated surgically or non-surgically, are shown below. If appropriate rehabilitation principles have been followed, then the criteria will usually all be satisfied:

- no effusion
- full range of movement
- normal quadriceps and hamstring function
- normal hip external rotator function
- good proprioception
- functional exercises performed without difficulty
- training performed without subsequent knee symptoms
- simulated match situations undertaken without subsequent knee symptoms.

### Surgical management of meniscal injuries

The aim of surgery is to preserve as much of the meniscus as possible. Some meniscal lesions are suitable for repair by arthroscopic meniscal suture. The decision as to whether or not to attempt meniscal repair is based on several factors, including acuity of the tear, age of the patient, stability of the knee, and tear location and orientation. The outer one-third of the meniscus rim has a blood supply and tears in this region can heal.

The tear with the best chance of a successful repair is an acute longitudinal tear in the peripheral one-third of the meniscus in a young patient.<sup>38</sup> Degenerative, flap, horizontal cleavages and complex meniscal tears are poor candidates for repair.<sup>33</sup> Young patients have a higher success rate of healing the meniscus. Peripheral meniscus tears in otherwise stable knees without concomitant ligament damage have a reduced success rate.<sup>39</sup>

Partial tears may require removal of the damaged flap of the meniscus. Patients with degenerative tears with no or minimal cartilage wear will be less symptomatic than those patients with concomitant cartilage damage.

### Rehabilitation after meniscal surgery

Rehabilitation should always commence prior to surgery and in some cases surgery can be avoided because 'prehabilitation' leads to full recovery. For patients scheduled for surgery it is important to:

- reduce pain and swelling with the use of electrotherapeutic modalities and gentle ROM exercises

- maintain strength of the quadriceps, hamstrings, and hip abductor and extensor muscles
- protect against further damage to the joint (patient may use crutches if necessary)
- explain the surgical procedure and the postoperative rehabilitation program to the patient.

The precise nature of the rehabilitation process will depend on the extent of the injury and the surgery performed (Table 35.7). Arthroscopic partial meniscectomy is usually a straightforward procedure followed by a fairly rapid return to activity. Some athletes with a small isolated medial meniscal tear are ready to return to sport after 4 weeks of rehabilitation.

#### PRACTICE PEARL

The rehabilitation process usually takes longer if there has been a more complicated tear of the meniscus, especially if the lateral meniscus is injured.

The presence of associated abnormalities, such as articular cartilage damage or ligament (MCL, ACL) tears, will necessarily slow down the rehabilitation process.

The time to return to pre-injury level of competition is significantly longer after lateral than medial meniscectomy in elite professional soccer athletes. Lateral meniscectomy has a higher incidence of adverse events in the early recovery period, including pain/swelling and the need for further arthroscopy. It is also associated with a significantly lower rate of return to play (RTP).<sup>40</sup>

If the athlete returns to play before the knee is properly rehabilitated, he or she may not experience difficulty during the first competition, but may be prone to develop recurrent effusions and persistent pain.

#### PRACTICE PEARL

A successful return to sport after meniscal knee surgery should not be measured by the time to play the first match. Clinicians must consider the player's longer term performance (season, multiple seasons). Is there acceleration of osteoarthritis?

Close monitoring is essential during post-meniscectomy rehabilitation as the remaining meniscus and underlying articular cartilage slowly increase their tolerance to load-bearing activities. Constant reassessment after progressively more difficult activities should be performed by the therapist monitoring the rehabilitation program. The development of increased pain or swelling should result in the program being slowed or revised accordingly.

Table 35.7 Rehabilitation program for both non-surgical management of meniscal injury and following arthroscopic partial meniscectomy

Phase	Goal of phase	Time post-injury	Physiotherapy	Exercise program	Functional/sport-related activity
Phase 1	Control swelling Maintain knee extension Knee flexion to 100°+ 4/5 quadriceps strength 4+/5 hamstring strength	0–1 week	Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Patient education	Gentle ROM (extension and flexion) Quadriceps/VMO setting Supported (bilateral) calf raises Hip abduction and extension Hamstring pulleys/rubbers Gait re-education drills Light exercise bike	Progress to FWB and normal gait pattern
Phase 2	Eliminate swelling Full ROM 4+/5 quadriceps strength 5/5 hamstring strength	1–2 weeks	Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Exercise modification and supervision	ROM drills Quadriceps/VMO setting Mini-squats and lunges Leg press (double, then single-leg) Step-ups Bridges (double, then single-leg) Hip abduction and extension with rubber tubing Single-leg calf raises Gait re-education drills Balance and proprioceptive drills (single-leg)	Swimming (light kick) Exercise bike Walking
Phase 3	Full ROM Full strength Full squat Dynamic proprioceptive training Return to running and restricted sport-specific drills	2–3 weeks	Manual therapy Exercise/activity modification and supervision	As above—increase difficulty, repetitions and weight where appropriate Jump and land drills Agility drills	Running Swimming Road bike Sport-specific exercises (progressively sequenced) (e.g. running forwards, sideways, backwards, sprinting, jumping, hopping, changing direction, kicking)
Phase 4	Full strength, ROM, and endurance of affected limb Return to sport-specific drills and restricted training and match play	3–5 weeks	As above	High-level sport-specific strengthening as required	Return to sport-specific drills, restricted training and match play

FWB = full weight-bearing; ROM = range of motion; VMO = vastus medialis obliquus

## MEDIAL (TIBIAL) COLLATERAL LIGAMENT INJURY

Injury to the MCL usually occurs as a result of a valgus stress to the partially flexed knee. This can occur in a non-contact mechanism such as downhill skiing or in contact sports when an opponent falls across the knee from lateral to medial. MCL tears are classified on the basis of their severity into grade I (mild, first degree), grade II (moderate partial ruptures, second degree) or grade III (complete tears, third degree).

In patients with a grade I MCL sprain, there is local tenderness over the MCL on the medial femoral condyle or medial tibial plateau but usually no swelling. When a valgus stress is applied at 30° of flexion, there is pain but no increased laxity. Ligament integrity is intact.

A grade II MCL sprain is produced by a more severe valgus stress. Examination shows marked tenderness, sometimes with localised swelling. A valgus stress applied at 30° of knee flexion causes pain. Some laxity (typically <5 mm) is present but there is a distinct end point. The knee is stable at full extension; ligament integrity is compromised but intact throughout its length.

A grade III tear of the MCL results from a severe valgus stress that causes a complete tear of the ligament fibres. The patient often complains of a feeling of instability and a 'wobbly knee'. The amount of pain is variable and frequently

not as severe as one would expect given the nature of the injury. On examination, there is tenderness over the ligament and valgus stress applied at 30° of flexion reveals gross laxity without a distinct end point. A minor valgus instability is usually also found at full extension. This test may not provoke as much pain as incomplete tears of the ligament due to complete disruption of the nociceptive fibres of the ligament.

Grade III MCL injuries are frequently associated with a torn ACL. The presentation of medial joint line tenderness and lack of full extension is more a reflection of MCL injury than meniscal pathology. The lateral meniscus is more at risk because the mechanism of injury typically opens the medial side and compresses the lateral side.

While swelling is uncommon in grade 1 sprains, it may occasionally be seen with grade 2 injuries. In grade 3 sprains, there is associated capsular tearing (deep fibres and superficial) and fluid escapes; some degree of swelling is common although a tense effusion is not present.

Distal MCL injuries have a tendency to recover more slowly than proximal lesions.<sup>41</sup>

## Treatment

A hinged knee brace (Fig.35.5a) provides support and protection to the injured MCL for a period of 4–6 weeks, during which time the athlete undertakes a

(a)

(b)

**Figure 35.5** Splints (a) Hinged knee brace (b) Limited-motion knee brace

comprehensive rehabilitation program. The brace and the exercise promote early healing of the ligament and any associated capsular injury.

In one study, there were no differences between patients with grade III MCL injuries that were treated non-surgically (i.e. bracing) or surgically, thus non-surgical treatment is recommended.<sup>42</sup> A typical rehabilitation

program for milder MCL injuries (grade I and mild grade II) is shown in Table 35.8.

The more severe MCL injury (the severe grade II or grade III tear) could be treated with a limited-motion knee brace (Fig.35.5b) and requires a longer period of rehabilitation and a rehabilitation program as shown in Table 35.9.

**Table 35.8 Rehabilitation of a mild MCL injury (see Figs 35.5 and 35.6)**

Phase	Goal of phase	Time post-injury	Physiotherapy treatment	Exercise program	Functional/sport-related activity
Phase 1	Control swelling Knee flexion to 100°+ Allow +20° extension 4/5 quadriceps strength 4+/5 hamstring strength	0–1 week	Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Patient education	Gentle ROM (flexion mainly) Quadriceps/VMO setting Supported (bilateral) calf raises Hip abduction and extension Hamstring pulleys/rubbers Gait re-education drills	Progress to FWB and normal gait pattern
Phase 2	Eliminate swelling Full flexion ROM Allow +10° extension 4+/5 quadriceps strength 5/5 hamstring strength Return to light jogging	1–2 weeks	Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Exercise modification and supervision	ROM drills Quadriceps/VMO setting Mini-squats and lunges Leg press (double, then single-leg) Step-ups Bridges (double, then single-leg) Hip abduction and extension with rubber tubing Single-leg calf raises Gait re-education drills Balance and proprioceptive drills (single-leg)	With hinged knee brace Straight-line jogging Swimming (light kick) Road bike
Phase 3	Full ROM Full strength Full squat Dynamic proprioceptive training Return to running and restricted sport-specific drills	2–4 weeks	Manual therapy Exercise/activity modification and supervision	As above—increase difficulty, repetitions and weight where appropriate Jump and land drills Agility drills	Progressive running Swimming Road bike Sport-specific exercises (progressively sequenced) (e.g. running forwards, sideways, backwards, sprinting, jumping, hopping, changing direction, kicking)
Phase 4	Full strength, ROM, and endurance of affected limb Return to sport-specific drills and restricted training and match play	3–6 weeks	As above	High-level sport-specific strengthening as required	With hinged knee brace Return to sport-specific drills, restricted training and match play

FWB = full weight-bearing; ROM = range of motion; VMO = vastus medialis obliquus

## ANTERIOR CRUCIATE LIGAMENT INJURIES

The annual incidence of ACL tears is 81 per 100 000 inhabitants aged 10–64 years in Europe.<sup>43</sup> In the United States more than 200 000 ACL reconstructions are performed annually at a cost of over US\$2 billion.<sup>44, 45</sup>

ACL injuries occur most frequently in sports involving pivoting and sudden deceleration (e.g. football, basketball, netball, soccer, European team handball, gymnastics, downhill skiing). The incidence rate of ACL tears is between 2.4 and 9.7 times higher in female athletes competing in similar activities.<sup>46–51</sup>

A genetic predisposition to ACL tear has been proposed; nonetheless, although specific gene polymorphisms and haplotypes have been identified, it is difficult to come to a conclusion on the basis of the existing literature. More studies are needed in larger populations of different ethnicities. Gene-gene interactions and gene expression studies in the future may delineate the exact role of these gene polymorphisms in ACL tears.<sup>52</sup>

Although ACL tears can occur in isolation, this is relatively uncommon. More frequent are those occurring in combination with associated injuries, such as meniscal tears, articular cartilage injuries or MCL injuries.<sup>53</sup> Principally, all ACL injuries have associated BMLs that are visible on MRI and form a footprint of the injury mechanism.<sup>30</sup>

### PRACTICE PEARL

As the torn ACL is only one part of a more complex problem in most ACL injured knees, the diagnosis 'ACL injury' may underplay the severity of an acute knee injury.

## Anatomy of the ACL

The ACL is one of four main ligaments that stabilise the knee joint and provides nearly 90% of the stability to anterior translation. The femoral insertion site of the ACL is located on the lateral intercondylar wall 43% of the distance from the proximal to distal femoral articular margin and, in the anterior to posterior dimension, 2.5 mm plus the radius of the ACL footprint anterior to the posterior articular margin.<sup>54</sup> The ACL's insertion on the tibial plateau is 15 mm anterior to the PCL insertion and two-fifths of the width from the medial to lateral tibial spine.<sup>54</sup>

The two bundles that make up the ACL are named according to their tibial insertion. The anteromedial (AM) bundle inserts anteriorly and medially on the tibia, near the medial intercondylar tubercle, while the posterolateral (PL) bundle inserts posteriorly and laterally on the tibia. The fibres of the AM bundle are isometric overall, while the PL bundle fibres are anti-isometric. This means that

**Figure 35.8** ACL bundles during knee flexion. From extension to full flexion, the posterolateral (PL) bundle femoral insertion moves in an arcuate path around the anteromedial (AM) bundle femoral insertion

the length of one portion of the ACL fibres varies during flexion-extension movements.<sup>55</sup>

During flexion, the PL bundle wraps around the AM bundle at the femur; the femoral insertion of the PL bundle forms an arc around the AM bundle's femoral insertion (Fig. 35.8). The anterior fibres of the AM bundle are more isometric, but nevertheless they are less taut between 0° and 30° flexion, which allows them to deform (deformation with superior concavity) as they make contact with the anterior side of the intercondylar notch, thereby allowing full knee extension. Conversely, they are continuously under tension between 30° and 130° flexion.

The posterior fibres of the PL bundle are the least isometric fibres; they are all parallel and completely taut in extension. Between 0° and 90° flexion, they gradually relax and then become taut again beyond 90° flexion. The PL bundle seems to have the most control over tibial rotation due to its more lateral position.<sup>55</sup>

An intact ACL stabilises the femur on the tibia and prevents anterior tibial translation and rotation during agility exercises, jumping, deceleration and pivoting with sudden changes of direction.

## Mechanism of ACL injury

In ball sports, two common mechanisms cause ACL tears:

1. a cutting manoeuvre<sup>56–58</sup>
2. single-leg landing.

Cutting or sidestep manoeuvres are associated with dramatic increases in the varus-valgus and internal rotation moments, as well as deceleration. The typical ACL injury occurs with the knee externally rotated and in 10° to 30° of flexion when the knee is placed in a valgus position as the athlete takes off from the planted foot and internally rotates their upper body with the

aim of suddenly changing direction (Fig. 35.9a).<sup>59, 60</sup> The ground reaction force falls medial to the knee joint during a cutting manoeuvre and this added force may tax an already tensioned ACL and lead to failure. Similarly, in the landing injuries, the knee is close to full extension.

High-speed activities such as cutting or landing manoeuvres require eccentric muscle action of the quadriceps to resist further flexion. It is hypothesised that vigorous eccentric quadriceps muscle action may play a role in disruption of the ACL. Although this normally may be insufficient to tear the ACL, it may be that the addition of a valgus knee position and/or rotation could trigger an ACL rupture.

One question that is often asked is why the ACL tears in situations and manoeuvres that the athlete has performed many times in the past. Frequently, there is some external factor that renders the athlete susceptible. The athlete could be off balance, be pushed or held by an opponent, be trying to avoid collision with an opponent or have adopted an unusually wide foot position. These perturbations may contribute to the injury by causing the athlete to plant the foot so as to promote unfavourable lower extremity alignment; this may be compounded by inadequate muscle protection and poor neuromuscular control.<sup>60</sup> Fatigue and loss of concentration may also be relevant factors.

What has become recognised is that unfavourable body movements in landing and pivoting can occur, leading to what has become known as the 'functional valgus' or 'dynamic valgus' knee, a pattern of knee collapse where the knee falls medial to the hip and foot. This has been called by Ireland the 'position of no return' or perhaps it should be termed the 'injury-prone position' since there is no proof that one cannot recover from this position (Fig. 35.9b).<sup>61</sup> Intervention programs aimed to reduce the risk of ACL injury are based on training safer neuromuscular patterns in simple manoeuvres such as cutting and jump-landing activities.

The mechanism of ACL injury in skiing is different from that in jumping, running and cutting sports such as football and basketball. In skiing, most ACL injuries result from internal rotation of the tibia with the knee flexed greater than 90°, a position that occurs when a skier who is falling backwards catches the inside edge of the tail of the ski.<sup>62</sup> Intervention programs in skiing are aimed at increasing the skier's awareness of patterns that are injurious to the knee and giving alternative strategies in the hope of avoiding these patterns altogether.

## Clinical features

The typical features of the history include the following.

- The patient often describes an audible 'pop', 'crack' or feeling of 'something going out and then going back'.

- Most complete tears of the ACL are extremely painful, especially in the first few minutes after injury.
- Athletes are often initially unable to continue their activity. Occasionally pain will limit further activity and this is usually associated with a large tense effusion. This is the clinical feature of a haemarthrosis. Occasionally, swelling is minimal or delayed.
- At times the athlete tries to recommence the sporting activity and feels instability or a lack of confidence in the knee. Occasionally the athlete may resume playing and suffer an acute episode of instability.

Most athletes with an ACL tear present to a sports medicine practitioner between 24 and 48 hours following the injury. At this stage, it may be difficult to examine the knee. The best time to examine a patient with this condition is in the first hour following the injury before the development of a tense haemarthrosis, which limits the examination. After a few days, when the swelling has started to settle and the pain is less intense, the examination becomes easier to perform in most cases.

After ACL rupture, the examination findings are typical:

- athletes have restricted movement
- they may have widespread mild tenderness
- lateral joint tenderness is often present (this is likely due to the impact pain from the collision of tibia and

- medial joint line tenderness may be present if there is an associated medial meniscus injury.

**PRACTICE PEARL**

**The Lachman's test is positive in ACL disruption and is the most useful test for this condition.**

The Lachman's test (Figs 35.2h-k) is a core competency for clinicians who see patients with knee injuries. It is judged on both the degree of anterior translation and the quality of the endpoint.<sup>3, 63</sup> With an effusion, maximum anterior tibial excursion may be restricted, but the quality of the endpoint is indistinct.

A positive pivot shift (or jerk) test (Fig. 35.2m) is diagnostic of ACL deficiency, but it requires the patient to have an intact MCL and iliotibial band, as well as the ability to extend the knee almost to full extension.<sup>3</sup> In cases of acute injuries, especially with associated injury (e.g. meniscal tear), the pivot shift test is difficult to

perform as the patient is unable to relax sufficiently. The anterior drawer test (Fig. 35.2l) is usually positive in cases of ACL tears but is the least specific test.<sup>3</sup> It should always be compared with the other side as often there is a degree of anterior tibial translation with this test which is quite variable within the population.

A plain radiograph of the knee should be performed when an ACL tear is suspected. Although radiographs are often normal, it may reveal an avulsion of the ligament from the tibia or a 'Segond' fracture at the lateral margin of the tibial plateau (Fig. 35.10); this has always been regarded as pathognomonic of an ACL rupture.<sup>64</sup> More recent studies have suggested that the Segond fragment is actually an avulsion of the anterior lateral ligament of the knee (the mid third capsular ligament) and represents a more severe injury than an isolated ACL tear.<sup>65</sup> Experienced clinicians and radiologists may also detect signs of increased joint fluid on plain radiographs.

MRI may be useful in demonstrating an ACL injury (Fig. 35.11) when the diagnosis is uncertain clinically, and will also demonstrate the typical bone bruise associated with ACL tears (see box below and Fig. 35.11). However, MRI should be used mainly to detect associated meniscal

**Figure 35.10** X-ray showing a Second fracture

**Figure 35.11** MRI of ACL (circled) showing the precise location of the tear (arrow)

tears and cartilage injuries when these injuries are suspected clinically.

### **Surgical or conservative treatment of the torn ACL?**

The optimal treatment of the torn ACL is not known, and there are several areas of controversy regarding the

### **What is a bone bruise?**

A post-traumatic bone marrow lesion (BML) (commonly referred to as a 'bone bruise') is only visible on MRI and accompanies an ACL injury in 80–98% of cases.<sup>30, 50</sup> The most common site is the lateral femoral condyle (Fig. 35.12a–c) and the lateral tibial condyle (Fig. 35.12d). The BML is most likely caused by impaction between the posterior aspect of the lateral tibial plateau and the lateral femoral condyle during displacement of the joint at the time of the injury. The presence of a BML indicates impaction trauma to the articular cartilage.<sup>31</sup>

The degree to which BMLs result in permanent injury to the cartilage continues to be investigated. At present it is not clear whether the presence of a BML is significant in the long term. Whether patients with a BML are more prone to osteoarthritis is a hot topic; one report indicated there was no difference in the longer term outcome between those with and without a post-traumatic BML.<sup>66</sup> Whether the presence of a BML should slow the rehabilitation process is also not clear but most clinicians favour a conservative course of treatment in this regard and limit pounding activities for 3 months post bone bruise.

(a)

**Figure 35.12** Bone bruising, evident on MRI, is an important diagnostic and prognostic feature often associated with ACL injury (a) Anteroposterior coronal MRI of a lateral femoral condyle bone marrow oedema in association with an ACL rupture. In radiology exams, this is considered pathognomonic of an ACL rupture until proven otherwise

(b)

(c)

management of ACL injuries. These include: the relative merits of non-surgical versus surgical management; the use of braces to prevent ACL injury or control the ACL-deficient knee; whether surgery should be performed immediately after the injury or should be delayed; whether a delayed reconstruction is to be performed weeks, months or even years after injury; the relative merits of the various surgical techniques; and the benefit of different rehabilitation programs.

(d)

**Figure 35.12 (cont.)** (b) The pathological appearance of a lateral femoral condyle bone marrow oedema in association with an ACL tear (c) Sagittal MRI appearance of the femoral condyle BML (d) The tibial plateau often also suffers bone marrow oedema; posterolateral tibial bruising (arrowheads in this coronal MRI) is also pathognomonic of ACL injury

There is only one RCT that has compared the results of a surgical and a non-surgical treatment strategy.<sup>67, 68</sup> In this study, 121 patients aged 18–35 with acute ACL injuries were randomly divided into two treatment groups: rehabilitation plus early ACL reconstruction; or rehabilitation alone with the possibility of a later ACL reconstruction if this was deemed necessary. Professional athletes and those who did not regularly practice sport were excluded from the study whereas competitive athletes on a subprofessional level and recreational athletes were included in the trial. After both 2 and 5 years, there were no differences in terms of knee function reported by the patient, return to sports or surgical treatment of meniscus injury between the groups. However, after 2 years 39% and after 5 years 51% of the group treated with initial rehabilitation needed to have an ACL reconstruction.

This study is used by the proponents of non-surgical rehabilitation treatment with an option of later reconstruction stating that the results at 2 years and 5 years were the same as the group who underwent early surgical reconstruction.<sup>67, 68</sup> The proponents of early surgical reconstruction use the 51% of the non-surgical group who required later reconstruction by 5 years as support for their claim as well as arguing that the delay in

reconstruction may lead to an increased risk of associated injuries of the meniscus and/or articular cartilage.<sup>69</sup>

Well-structured and extensive rehabilitation seems to be crucial for patients with ACL injury. Still, rehabilitation only is not sufficient for some 50% who are likely to need surgery in order to cope with their injury. Little is known about individual factors related to a good treatment outcome and thus the decision on selecting patients for surgery or rehabilitation is difficult.

Early phase instability at rest (i.e. within the first 3 months after injury) was not a good predictor for the need for later surgical treatment, whereas instability after 3 months was a relatively good prospective predictor.<sup>70</sup> The following factors should be considered when deciding whether or not to take the surgical option:

- the age of the patient
- the degree of instability in function
- a repairable meniscus tear
- associated knee injuries (e.g. MCL tear, meniscal tear)
- the patient's desire to return to jumping and pivoting sports
- the patient's occupation (e.g. firefighter, police).

The use of functional tests to help 'predict' those that may need operative ACL treatment is currently being investigated. Early reports suggest performing screening examination after 10 sessions of progressive exercise therapy was of value in helping to inform decision making for ACL reconstruction. Those who had surgery were also younger and had a higher activity level.<sup>71</sup>

A systematic review of the factors related to the need for surgical reconstruction after ACL rupture reviewed seven studies, three of which were of high quality.<sup>72</sup> Based on these studies, neither sex (strong evidence) nor the severity of knee joint laxity (moderate evidence) can predict soon after ACL injury whether a patient will need ACL reconstruction following non-operative treatment. All other factors identified in this review either had conflicting or only minimal evidence as to their level of association with the need for surgical reconstruction.

Still, it is important to note that there is limited evidence in determining who will benefit from what treatment. Most decisions are made in consensus between the treating clinician and the patient and are based on empiric knowledge rather than scientific evidence.

The degree of instability may be assessed by a number of parameters. It is important to note that instability at rest (i.e. at clinical examination of the knee) is not a reliable indication of the functional instability experienced by the patient. However, as recurrent episodes of giving way indicate functional instability, this is likely to be a reliable indication of disability and an increased likelihood of needing surgery.

#### PRACTICE PEARL

For patients presenting with a history of 'giving way' or a history of instability in function despite adequate strength, an ACL reconstruction is recommended.

Many surgeons would advocate ACL reconstruction in patients with concomitant meniscal injuries (50% prevalence) that could be repaired. The decision is also influenced by the demands placed on the knee. A young athlete who wishes to return to a pivoting sport, such as football or basketball, is more likely to need an ACL reconstruction than an athlete who is prepared to confine activity to those sports that do not involve a large amount of twisting, turning and pivoting. However, some of the patients in this category do perform well after 2 years, also after rehabilitation alone.<sup>67</sup> It is likely that repeated episodes of giving way increase the risk of developing knee osteoarthritis but there is no scientific evidence to support that an ACL reconstruction reduces the incidence of future osteoarthritis. A recent report did not reveal any differences in the frequency of osteoarthritis between surgically reconstructed and non-surgically treated patients 10 years after ACL injury.<sup>73</sup>

Another important factor to assess is the likelihood of the patient adhering to a comprehensive, time-consuming rehabilitation program. If the patient indicates a lack of willingness to undertake appropriate rehabilitation, treatment may not be successful. It is important to also note that the results of an ACL reconstruction are dependent on a successful postoperative rehabilitation. Other factors to consider are the cost of surgery, rehabilitation and the amount of time off work.

In summary, surgery is generally recommended for athletes wishing to participate in a high-speed sport with constant change of direction and pivoting. Rehabilitation without surgery, however, has been shown to be an alternative for this patient category.<sup>67</sup> A trial of non-surgical management does not rule out the possibility of eventual later surgery when indicated.

### Surgical treatment

There are numerous surgical techniques used to treat ACL injuries. As ACL tears are usually in-substance tears and therefore not suitable for primary repair, reconstruction of the ACL (ACLR) is the surgical treatment of choice. ACLRs are performed 'arthroscopically aided' through small arthroscopic incisions (see box below). Arthroscopic surgery utilises small incisions to help visualise the inside of the joint and facilitates tunnel placement of the ACL graft. Depending on the type of graft, incisions to harvest the graft and secure tunnel access for graft fixation will be made as well.

### What happens during ACL reconstruction surgery?

The surgical reconstruction technique involves harvesting the tendon (patellar or hamstring, Fig. 35.13a) through a small incision and threading the tendon through tunnels drilled in the bones. The most crucial parts of the operation are locating the points of entry of the tibial and femoral tunnels and then the fixation of the graft.

The tibial attachment should be in the centre of the previous anterior cruciate attachment (at the level of the inner margin of the anterior portion of the lateral meniscus). The femoral attachment is to the position of optimal or maximised

isometry. This is a position in the intercondylar notch on the femur at which the graft is at a fixed tension throughout the range of knee movement.

Once the graft attachment areas have been delineated and prepared, the graft is fixed by one of a variety of different methods. These methods include interference screw fixation (Fig. 35.13b), staples or the tying of sutures around fixation posts. The better the quality of graft fixation, the more comfortable one is in advancing rehabilitation in the first weeks after surgery.

(b)

(c)

### Type of graft

The aim of an ACLR is to replace the torn ACL with a graft that reproduces the normal kinetic functions of the ligament. In most cases, an autogenous graft, taken from around the knee joint, is used. The most common grafts used are the bone-patellar tendon-bone (BTB) autograft involving the central third of the patellar tendon or a multi-stranded hamstring (semitendinosus +/- gracilis tendons) graft using the ipsilateral limb. Other autograft choices include the quadriceps tendon and autografts from the contralateral limb. Allografts (donated tissue from cadaveric specimens) have also been used with the potential benefit of reducing harvest site morbidity but introducing questions of graft incorporation or disease transmission (e.g. HIV, hepatitis, bacterial). Graft choice is dependent on a number of factors including surgeon competency and familiarity with the various techniques.

### Patellar tendon versus hamstring tendon graft

There is debate on graft choice, in particular patellar tendon versus hamstring tendon. Reviews of the numerous research papers comparing the two techniques have shown very little difference in outcome measures and there is no universal agreement on which technique is superior.<sup>74,75</sup> Each case should be considered on its merit, taking into account some of the differences in potential postoperative issues.

For example, after patellar tendon reconstruction, pain with kneeling is common and up to 50% of patients report anterior knee pain with kneeling. Patients who have a hamstring graft ACL reconstruction have decreased end-range knee flexion power. The incisions used for hamstring grafts are smaller and more cosmetic. Potential problems need to be addressed in the rehabilitation program and for that reason we advocate rehabilitation regimens with different emphasis for the two types of surgery.

### Autograft versus allograft

There has been considerable debate regarding the relative merits of autograft (using the patient's own tissue) and allograft (using another person's tissue). A summary of the nine RCTs and 10 systematic reviews showed statistically significant differences in favour of autograft for clinical failure, the Lachman test, the instrumented laxity test and the Tegner score.<sup>76</sup> When subgroup analyses were conducted based on whether irradiation was used, autograft achieved better clinical outcomes than irradiated allograft in terms of the Lysholm score, clinical failure, the pivot shift test, the Lachman test, the instrumented laxity test and the Tegner score. In addition, there were no significant differences between the autograft and non-irradiated allograft groups for all eight indices. The authors concluded that autograft had greater advantages than irradiated allograft with respect to function and stability,

whereas there were no significant differences between autograft and non-irradiated allograft.

### Single bundle versus double bundle

The ACL has two distinct bundles: the anteromedial (AM) bundle and the posterolateral (PL) bundle. It is possible to reconstruct the bundles individually (anatomic double-bundle ACL reconstruction) particularly in large knees. Double-bundle ACL reconstruction (DBACLR) restores the native footprint of the ligament and is definitely superior to isometric ACLR. Whether or not double-bundle anatomic is better than single-bundle anatomic is as yet undecided.

Meta-analyses have suggested that double bundle may result in superiority in rotational stability, the degree of osteoarthritis (OA) changes, and subjective function score postoperatively compared with the single-bundle procedure<sup>77</sup> and less anterior laxity.<sup>78</sup> However, there was no difference on functional outcomes between the treatment procedures at long-term follow-up. Given the lack of conclusive evidence of superiority and the doubling of implant costs involved with double-bundle ACLR, single bundle is probably the procedure of choice at this point in time.

### Timing of surgery—early or late

The timing of ACL reconstruction after an acute injury has come under review. Traditionally and with very little evidence in support, ACLRs were performed as soon as practical after the injury. However, there is some evidence that delaying the surgery may decrease the postoperative risk of arthrofibrosis (see 'Soft tissue stiffness').<sup>79</sup> Initial reports suggested 3 weeks as the appropriate delay in surgery but now focus is more on the condition of the knee rather than the actual time. The injured knee should have little or no swelling and have near full ROM; the patient should have a normal gait.

A systematic review examined 22 articles (3583 patients).<sup>80</sup> Eight articles promoted early reconstruction, whereas the majority of articles found no difference in outcome between early and delayed surgery. Two articles were inconclusive. The authors concluded that there were few or no differences in subjective and objective outcomes related to timing of ACL reconstruction.

### Combined injuries

Injuries of the ACL rarely occur in isolation and thus most of all ACL injuries occur in combination with other injuries. The presence and extent of associated injuries may affect the way in which the ACL injury is managed. Associated injury to the MCL (grades II-III) poses a particular problem due to the tendency to develop stiffness after this injury. Most orthopaedic surgeons would initially treat the MCL injury in a knee brace for a period of 4-6 weeks, during

which time the athlete would undertake a comprehensive rehabilitation program (see below). This allows for early healing of the ligament injury and any potential capsular injury, reducing the risk of chronic valgus instability.

ACL injuries are frequently associated with chondral damage. The majority of the literature supports the clinical relevance of cartilage lesions which are correlated with a poorer outcome after ACL reconstruction.<sup>81</sup>

Injuries to the posterolateral corner which may occur in conjunction with an ACL injury are considered later in the chapter.

### Rehabilitation after ACL injury

Traditionally, most rehabilitation principles have been evaluated as postoperative rehabilitation protocols due to the frequent use of ACL reconstruction as the treatment of choice. However, rehabilitation alone, performed according to a protocol similar to that used postoperatively, was recently shown to provide similar 2-year outcomes as the combination of ACL reconstruction plus rehabilitation.<sup>67</sup> Thus, rehabilitation may be performed in a similar setting regardless of whether or not additional reconstructive surgery is performed.

Rehabilitation after ACL injury has changed dramatically over time, resulting in greatly accelerated rehabilitation programs.<sup>82</sup> The speed at which an ACL injury is rehabilitated must take into account the time it takes for soft tissues to heal and remodel as well as the neuromotor control and coordination of the athlete. The most important aims are: reduction of pain, swelling and inflammation; and regaining ROM, strength and neuromuscular control.<sup>83</sup> The major change over the past few years is the incorporation of a core stability program along with increased emphasis on proprioceptive and balance exercises. These exercises have been used in successful ACL prevention programs (see Chapter 12). Despite the widespread acceptance of these elements into rehabilitation programs, the two RCTs have not shown convincing evidence of their efficacy.<sup>84, 85</sup>

The rehabilitation program is shown in Table 35.10. The time frames in the table are a guideline only and must be adjusted depending on the progress of the individual patient. It is essential to rehabilitate each patient individually, taking into consideration the extent of damage to the knee (e.g. articular cartilage damage), the patient's adherence to the exercise program, the amount of knee stiffness, which varies considerably between patients, and the eventual functional aims of the patient (e.g. daily activities, high-level sport). The patient must be taught to monitor the signs and symptoms around the knee following each work-out. Ice may need to be applied if pain, inflammation or swelling is present.

The timing of return to sport (see next section) is dependent on several different factors, including knee

stability, neuromotor function, the nature of the sport, the therapist's and coach's opinion, and the confidence of the patient.

Neuromotor function and muscle strength should be regularly assessed during rehabilitation and prior to return to play. An excellent functional test that can be easily conducted in the clinical setting during the later stages of rehabilitation is the single-leg hop test. The patient performs the single-leg hop by hopping as far as possible using the injured leg, with distance being measured. Athletes with good function are able to land confidently, and 'stick it'. Those with functional disability step further or take another small hop. Comparison should be made with the uninjured leg. Another way of testing function is by incorporating sport-specific drills. Isokinetic testing may be used to evaluate muscle strength. Quadriceps and hamstring strength should approximate that of the uninjured leg. In the light of all these factors and the varying progress of different athletes and the sport to which they are returning, the time for return to sport after ACL injury may vary from 4–12 months.

The use of a brace on return to sport is not necessary but may help the athlete's confidence. Several systematic reviews and RCTs on the topic do not recommend the use of postoperative brace after ACLR. Bracing does not seem to help with pain, function, rehabilitation and stability.<sup>74</sup>

The research into the effectiveness of various rehabilitation techniques has generally been of poor quality and thus limited conclusions can be drawn. The Orthopaedic Section of the American Physical Therapy Association publishes clinical practice guidelines, including the level of supporting evidence, for treatment of knee sprains based on an international classification of functional disability.<sup>86</sup> The MOON Group (a collection of orthopaedic surgeons) has developed, in conjunction with their physiotherapists, rehabilitation guidelines based on a systematic review of the available evidence.<sup>87</sup>

### Considerations in rehabilitation after ACLR

When performed after ACLR, management principles have changed as surgical techniques have changed. There is a better understanding of the initial graft strength and the strength of various graft fixation techniques. There is no difference in joint laxity or clinical outcome between those who underwent accelerated rehabilitation compared to those with a non-accelerated program at 2 years post-surgery.<sup>88</sup>

Without an open arthrotomy, the extensor mechanism has been better preserved with reduced joint adhesions. The principle of complete immobilisation has been replaced with protected mobilisation, with a resultant dramatic decrease in stiffness and increase in ROM of the knee joint. This has allowed earlier commencement of a strengthening program and rapid progression to functional

Table 35.10 Rehabilitation following ACL reconstruction (see Figs 35.5 and 35.6)

Phase	Goal of phase	Time post-surgery	Physiotherapy treatment	Exercise program	Functional/sport-related activity
Prehabilitation (preoperative rehabilitation)	No/minimal swelling Restore full ROM, particularly extension General 4+/5 lower limb strength or better Patient education—anatomy, surgical procedure, rehabilitation commitment, and goal setting	NA	Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Exercise modification and supervision	Dependent on ability of patient In early stages, follow the exercise program from phase 1 and progress to phase 2 If patient has high level of function, start with exercise program from phase 2 and progress weights and repetitions as appropriate	Walking Bike riding Swimming (light kick and no breaststroke)
Phase 1	PWB-FWB Eliminate swelling 0–100° ROM 4+/5 quadriceps strength 5/5 hamstring strength	0–2 weeks	Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Patient education	Gentle flexion ROM Extension ROM to 0° Quadriceps/VMO setting Supported (bilateral) calf raises Hip abduction and extension Hamstring pulleys/rubbers Gait drills	Nil
Phase 2	No swelling Full knee hyperextension Knee flexion to 130°+ Full squat Good balance and control Unrestricted walking	2–12 weeks	Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Exercise modification	ROM drills Quadriceps/VMO setting Mini squats and lunges Leg press (double-leg, then single-leg) Step-ups Bridges (double-leg, then single-leg) Hip abduction and extension with rubber tubing Single-leg calf raises Gait re-education drills Balance and proprioceptive drills (single-leg)	Walking Exercise bike

Table 35.10 (cont.)

Phase	Goal of phase	Time post-surgery	Physiotherapy treatment	Exercise program	Functional/sport-related activity
Phase 3	Full ROM Full strength and power Return to jogging, running, and agility Return to restricted sport-specific drills	3–6 months	Manual therapy Exercise/activity modification and supervision	As above—increase difficulty, repetitions, and weight, where appropriate Jump and land drills Agility drills	Straight-line jogging Swimming (light kick) Road bike Straight-line running at 3 months Progressing to sport-specific running and agility (progressively sequenced) (e.g. running forwards, sideways, backwards, sprinting, jumping, hopping, changing directions, kicking)
Phase 4	Return to sport	6–12 months	As above	High-level sport-specific strengthening as required	Progressive return to sport (e.g. restricted training, unrestricted training, match play, competitive match play)

FWB = full weight-bearing; PWB = partial weight-bearing; ROM = range of motion; VMO = vastus medialis obliquus

exercises. The average time for rehabilitation after ACLR to return to sport has been reduced from around 12 months to 6–9 months before the injured individual could regain sporting activity. The importance of early return to sports in relation to later osteoarthritis development needs to be determined.

Rehabilitation must commence from the time of injury, not from the time of surgery, which may be days, weeks or months later if needed at all.<sup>89</sup> The initial management aims to reduce pain, swelling and inflammation, thus reducing the amount of intra-articular fibrosis and resultant loss of ROM, strength and function. Treatment should commence immediately after injury, including interferential stimulation, ultrasound and transcutaneous electrical nerve stimulation (TENS), as well as strengthening exercises for the quadriceps, hamstring, hip extensor, hip abductor and calf muscles. Pain-free ROM exercises should also be performed.

Additional muscle strengthening and neuromuscular rehabilitation prior to surgery can improve outcomes.<sup>90, 91</sup> This is often referred to as 'pre-habilitation' or 'pre-hab'. This period is also an opportunity for the clinician to explain the hospital protocol and the progression and goals of the rehabilitation program. The therapist should set a realistic goal, taking into consideration the individual patient. It is helpful to provide a written explanation as well. If necessary, the postoperative knee brace should be fitted and the use of crutches taught.

Immediately following surgery, weight-bearing status is largely determined by concomitant injuries (e.g. meniscal repair, intra-articular fracture or function of other ligaments). Isolated ACLRs are typically treated as weight-bearing as tolerated, using a brace and/or crutches until adequate quadriceps muscle strength is restored. Instructions should be given regarding the use of crutches as the patient will progress from limited weight-bearing to full weight-bearing for the first 2 weeks.

The rehabilitation programs for patellar tendon and hamstring tendon graft ACLRs are slightly different due to the need to prevent the particular complications associated with each type of reconstruction. Potential problems with the patellar tendon graft are kneeling pain, patellar tendinopathy and/or reduced patellar mobility (see the next section). Therefore, attention must be paid to this area during the rehabilitation program with the use of soft tissue therapy to the patellar tendon, accompanied by a strengthening program for the tendon and patellar taping (Chapter 35) to prevent patellofemoral and fat pad problems. The hamstring graft should be treated as though the patient has had a hamstring tear (Chapter 34), with an appropriately paced rehabilitation program to restore full ROM and strength.

## **Problems encountered during ACL rehabilitation**

### **Problems that are not treatment dependent**

#### **Low back pain**

Low back pain is not uncommon in the early stages of the rehabilitation program possibly due to the use of crutches, altered gait patterns or altered sleep patterns. It usually occurs in patients who have a prior history of low back pain.

### **Problems in non-surgically treated patients**

#### **Instability**

The main problem that may occur in the rehabilitation of non-surgically treated patients is remaining functional instability. All non-surgically treated patients should have a scheduled appointment with the treating clinician within the first 3 months after injury. When having complaints on symptomatic instability or lack of trust in their knee due to instability despite a successful rehabilitation, an ACLR could be recommended. This is especially true for patients still wishing to resume sporting activities.

#### **Symptomatic meniscus tears**

Another problem that may increasingly occur among this group is a symptomatic meniscus tear. Unlike those undergoing ACLR, the non-surgically treated patient does not routinely undergo surgery for meniscus tears associated with their initial injury. Some of these meniscus tears remain asymptomatic, some might heal but some will develop to be symptomatic. Here it is important to differentiate between symptoms adhering to the injured meniscus and symptoms related to the ACL injury and to treat that symptomatic injury. When such problems are encountered, the best option is to let an experienced orthopaedic surgeon assess the injury and discuss treatment alternatives with the patient.

### **Problems in surgically treated patients**

Apart from surgical complications (e.g. infection, deep venous thrombosis, graft harvest site morbidity), a number of secondary problems may occur during the postoperative rehabilitation process.

#### **Patellar region pain**

Patellofemoral pain may occur on the injured or the uninjured side. Patients may present with typical symptoms of patellofemoral pain (Chapter 36) but often will not comment on the presence of anterior knee pain as they assume that it is part of the normal process following surgery. The patient should always be asked about symptoms at the front of the knee and the patellofemoral joint should be examined at each visit.

Such factors may be the same as those that predispose a person without ACLR to having patellofemoral pain (Chapter 36), such as altered patellofemoral alignment, altered lower limb mechanics (including internal hip rotation and adduction, apparent knee valgus), quadriceps and hip muscle insufficiencies; or may have developed as part of the ACL injury and reconstruction process. For example, following ACLR, some people have fat pad thickening and oedema, often associated with patella baja or alta, insufficient restoration of quadriceps and hip muscle strength and control, altered tibial rotation (relative to the femur), or persistent loss of knee extension or flexion range. Some of these factors may be aggravated by persistent swelling and/or pain. Such factors should be evaluated and treated as appropriate.

Closed chain activities such as squats and lunges are preferred to open chain activities, as open chain loaded knee extension results in larger patellofemoral forces in the functional knee flexion range of 0° to 60°. <sup>92</sup> To minimise patellofemoral force, open chain exercises should be performed between 60° and 90° of knee flexion, while closed chain exercises should be maintained to <60° flexion. However, loaded knee extension at knee flexion angles <60° is thought to strain the ACL graft; clinicians need to exercise caution during early strengthening interventions in this knee range. <sup>93</sup> Notably, patellofemoral problems occur not only with patellar tendon graft reconstructions but also with hamstring tendon graft reconstructions with considerable morbidity. <sup>94</sup>

The infrapatellar fat pad may be damaged by the arthroscope and can be the source of considerable discomfort after ACL reconstruction. Taping techniques (Chapter 36) can be used to unload the fat pad.

Another complication seen after patellar tendon ACL reconstruction is inferior displacement of the patella (patella baja) due to traction on the patella by tight infrapatellar soft tissue structures. Patellar tendinopathy (Chapter 36) is also seen following ACL reconstruction, especially with patellar tendon grafts.

A common and as yet unexplained finding in cases of chronic ACL insufficiency and following reconstruction is trochlea chondral damage. Factors related to the development and persistence of chondral damage in the tibiofemoral and patellofemoral compartments are currently being studied. <sup>95, 96</sup>

### Lower limb stiffness

Stiffness in the foot and ankle commonly occurs as a result of a period of non weight-bearing and the wearing of a brace. Tightness of the Achilles tendon is common. These problems may not be recognised until the patient returns to running. Full ROM of these joints should be maintained early in the rehabilitation program with mobilisation and stretching in addition to active plantarflexion/dorsiflexion exercises.

### Soft tissue stiffness (arthrofibrosis following surgery)

The rehabilitation program and its rate of progression will be influenced by the intrinsic tissue stiffness or laxity of the patient. This depends on the nature of the patient's collagen and appears to correlate with generalised ligamentous stiffness or laxity throughout the body. Patients with stiff soft tissues may develop a large bulky scar with adhesions after ACLR. These patients are usually slow to regain full flexion and extension and the knee may require passive mobilisation by the therapist. Patients tend to have tight lateral structures around a stiff patellofemoral joint. This is known as arthrofibrosis or stiff knee syndrome. <sup>97</sup>

Treatment involves encouraging active movement, early passive mobilisation, soft tissue therapy and encouraging early activity. Efforts to control swelling are critical. It may be helpful to remove the brace earlier than usual in these patients. Severe cases may require arthroscopic scar resection as well as a vigorous rehabilitation program.

As mentioned previously, delaying the surgery until all signs of the haemarthrosis have resolved and full ROM has been regained in particular full extension, reduces the incidence of arthrofibrosis in ACL reconstructions.

### Soft tissue laxity

The group of patients classified as having 'loose' soft tissue are characterised by generalised increased ligamentous laxity. These patients tend to rapidly gain good ROM in extension and flexion. They are treated by prolonging the time in the brace to prevent hyperextension and restricting the range available. ROM exercises are discouraged, mobilisation contraindicated and full extension work reduced to avoid stretching the graft. The rehabilitation program is slowed in these patients to allow time for the graft to develop as much scar tissue as possible.

### Muscle weakness

Muscle weakness occurs following ACL reconstruction despite significant regeneration of the tendon used for the graft (hamstring or patellar). <sup>98, 99</sup> A systematic review found that the majority of studies could demonstrate specific muscular imbalances in the ACL-reconstructed leg with control or the contralateral leg with the knee flexors and extensors involved. <sup>100</sup> In addition, some recent studies have also shown deficits of the hip muscles after ACLR.

Muscular deficits are pronounced within the first 6 months after surgery, but they can persist up to 2 years and longer. The muscular deficits after ACLR are graft related. Extensor deficits are associated with patellar tendon grafts; flexion deficits are associated with hamstring grafts. There is limited evidence with inconsistent study results that there is a difference in postoperative flexor strength between patients with semitendinosus tendon autograft and semitendinosus/gracilis tendon autograft.

The authors of the systematic review recommended that isokinetic examination of flexor and extensor strength should be used as one criterion to decide if an athlete can be allowed to return to unrestricted sporting activities and that the rehabilitation protocol after ACLR should focus on the used graft and aim on negotiation of graft-related muscle weakness. Training to improve hip muscle strength may help to prevent a dynamic valgus during landing positions.<sup>100</sup>

### Proprioception

Postural control is impaired following ACLR. A systematic review included 10 studies evaluating 644 participants at a mean 29 months follow-up.<sup>101</sup> In static balance tasks, there was a trend towards improved postural control in the control group for eyes-open but not eyes-closed conditions. Only four studies evaluated dynamic balance and the results from these were somewhat mixed. They concluded that there appeared to be a trend towards impaired static and dynamic postural control in patients following ACLR surgery, although the limited number of studies and differing methodologies made conclusions tentative.

Patients with ACL injury have poorer proprioception than people without such injuries when measured using joint position sense and threshold to detect passive motion techniques respectively. Patients had poorer proprioception in the injured than uninjured leg and the proprioception of people whose ACL was repaired was better than those whose ligament was left unrepaired.<sup>102</sup>

A review of 22 studies covering a total of 479 patients with a mean age of 27.3 showed that patients after ACLR have altered gait patterns that can persist for up to 5 years after surgery.<sup>103</sup>

### Psychological problems

Psychological responses are important factors in RTP after ACLR.<sup>104</sup> In one study, 56 out of 187 athletes (31%) had returned to their pre-injury level of sports participation at 12 months. Significant independent contributions to returning to the pre-injury level by 12 months after surgery were made by psychological readiness to return to sport, fear of re-injury, sport locus of control and the athlete's estimate of the number of months it would take to return to sport, as measured preoperatively and at 4 months postoperatively.

Another study looked at fear of injury and found that athletes participating in sport 2-7 years following their ACL reconstruction generally appear to do so without fear of re-injury.<sup>105</sup> However, they commented that gender, the timing of surgery following injury and the level of sport the athletes returned to may be associated with fear of re-injury following surgery.

Patient psychological factors are predictive of ACLR outcomes.<sup>106</sup> Self-confidence, optimism and self-motivation are predictive of outcomes, which is consistent with the theory of self-efficacy. Stress, social support and athletic self-identity are predictive of outcomes, which is consistent with the global relationship between stress, health and the buffering hypothesis of social support.

In a review of psychosocial factors influencing the recovery of athletes with ACL injury a high internal health locus of control and a high self-efficacy were useful cognitive factors to facilitate the recovery.<sup>107</sup> Athletes with a low level of fear of re-injury had the best knee outcome after the injury followed by a reconstruction. In addition, athletes who returned to sport had less fear of re-injury, and were more experienced and established athletes compared with athletes who did not return to sport. Furthermore, researchers showed that there was a positive relation between goal setting and adherence, which in turn yielded a positive relation with the outcome of the rehabilitation of an ACL injury. There were several psychosocial interventions that appeared to be facilitating the rehabilitation process.

### Outcomes after ACL treatment

While the general consensus among the surgical and sporting communities is that those sustaining an ACL injury can and often do make a full recovery after ACLR surgery, research findings suggest otherwise. Four main outcome measures are used to determine the success or failure of ACL treatment:

1. the patient's own perspective of (self-reported) knee function
2. return to pre-injury sporting activities
3. re-injury rate
4. prevalence of osteoarthritis.

### Self-reported knee function

The recommended assessment of outcome after ACL injury has changed over the last 15 years. Traditionally, outcome was obtained by an observer, often using a scoring scale such as the Lysholm Knee Scoring Scale,<sup>22</sup> the Cincinnati Knee Ligament Rating Scale<sup>108</sup> or the International Knee Documentation Committee (IKDC).<sup>109</sup> It is well known that treating surgeons underestimate symptoms and overestimate function when compared to the patient's own opinion. This was also confirmed after ACL reconstruction in a study from 2001.<sup>110</sup> Thus, the patients' own perspective of knee function has been in focus over the last two decades and the use of validated self-administered questionnaires has been promoted. Patient-reported outcomes are generally good at a minimum of 10 years following ACL reconstruction.<sup>111</sup>

After ACLR, data from large samples could be obtained from registries, mainly from Sweden, Norway and Denmark. Here, a large improvement could be seen over the first 2 years after surgery, suggesting that the self-reported knee function is greatly improved by treatment. However, a report from the Swedish ACL registry with data from more than 2000 individuals reported that self-reported knee-related quality of life, knee pain and knee symptoms were much worse after ACL reconstruction<sup>112</sup> as compared to an age-matched community-based sample.<sup>113</sup>

Little is known about self-reported knee function after non-surgical treatment. In an RCT comparing surgical and non-surgical treatment strategies, no differences were found between the two treatment arms after 2 and 5 years.<sup>67, 68</sup> The results were comparable to those previously reported after ACLR.

Eleven studies reported quality of life (QoL) in 473 ACL-deficient individuals, at a mean of 10 (range 5–23) years following ACL rupture.<sup>114</sup> Eight studies reported knee-related QoL using the Knee injury and Osteoarthritis Outcome Score QoL subscale (KOOS-QoL); scores were impaired compared to population norms. Health-related QoL, measured with the SF-36 domain scores in five studies, was similar to population norms, but impaired compared to physically active populations. Meta-analysis revealed no significant differences in KOOS-QoL and SF-36 scores between ACL-deficient and ACL-reconstructed groups.

In summary, both surgical and non-surgical treatment has been shown to improve self-reported knee function after ACL injury. There exists no scientific evidence to support superiority of one treatment over the other. Two years after injury, ACL-injured patients report a worse outcome than an age-matched community-based sample, which indicates that none of the current treatment options are successful in restoring knee function from the patients' own point of view.

### Return to sport

One of the major aims of treatment of ACL injury is to restore the knee and to return the athlete to pre-injury activity levels. This is also the main argument for surgical treatment. Reports of return to sports following ACL injury do not use a consistent definition and thus results should be interpreted with some caution. One frequent source of misinterpretation is that the definition of return to pre-injury activity is vague and includes one, and sometimes two, levels below the actual pre-injury activity level on a 10-graded scale.

Following ACLR, there is a large variation in reports of return to sport, with rates from 65–88% being able to return to sport within the first year.<sup>115–118</sup> In a meta-analysis of 392 patients, 72% (n = 281) had returned to their pre-injury activity level 2 years after ACLR.<sup>119</sup>

A report on elite soccer players showed a return to sports rate of 94% after ACLR.<sup>120</sup> The authors speculate that one of the main contributing facts might be the extraordinary care and rehabilitation provided by the team physiotherapist in these professional soccer clubs. In contrast, another publication showed that only 63% of NFL athletes returned to NFL game play at an average of 10.8 months after ACL surgery.<sup>121</sup> A success rate around 70% is not excellent for a surgical treatment option but it should be noted that some of these athletes do not return to sports for reasons other than knee problems. However, the proportion of such individuals is not well described.

A systematic review examined 69 articles, reporting on 7556 participants.<sup>122</sup> On average, 81% of people returned to any sport, 65% returned to their pre-injury level of sport and 55% returned to competitive-level sport after surgery. Symmetrical hopping performance and the contextual factors of younger-age males playing elite sport and having a positive psychological response favoured returning to the pre-injury level sport. Another systematic review found weak evidence in 16 articles suggesting that variables associated with return to sport included higher quadriceps strength, less effusion, less pain, greater tibial rotation, higher Marx Activity score, higher athletic confidence, higher preoperative knee self-efficacy, lower kinesiophobia and higher preoperative self-motivation.<sup>123</sup>

In a recent review, Nagelli and Hewett advocate waiting 2 years before RTP after ACL reconstruction.<sup>124</sup> They presented evidence showing that at 2 years after ACLR, biological healing (absence of bone bruises, ACL graft maturation and sensory restoration) has occurred and functional recovery (biomechanical and neuromuscular control and quadriceps strength) of the knee has normalised or is not significantly different from baseline.<sup>124</sup> Therefore, delaying a return to high-level activity for high-risk athletes until 2 years after ACLR will restore knee joint homeostasis and significantly reduce the risk of subsequent injury. They do, however, acknowledge the potential deleterious impact on an athlete's career if he or she misses 2 years of their sport.

Among patients treated non-operatively, the return to sports rates vary even more than among those treated surgically. Scientific reports suggest a range from 19% to 82% for return to pre-injury activity.<sup>67, 125–127</sup> While there is no firm evidence to support that return to pre-injury sports is more likely after ACL reconstruction than after non-surgical treatment, individuals active on a professional or subprofessional level often lack the possibility to wait and see and thus undergo surgery in most cases. Athletes who successfully return to sport after non-operative treatment could represent a group gaining functionally stable knees without fully restored stability at rest. Factors associated with success after non-surgical treatment need to be better explored.

There is some evidence that those returning to pre-injury sports after ACL injury may stop playing earlier than their non-injured counterparts.<sup>127-129</sup> In the only study in which the reduction in sport participation can be related to a control group, Roos et al.<sup>126</sup> found that only 30% of those who had ACL injury were active after 3 years compared with 80% of controls and that after 7 years none of the elite injured players were active regardless of the type of treatment. In addition, previously injured athletes retire at a higher rate than athletes without previous ACL injury.<sup>130</sup> The reason for this may be that many of the athletes who return to sport experience significant knee problems such as instability, reduced ROM and/or pain.<sup>125</sup>

### Criteria for RTP after ACL reconstruction

As previously mentioned, strength deficits persist following ACLR.<sup>100</sup> Various authors have recommended the use of isokinetic testing as a possible objective marker for RTP. In a review of the various protocols used in isokinetic testing involving 39 studies, the variables that were most commonly used were concentric/concentric mode of contraction (31 studies), angular velocity of 60°/s (29 studies), three to five repetitions (24/39 studies), ROM of 0-90° (6 studies) and using gravity correction (9 studies).<sup>131</sup> Eight studies reported strength limb symmetry index scores as part of their RTP criteria. The authors concluded that there was no standardised isokinetic protocol following ACLR and that isokinetic strength measures have not been validated as useful predictors of successful RTP.<sup>131</sup>

In the only prospective study that addressed neuromuscular control and coordination, poor neuromuscular control was a risk factor for ACL graft rupture.<sup>132</sup> In this study of 56 athletes, transverse plane net moment impulse at the hip, dynamic frontal plane knee ROM, side-to-side differences in sagittal plane, knee moment at initial contact and deficits in postural stability were associated with a three times greater risk of ACL graft rupture.<sup>132</sup>

A review of guidelines used for RTP identified three objective criteria used to allow release to sports activities.<sup>133</sup> The most common was lower extremity muscle strength, followed by lower limb symmetry, and knee examination parameters of range of knee motion and effusion. Twelve studies listed one criterion for release to sports, eight studies listed two criteria and one study recommended three criteria.

A recent study followed 158 male professional athletes who underwent an ACLR and returned to their previous professional level of sport.<sup>134</sup> Before players returned to sport they underwent a battery of discharge tests (isokinetic strength testing at 60°, 180° and 300°/s, a running T-test,<sup>135</sup> single-hop, triple-hop and triple crossover-hop tests). The criteria for each test was as follows:

- isokinetic test at 60, 180 and 300°/s: quadriceps deficit <10% at 60°/s
- single-hop: limb symmetry index >90%
- triple-hop: limb symmetry index >90%
- triple crossover-hop: limb symmetry index >90%
- on-field sports-specific rehabilitation: fully completed
- running T-test <11 s.<sup>135</sup>

The athletes returned to their previous competitive level a mean of 229 days after surgery (range 116-513 days). Of these, 26 (16.5%) sustained an ACL graft rupture and 11 (7.0% of 158) sustained a contralateral rupture of their native ACL. Athletes who did not meet the specific discharge criteria before return to sport and were not fully discharged from ACLR rehabilitation by the surgeon had a four times greater risk of sustaining an ACL graft rupture (73%) compared with those who returned to their sport after passing the necessary criteria (27%). The study also looked at hamstring to quadriceps ratio and found that those who had a lower ratio at 60°/s had a greater risk of ACL graft rupture (HR 10.6 per 10% difference, 95% confidence interval of 10.2 to 11,  $p = 0.005$ ). The authors concluded that two factors were associated with increased risk of ACL graft rupture: 1. not meeting all six of the discharge criteria before returning to team training; and 2. decreased hamstring to quadriceps ratio of the involved leg at 60°/s.<sup>134</sup>

### Re-injury rate

The rate of graft re-rupture after 10 years is approximately 6%. It appears that the risk of re-rupture or a graft failure is highest within the first 12 months after an ACL injury.<sup>136</sup> After the first 12 months, the overall increase in risk is divided fairly evenly between the reconstructed knee and the contralateral knee.<sup>137</sup>

The aetiology of ACL graft failure is varied and often more than one cause exists. In general, the aetiology of ACL graft failure can be divided into five categories: 1. surgical technique; 2. trauma; 3. poor graft incorporation and healing (failure of ACL graft to undergo the ligamentisation process); 4. arthrofibrosis; 5. inadequate rehabilitation. The most common reasons for failure due to surgical technique are non-anatomic tunnel placement, failure to address associated ligamentous laxity or secondary restraints at the time of the primary reconstruction, graft impingement, inadequate strength of the primary ACL graft and abnormal graft tension (under or over-tensioning).

Early failures (<3 months) are usually related to loss of fixation and infection. Midterm failures (3-12 months) are most frequently due to errors in surgical technique, aggressive physical therapy, premature return to full activity or unrecognised loss of secondary restraints. Late failures (>12 months) are usually related to trauma.

The risk of a contralateral ACL injury is similar to that of a rupture of the graft (i.e. about 6%).<sup>137, 138</sup> When reviewing the literature, it appears to be clear that the risk of contralateral ACL injuries is greater than the risk of first-time ACL injuries.<sup>137</sup> The most prominent risk factor for a contralateral ACL injury is the return to a high level of activity. There are some indications that young age at the initial ACL injury and at the subsequent ACLR,<sup>139</sup> ACLR with patellar tendon autograft (compared to hamstring tendon autograft) and a narrow intercondylar notch can increase the risk for a contralateral ACL injury. Female gender does not seem to be a risk factor for a contralateral ACL injury. Altered biomechanics and altered neuromuscular function as a result of the initial ACL injury, affecting both the injured and the uninjured leg, most likely, further increase the risk for a contralateral ACL injury.

Data from non-surgically treated individuals are lacking. One prospective investigation of consecutively recruited ACL injured patients, initially treated conservatively without ACLR with later surgical intervention only when deemed necessary, where the patients were advised to avoid contact sports, found an annual incidence of contralateral ACL injuries of 0.4% over 15 years.<sup>127</sup>

### Revision surgery

If failure of the original ACL graft occurs, a revision procedure can be performed. Outcomes of revision surgery are predictably not as good as in primary reconstruction. In a meta-analysis including studies with 300 revision ACLRs and 413 primary ACLRs, patients who had had revision surgery reported inferior Lysholm Knee Scoring Scale scores, had inferior clinician-reported knee function as assessed with the objective IKDC classification and pivot shift test and more radiographic evidence of tibiofemoral osteoarthritis (50% versus 25%) compared with patients who had had primary surgery.<sup>140</sup>

A previous review included 31 articles which documented rate of return to sport and showed that whereas 73% had good objective and satisfactory subjective results, 57% of patients did not return to the same level of sport activity, significantly inferior to that of a primary procedure.<sup>141</sup>

### Osteoarthritis

A frequent consequence of ACL rupture is the increased risk of knee osteoarthritis (OA).<sup>142</sup> Following ACL injury, rates of radiographic knee OA are typically reported to be approximately 50% at 10–20 years post-injury.<sup>142, 143</sup> As ACL injury frequently occurs in adolescents and young adults, these individuals typically develop OA before they reach 40 years, which would not be expected in the absence of joint trauma. An ACL injury is therefore said to be responsible for *early-onset* knee OA.

Current evidence does not indicate that ACLR reduces the rate of OA development.<sup>144, 145</sup> Indeed, higher rates of OA may be evident following surgical compared to non-surgical management of the ACL-deficient knee, which may be related to the return to high-impact cutting and pivoting sports activity, which non-operative treatment algorithms often advise against.<sup>146, 147</sup>

An ACL rupture causes a significant disruption to the homeostasis of the knee. The considerable force required to rupture a healthy ACL is consistent with the frequent presence of subchondral BMLs,<sup>148</sup> articular cartilage damage<sup>149</sup> and meniscal tears.<sup>148, 150</sup> The considerable mechanical impact to the articular cartilage and subchondral bone can disrupt the cartilage matrix and alter cell metabolism,<sup>151, 152</sup> which can predispose to OA development even in the absence of altered mechanical loading.<sup>151</sup> However, the altered mechanical environment following an ACL injury is thought to be a fundamental driver for post-traumatic OA development.<sup>153, 154</sup>

The instability and altered kinematics following ACL injury are theorised to shift load bearing to areas of cartilage unaccustomed to such load, potentially contributing to the early onset of OA.<sup>153</sup> Perhaps altered kinematics in the setting of already damaged cartilage is most deleterious following ACL injury, as cartilage response to load is dependent on the health of the cartilage.<sup>153</sup> Abnormal knee kinematics persist despite ACLR, which might explain why rates of OA are not reduced with surgical stabilisation.<sup>155</sup> Dynamic knee joint loading and OA development may also be affected by prolonged muscle weakness, in particular quadriceps weakness, which can persist for years after ACL injury.<sup>156</sup>

Inherent biomechanical characteristics preceding ACL injury may also be implicated in the development of post-traumatic OA. Specifically, high external knee abduction loads during a jump-landing task can predict ACL injury in young female athletes,<sup>157</sup> while increased external knee abduction moments during gait have been associated with lateral tibiofemoral OA following ACLR.<sup>158</sup>

The unique biomechanical characteristics following ACL injury, including high knee abduction loads, may contribute to the distinct patterns of post-traumatic disease typically observed.<sup>159</sup> Pre-injury kinematic and kinetic patterns are likely to persist following ACL injury, irrespective of surgical reconstruction, although targeted neuromuscular training may help to decrease knee abduction loads.<sup>160</sup>

Importantly, post-traumatic knee OA displays distinct patterns of disease compared to a typical non-traumatic OA presentation. Post-traumatic OA affects the medial and lateral tibiofemoral compartment equally, likely reflecting the local factors unique to ACL injury and reconstruction.<sup>158, 159</sup>

Patellofemoral OA is also particularly prevalent at all time points following ACLR regardless of autograft type<sup>161, 162</sup> and early signs of patellofemoral deterioration are evidence as early as 1 year post-surgery.<sup>163</sup> Altered biomechanics, including tibial rotations and knee flexion, may play a role in patellofemoral OA following ACLR<sup>164, 165</sup> and lower limb function or the presence of patellofemoral cartilage lesions can predict the presence of poorer prognosis following ACLR.<sup>166</sup> Post-traumatic OA should therefore be considered a distinct entity and clinicians should pay particular attention to the status of the patellofemoral joint following ACLR.

The increased risk of OA development following ACL injury and reconstruction appears to be driven by factors such as concomitant trauma to other knee structures, altered kinematics and loading environment, and muscle weakness. However, systemic factors that increase the risk of incident non-traumatic OA, such as older age, female sex and higher body mass index (BMI), also appear to accentuate the development of post-traumatic OA. The interaction of

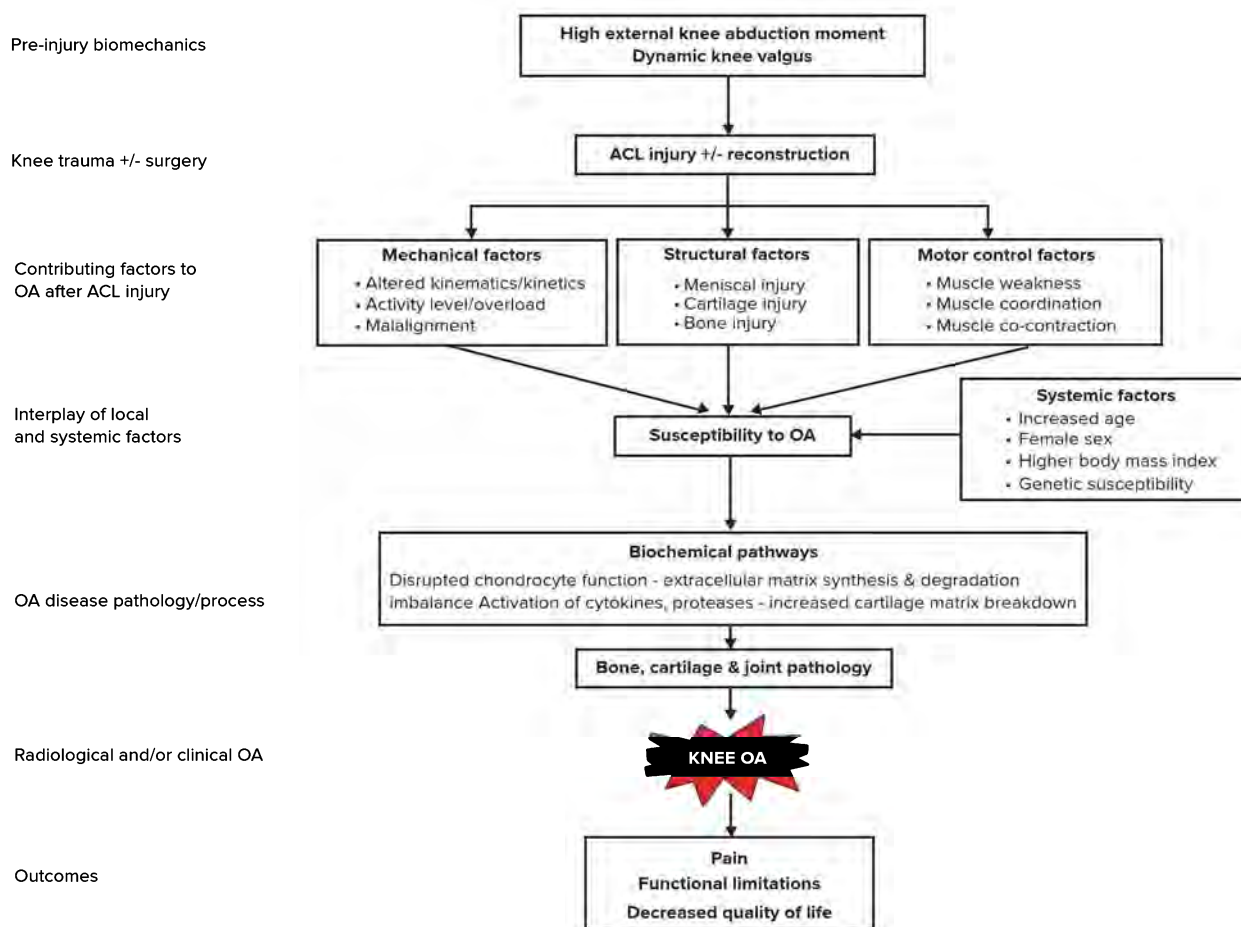

local and systemic risk factors likely creates an imbalance of biochemical markers, leading to cartilage degradation and ultimately OA. This is summarised in Figure 35.14.

### Sex difference

In light of the increased prevalence of ACL injuries in female athletes discussed previously, attention has been paid to possible differences in outcome after ACLR between males and females. The majority of studies show increased post-surgical laxity in females, but no difference in graft failure, activity level, or subjective or functional assessment.<sup>115, 167-171</sup>

The most recent review included 13 studies.<sup>172</sup> Meta-analysis revealed no difference in graft failure risk (eight studies), contralateral ACL rupture risk (three studies) or postoperative knee laxity on physical examination (six studies). There was no evidence of a clinically important difference in patient-reported outcomes according to sex.

However, one study of several thousand patients treated with ACLR from the Swedish ACL registry showed

**Figure 35.14** Development of osteoarthritis following ACL injury  
COURTESY DR ADAM CULVENOR

significant gender differences in the self-reported outcome 1 and 2 years after surgery.<sup>112</sup> The authors reported that female patients showed worse outcomes than male patients before surgery and at 1 and 2 years after ACLR, and suggested that possible sex differences should be analysed in future studies on evaluation after ACL injury/reconstruction.

### Age

Younger athletes have been shown to have a higher chance of graft rupture than older athletes.<sup>173</sup> A 10-year difference in age was associated with a 2.6 times greater chance of ACL graft rupture. Among 1820 patients after primary ACLR, younger athletes had a higher activity level and a higher incidence of ACL re-injury.<sup>174</sup> Based on data from the Swedish National Knee Ligament Register, the combination of being young and playing soccer is a substantial risk factor for revision surgery.<sup>175</sup>

Results after ACL reconstruction in patients older than 40 years and comparison with younger populations were recently the subject of a systematic review.<sup>176</sup> Twelve studies with a total of 452 patients were included. The mean patient age was 47.8 years (range, 40–66 years) with a mean follow-up of 53.3 months (minimum, 24 months). Lysholm scores improved from 53.9 to 90.5 in the 11 operative studies. IKDC scores of A or B were found in 81%. Tegner activity scores averaged 4.7 pre-injury, fell to 2.9 preoperatively and returned to 4.7 postoperatively. The reported failure rate was 2.3%. There were few complications and failure rate was similar in younger patients. The data confirm that ACLR can be recommended to patients older than 40 years who wish to maintain an active lifestyle or have symptomatic instability with daily activities.

### Partial ACL tear

Approximately 5–15% of ACL injuries are thought to be partial tears.<sup>177</sup> There is no consensus on the definition of a partial ACL tear. The presence of an intra-substance incomplete tear of the ACL on MRI (Fig. 35.15) or at arthroscopy is generally regarded as being the gold standard diagnosis. Rather than an anatomical diagnosis, a functional assessment of stability is more practical from a treatment viewpoint.

If clinical instability is present and the pivot shift is positive, then ACL instability is diagnosed. Most would consider a 'partial' tear to be associated with a negative pivot shift test. Controversy centres around whether a complete tear of one of the two bundles (anteromedial and posterolateral) should be considered under the definition of a partial tear and whether some asymmetrical laxity on Lachman's test albeit with a definite end point should be included.<sup>178</sup> The partial tear is often described on MRI reports as a percentage of ACL remaining.

**Figure 35.15** Sagittal T2 image showing partial ACL rupture characterised by increased T2 signal (yellow arrow) and some fibre disruption within its proximal aspect. The normal angle and some continuous fibres distinguish this partial tear from a full-thickness rupture

The management of partial ACL tears depends on the degree of instability. A clinically and functionally stable partial tear can be treated non-surgically with the option of later surgery if needed. Unstable lesions especially in those who wish to play high-intensity sports can be treated surgically either with a full knee reconstruction or augmentation of the remaining ligament. Degenerative changes were present in 15% of patients 8 years after partial ACL tear managed conservatively.<sup>179</sup>

### Prevention of ACL injuries

Prevention of ACL injuries is thoroughly discussed in Chapter 12. Risk factors and prevention programs including the FIFA-11 are described in detail.

### ACL rupture in children with open physes

Rupture of the ACL in children with open physes presents an additional challenge to the treating practitioner. This topic is covered extensively in Chapter 44.

### POSTERIOR CRUCIATE LIGAMENT INJURIES

The PCL is composed of two bundles, the larger anterolateral (AL) bundle and the smaller posteromedial (PM) bundle, which are most readily identified at their femoral locations.

However, at their tibial attachment to the PCL facet, the bundles are more compact and difficult to separate. Historically, the two bundles of the PCL were believed to function independently, with the ALB primarily functioning in flexion and the PMB in extension. However, in light of recent biomechanical investigations, a more synergistic and co-dominant relationship between the two bundles has been validated. Ahmad et al. investigated the spatial orientation of the PCL bundles and reported that changes in the orientation of each bundle during knee flexion and extension prevented either bundle from exercising complete dominance in the restraint of posterior tibial motion.<sup>180</sup>

The PCL has historically been considered a primary restraint to posterior tibial translation and more recent studies have also identified it as a secondary restraint to rotation, particularly between 90° and 120° of flexion.<sup>181</sup> Complete sectioning of the PCL has reportedly led to a significant increase in posterior tibial translation at 0° to 120° of flexion and an increase in internal rotation at 90° to 120° of flexion. The magnitude of abnormal translation and rotation appears to depend on whether one or both of the bundles are injured. An isolated tear of either PCL bundle results in a minimal clinically important increase in posterior tibial translation. Generally, the literature supports that the PCL has a more expansive role in providing rotational stability than previously thought, and it is important to assess internal and external rotation stability when considering PCL injury.<sup>181</sup>

PCL injury typically presents concurrently with other knee injuries, including ACL, MCL or posterolateral corner (PLC) injury or, less commonly, in isolation. Recent studies have helped to clarify and elucidate the prevalence of concurrent ligament injuries with a complete (grade III) PCL tear.<sup>181</sup> A majority of grade III PCL tears are associated with multi-ligament knee injuries, with one study reporting that 79% of multi-ligament knee injuries involved the PCL in a trauma setting.<sup>182</sup> Furthermore, 46%, 31% and 62% of PCL injuries have been reported to be concomitant with ACL, MCL and PLC knee injury in a trauma setting, respectively.<sup>183</sup>

PCL injuries are often associated with meniscal and chondral injury. The incidence of associated meniscal tears varies from 16% to 28%. Longitudinal tears of the anterior horn of the lateral meniscus are the most common location. There is also a high incidence of radial tears in the middle or posterior lateral meniscus.<sup>184</sup> The incidence of significant chondral damage with isolated PCL injury was not thought to be as high as with ACL injury, but one study showed chondral damage in 52% of those with PCL tears, with lesions of grade III or more found in 16%.<sup>184</sup>

## Clinical features

The mechanism of PCL injury is usually a direct blow to the anterior tibia with the knee in a flexed position (i.e. dash-board injury). This can be from contact with an opponent, equipment or falling onto the hyperflexed

knee. Hyperextension may also result in an injury to the PCL and posterior capsule.

### PRACTICE PEARL

Whereas a patient with an ACL or MCL injury often describes the feel of a distinct 'pop' or 'tear', PCL tears typically have vague symptoms such as unsteadiness or discomfort.

A patient with an acute isolated PCL injury may have a mild-to-moderate effusion, pain in the posterior aspect of the knee or pain with kneeling. In a case of subacute or chronic PCL injury, the patient may describe vague anterior knee pain, pain with deceleration and descending inclines or stairs, or pain with running at full stride.

On examination, there is usually minimal swelling as the PCL is an extrasynovial structure. The posterior drawer test (Fig. 35.2o) is the most sensitive test for PCL deficiency. This is performed in neutral, internal and external rotation. A posterior sag of the tibia (Fig. 35.2n), and pain and laxity on a reverse Lachman's test, may be present. PCL rupture is particularly disabling for downhill skiers, who rely on this ligament for stability in the tucked up position adopted in racing.

PCL tears are graded I, II and III on the position of the medial tibial plateau relative to the medial femoral condyle at 90° of knee flexion (the posterior drawer position). The tibia normally lies approximately 1 cm anterior to the femoral condyles in the resting position. In grade I injuries, the tibia continues to lie anteriorly to the femoral condyles but is slightly diminished (0-5 mm laxity). In grade II injuries, the tibia is flush with the condyles (5-10 mm laxity). When the tibia no longer has a medial step and can be pushed beyond the medial femoral condyle (>10 mm laxity), it is classified as a grade III injury.

It is important to distinguish between isolated PCL injury and a combined PCL and posterolateral corner injury. In isolated PCL tears, there is a decrease in tibial translation in internal rotation due primarily to the influence of the MCL.<sup>185</sup>

Plain radiographs are advocated when one is examining the presence of avulsion fracture fragments, Segond fractures, fibular head avulsions and lateral joint space widening. Any perceptible degree of posterior tibial sag should be documented. Stress radiographs provide reproducible objective assessment of the degree of posterior tibial translation between the injured and normal contralateral knee.<sup>186</sup> It has been reported that partial PCL tears result in <8 mm of increased posterior tibial translation, isolated complete PCL tears in 8-12 mm and combined complete PCL tears (usually with a PLC injury) in >12 mm.<sup>187</sup>

MRI has a high predictive accuracy in the diagnosis of the acute PCL injury,<sup>188, 189</sup> but a lesser accuracy in chronic injuries.<sup>190</sup> The normal appearance of a PCL is a

well-defined continuous band of low signal intensity in all pulse sequences with a maximum anteroposterior diameter of 6 mm when measured on sagittal T2-weighted images. Conversely, a torn PCL (Fig. 35.16) has been reported to have an abnormally large (>7 mm) anteroposterior diameter.<sup>191</sup>

Bone bruises are seen in over 80 % of acute grade II and III PCL injuries on MRI. In contrast to the bone bruises associated with ACL tears, which commonly occur on the posterior tibia and lateral femoral condyle, the location of bone bruises observed with PCL injuries is less predictable. Bone bruises in the medial compartment were significantly more often associated with a PCL-PLC combined injury, while lateral compartment bone bruises were significantly more often associated with a concomitant PCL-MCL injury.<sup>192</sup>

### Treatment

Grade I, II and most grade III PCL injuries can generally be managed non-surgically with a comprehensive rehabilitation program. A suggested program emphasising intensive quadriceps exercises is shown in Table 35.11. More severe injuries (grade III) should be immobilised in extension for the first 2 weeks.

The PCL has been reported to have an intrinsic healing ability after injury, although this healing may occur in a lax or attenuated position. Therefore, in cases of acute isolated PCL injury, non-operative management has been recommended. However, acute multi-ligament knee injuries with a concomitant or chronic PCL tear are believed to be best treated by surgery.<sup>180</sup> The use of a brace (e.g. the Jack or Rebound PCL brace) that applies a constant or dynamic

anterior force to counteract the posterior sag of the tibia, may help to increase healing after PCL injury by reducing the ligament to a more physiological position.<sup>193</sup>

Patients with isolated PCL tears have a good functional result despite ongoing laxity after an appropriate rehabilitation program. Regardless of the amount of laxity, half of the patients in one large study returned to sport at the same or higher level, one-third at a lower level and one-sixth did not return to the same sport.<sup>194</sup> Other studies have shown that knee instability did not correlate with return to sport or knee satisfaction.<sup>195-197</sup>

Although favourable non-operative results have been observed, the long-term consequences of isolated PCL deficiency remain unknown.<sup>198</sup> Boynton and Tietjens have observed deterioration at extended follow-up of non-operative treatment despite good early results.<sup>199</sup> In 38 patients with isolated tears with a mean follow-up of 13.4 years, eight patients had subsequent meniscal injuries and surgery. Of the remaining 30 patients with normal menisci, over 80% had occasional pain and over 50% had occasional swelling. With time, an increase in articular cartilage degeneration was seen on plain radiographs. Investigators who evaluated isolated PCL tears that were treated with non-operative rehabilitation programs reported radiographic evidence of arthritic changes in 23% of patients at 7-year follow-up<sup>200</sup> and 41% at 14-year follow-up.<sup>201</sup> However, only a small percentage of the patients in the long-term follow-up had moderate or severe osteoarthritis (11%), and the majority of patients had good strength and subjective outcome scores, although stress radiographs were not reported.<sup>180</sup>

**Figure 35.16** Sagittal T2 MRI showing a defect with associated oedema (arrow) in the midsubstance of the PCL

### Indications for surgical repair

Operative management is reserved for acute or chronic isolated grade III PCL injuries with symptoms of pain or instability which have failed an adequate rehabilitation program treatment, or PCL insufficiency in the setting of a multi-ligamentous knee injury.<sup>198</sup> Complete PCL tears, as indicated by PCL stress radiographs with an increased anteroposterior laxity measurement of >8 mm, combined with repairable meniscal body or root tears are a possible indication for PCL reconstruction.<sup>180</sup>

Similar to ACL reconstruction, grafts can be either autograft (hamstring tendon or bone-patellar tendon-bone) or allograft, single or double bundle. Single-bundle PCL reconstruction is typically indicated for symptomatic chronic PCL injuries, either in isolation or combined with other knee ligamentous injury, and for acute, multi-ligament PCL injuries. Recent efforts have focused on an anatomic single-bundle reconstruction using arthroscopic and radiographic reference points instead of the historical non-anatomic 'isometric' reconstruction that has been reported to result in initial joint overconstraint and increased laxity over time.

Controversy exists regarding the use of transtibial versus tibial inlay techniques of PCL reconstruction. In the transtibial

Table 35.11 Rehabilitation of a PCL tear (see Figs 35.6 and 35.7)

Phase	Goal of phase	Time post-injury	Physiotherapy treatment	Exercise program	Functional/sport-related activity
Phase 1	PWB-FWB Eliminate swelling 0–100° ROM 4+/5 quadriceps strength 5/5 hamstring strength	0–2 weeks	Jack or Rebound PCL brace Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Patient education	Gentle flexion ROM Extension ROM to 0° Quadriceps/VMO setting Supported (bilateral) calf raises Hip abduction and extension Hamstring pulleys/rubbers Gait drills	Nil
Phase 2	No swelling Full ROM 4+/5 quadriceps strength 5/5 hamstring strength	2–4 weeks	Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Exercise modification	ROM drills Quadriceps/VMO setting Mini-squats and lunges Leg press (double, then single-leg) Step-ups Bridges (double, then single-leg) Hip abduction and extension with rubber tubing Single-leg calf raises Gait re-education drills Balance and proprioceptive drills (single-leg)	Walking Exercise bike
Phase 3	Full ROM Full strength and power Return to jogging, running and agility Return to restricted sport-specific drills	4–6 weeks	Manual therapy Exercise/activity modification and supervision	As above—Increase difficulty, repetitions and weight where appropriate Jump and land drills Agility drills	Straight-line jogging Swimming (light kick) Road bike Straight-line running Progressing to sport-specific running and agility (progressively sequenced) (e.g. running forwards, sideways, backwards, sprinting, jumping, hopping, changing directions, kicking)
Phase 4	Return to sport	6–10 weeks	As above	High-level sport-specific strengthening as required	Progressive return to sport (e.g. restricted training, unrestricted training, match play, competitive match play)

PWB = full weight-bearing; PWB = partial weight-bearing; ROM = range of motion; VMO = vastus medialis obliquus

technique, the tibial and femoral tunnels are drilled and the graft must make an acute turn as it surfaces from the tibial tunnel and changes direction before entering the knee joint. Subsequent graft abrasion and attenuation may result in graft rupture or laxity.<sup>202</sup> This sharp turn has been implicated in the residual posterior knee laxity observed clinically after transtibial PCL reconstruction. The tibial inlay was developed as an alternative to the transtibial technique to avoid this problem. In tibial inlay reconstruction, the graft is fixed directly to the PCL's native insertion site on the tibia.<sup>198</sup>

Double-bundle PCL reconstructions have evolved as an alternative to single-bundle reconstructions with the same indications for surgery. As reported by biomechanical studies, the AL and PM bundles perform in a co-dominant manner and these roles theoretically would not be restored by a single-bundle PCL reconstruction.<sup>203</sup> Therefore, an anatomic double-bundle PCL reconstruction may be able to more closely restore native kinematics than the single-bundle technique.

Results of surgical reconstruction are generally good,<sup>204, 205</sup> but one review<sup>206</sup> suggested that the rate of graft failure was 11.6%. In the isolated PCL studies, 50–82% of patients were able to return to pre-injury activity level. The most commonly reported complications after PCL reconstructions are residual posterior laxity, usually defined as more than 4 mm of increased posterior translation on PCL stress radiographs, and flexion loss due to prolonged immobilisation of the knee in extension.

Since PCL graft healing times have been reported to be almost double the time of ACL graft healing, it has been suggested that PCL reconstruction patients should be kept non weight-bearing for 6 weeks. Patients are placed in an immobiliser brace in extension after surgery for 3 days before transitioning to a dynamic or static anterior drawer knee brace. The Jack Brace and the Rebound® PCL brace which apply increasing force as a function of flexion angle, are the only currently available dynamic braces and it has been recommended that the brace of choice should be worn at all times for up to a minimum of 24 weeks postoperatively.<sup>207</sup>

## LATERAL COLLATERAL LIGAMENT TEARS

Lateral (or fibular) collateral ligament (LCL) tears are much less common than MCL tears. In contrast to the common pattern of isolated MCL injury, an injury to the lateral side of the knee usually requires higher magnitude of force and thereby affects additional structures in the area. Isolated injuries to the LCL involve forces of lower magnitude, resulting in lower-grade damage to the ligament. Isolated high-grade injuries to the LCL are therefore fairly rare.<sup>208</sup>

## Posterolateral corner injuries

Posterolateral corner injuries are being increasingly recognised. In a consecutive series of 187 patients with

an acute knee injury and a complete ligament tear found on MRI, the incidence of grade III PLC injuries was 16%.<sup>209</sup>

The posterolateral corner (PLC) of the knee was once referred to as 'the dark side of the knee' due to the limited understanding of the structures, biomechanics and possible treatment options.<sup>210</sup> A number of studies in recent years have led to a heightened understanding of the PLC and biomechanically validated reconstruction techniques. Posterolateral corner injuries are commonly associated with ACL or PCL tears. The LCL, popliteofibular ligament, arcuate ligament, oblique popliteal ligament, fabellofibular ligament, posterolateral capsule, popliteus tendon, biceps femoris tendon, lateral head of the gastrocnemius, lateral meniscus and the iliotibial band may all be involved in the injury pattern to some degree.

The three major static stabilisers of the PLC are the LCL, the popliteus tendon (PLT) and the popliteofibular ligament (PFL).<sup>211</sup> The PLC structures provide the primary restraint to varus forces of the knee as well as posterolateral rotation of the tibia relative to the femur in cases of cruciate deficient knees. These structures are also important secondary stabilisers to anterior and posterior tibial translation.

Mechanisms of injury usually cause force at multiple vectors of varying magnitude—with varus, extension, rotation and translation all playing a role. A common mechanism of injury to the PLC is a direct blow to the anteromedial knee. However, hyperextension and non-contact varus stress injuries can also damage the PLC. Most often, PLC tears are associated with ACL and/or PCL injuries, justifying close examination for a PLC injury for every cruciate ligament tear.<sup>210</sup>

Frequently reported symptoms include pain, perceived side-to-side instability near extension, increased difficulty walking on uneven ground or up and down stairs, bruising and swelling. This instability and difficulty walking can present as a varus thrust gait seen during the initiation of the stance phase.<sup>212</sup> It is not uncommon for the patient to complain of paraesthesia of the common peroneal nerve distribution or foot drop. Common peroneal nerve injury has been reported to occur in up to one-third of PLC injuries.<sup>213</sup>

The varus stress (Fig. 35.2g) test should be performed in both full extension and at 20–30° of flexion. Lateral compartment gapping in comparison to the contralateral side with the knee flexed to 30° indicates an injury to the LCL and potentially to the secondary stabilisers of the PLC. If stability is restored when tested in full extension, an isolated injury to the LCL is presumed. However, if the varus instability persists in full extension, a combined LCL, PLC and cruciate ligament injury is assumed.<sup>210</sup>

A routine radiographic work-up with standing anteroposterior (AP), lateral and axial views should be performed to rule out the presence of fractures. A standing

long-leg AP view should be obtained in chronic cases because the limb alignment should be corrected using an osteotomy prior to or at the same time as a reconstruction procedure. Additionally, varus and PCL stress radiographs can be used to obtain objective quantification of the amount of lateral compartment varus gapping and a combined PLC and PCL injury, respectively.<sup>214</sup>

MRI allows identification of concurrent lesions such as meniscus tears, cartilage lesions and occult fractures. It has been shown to have 90% sensitivity and specificity for IT band, biceps tendon, LCL and PLT injury. The only PLC structure with lower diagnostic accuracy values was the popliteofibular ligament, with 68.8% sensitivity and 66.7% specificity.<sup>209</sup> For optimal MRI diagnostic accuracy for PLC injuries, an imaging sequence using 2 mm slices in a coronal oblique plane following the obliquity of the PLT should be employed. Bone bruise patterns are found in 81% of all PLC injuries, usually on the anteromedial femoral condyle. Together, these imaging techniques are excellent tools to augment the diagnosis of PLC injury.<sup>214</sup>

### Non-surgical management

Good results have been reported for non-surgical treatment for grade I and II injuries with minimal radiographic changes at 8 year follow-up following the use of an early mobilisation protocol.<sup>215</sup> However, poor functional outcomes for non-operatively treated grade III PLC injuries with persistent instability and degenerative changes have been reported.<sup>216</sup> Increased forces on the PCL and ACL reconstruction grafts have been reported if concurrent PLC injuries are not addressed.<sup>217</sup>

### Surgical management

Surgical treatment of PLC injuries is the treatment of choice for patients with isolated grade III PLC injuries, combined PLC injuries and failed non-operative treatment.<sup>214</sup> Acute surgical treatment (<3 weeks) results in improved outcomes and can avoid the need for an additional procedure for limb alignment correction that may be necessary in chronic cases. Patients treated acutely may undergo repair or reconstruction procedures. Primary repairs of LCL and PLTs avulsions, without midsubstance injury, may be performed within 2-3 weeks after the injury. After that point, the tissue becomes retracted and scars down, making it nearly impossible to reattach the injured structures to their native anatomic locations. Improved outcomes have been demonstrated with primary repair of avulsed ligament structures and augmentation of midsubstance ligament injuries.

Several reconstruction techniques have been described and can be broadly categorised as biceps tendon transfer, fibular-based sling or anatomic-based reconstruction of the LCL, PLT and popliteofibular ligament.<sup>218</sup> Outcomes following reconstruction have been shown to be

significantly better than those following repair.<sup>219, 220</sup> A recent systematic review found the repair of acute grade III PLC injuries with staged cruciate reconstruction was associated with a 38% failure rate, whereas a more robust reconstruction-focused approach for PLC injuries with concurrent reconstruction of cruciate injuries resulted in an overall mean 9% failure rate.<sup>218</sup>

Surgical reconstruction of a chronic LCL tear is difficult. Surgical techniques include variations of fibular slings, capsular shifts and anatomic-based techniques (fibular tunnel and tibial tunnel). A recent systematic review included 15 studies with a total of 456 patients of which 59% had combined PCL injuries, 23% had combined ACL injuries, 6% had combined ACL and PCL injuries and 12% had isolated PLC injuries.<sup>221</sup> Cruciate ligament tears were treated simultaneously with PLC reconstruction in the majority of the 15 studies. Surgical management of these chronic PLC injuries had a 90% success rate and a 10% failure rate according to the authors' objective assessment of outcomes.<sup>221</sup>

In chronic injuries (greater than 6 weeks from injury), lower extremity alignment should be evaluated and corrected with an osteotomy prior to ligament reconstruction because failure to address malalignment can lead to increased stress and stretching of the reconstruction grafts and failure.<sup>222</sup> A varus knee with lateral and/or posterolateral instability is associated with worse results.

### ARTICULAR CARTILAGE DAMAGE

Chondral defects are seen in 3.4-62% of knee arthroscopies, while full-thickness focal lesions with an area of at least 1-2 cm<sup>2</sup> are seen in 4.2-6.2% of all arthroscopies in patients younger than 40 years of age.<sup>223</sup> The incidence is higher in athletes.

### Epidemiology

A systematic review included 11 studies containing 931 athletes of which 40% were professionals (US National Basketball Association and National Football League).<sup>223</sup> The overall prevalence of full-thickness focal chondral defects in athletes was 36%. Fourteen per cent of athletes were asymptomatic at the time of diagnosis. Patellofemoral defects (37%) were more common than femoral condyle (35%) and tibial plateau defects (25%). Medial condyle defects were more common than lateral (68% versus 32%) and patella defects were more common than trochlea (64% versus 36%). Meniscal tear (47%) was the most common concomitant knee pathological finding, followed by ACL tear (30%) and then medial collateral ligament or lateral collateral ligament tear (14%).

Articular cartilage damage may occur as an isolated condition in which chondral or subchondral damage is the primary pathology or in association with other injuries, such as ligamentous instability resulting from MCL, ACL or PCL injuries or patellar dislocations.

**Table 35.12 Outerbridge classification of chondral defects**

1. Softening
2. <1 cm (<0.4 in.) partial thickness lesion
3. >1 cm (>0.4 in.) defect, deeper
4. Subchondral bone exposed

**Table 35.13 International Cartilage Repair Society (ICRS) classification of chondral defects**

1. Superficial lesions
  - A. Soft indentation
  - B. Superficial fissures or cracks
2. Lesions <50% cartilage depth
3. A. Lesions >50% depth
  - B. Down to calcified layer
  - C. Down to but not through subchondral bone
  - D. Blisters
4. Full thickness into subchondral bone

Articular cartilage damage may also be seen in association with meniscal injury and patellar dislocation.

### Quantifying chondral injury

Chondral injury is graded according to the Outerbridge classification and more recently the International Cartilage Repair Society (ICRS) grading system (Tables 35.12 and 35.13). Articular cartilage damage varies from gross, macroscopically evident defects in which the underlying bone is exposed (grade IV), to microscopic damage that appears normal on arthroscopy but is soft when probed (grade I).

Articular cartilage damage in the knee has both short-term and long-term effects. In the short term, it causes recurrent pain and swelling. In the longer term, it accelerates the development of osteoarthritis. Various methods have been used to encourage healing of articular cartilage defects. These include microfracture (piercing the subchondral bone with an 'ice pick' to recruit pluripotent stem cells from the marrow), mosaic plasty such as Osteoarticular Transfer System Surgery or OATS (osteochondral plugs are taken from the trochlea margin and implanted within the injured area) and autologous chondrocyte implantation (ACI), where cultured chondrocytes (harvested from the patient and cultured in the laboratory) are re-implanted to the chondral defect. Gene therapy and bone morphogenetic proteins are currently in the experimental stage.

### Management

There is currently considerable debate as to the efficacy of the various treatments and as yet no consensus on optimal treatment has been reached. Although short-term reduction

of symptoms has been shown with these treatments, long-term reduction of arthritic disability has not been shown. Successful results also vary according to size and location of the articular lesion and between treatments. As yet, no method of treatment has been able to reproduce true hyaline cartilage with its complex layered structure.

A systematic review to determine which surgical technique/s have improved outcomes and enabled athletes to return to their pre-injury level of sports, and which patient and defect factors significantly affect outcomes after cartilage repair or restoration identified 11 studies for inclusion (658 subjects).<sup>224</sup> Only one RCT was identified. All other studies were prospective cohorts, case-control studies, or case series reporting results after microfracture, ACI or OATS. Better clinical outcomes were observed after ACI and OATS versus microfracture. Results after microfracture tended to deteriorate with time. The overall rate of return to pre-injury level of sports was 66%. The timing of return to the pre-injury level of sports was fastest after OATS and slowest after ACI. Defect size of less than 2 cm<sup>2</sup>, preoperative duration of symptoms of less than 18 months, no prior surgical treatment, younger patient age and higher pre-injury and post-surgical level of sports all correlated with improved outcomes after cartilage repair, especially ACI. Results after microfracture were worse with larger defects. The rate of return to sports was generally lower after microfracture versus ACI or OATS and if a patient was able to return to sports, performance was diminished as well.

Another review surveyed the literature regarding factors used in determining a course of surgical treatment for symptomatic cartilage lesions of the knee to determine which factors affect treatment outcomes and should be incorporated in the treatment algorithm.<sup>225</sup> Twenty-seven studies examining 1450 human (1416 in vivo; 34 cadaveric) and 90 animal subjects met inclusion criteria. Female sex and higher BMI significantly predicted cartilage loss rates and recovery after microfracture and autologous matrix-induced chondrogenesis. Defect size and location significantly predicted treatment outcomes. Sizes >2–4 cm demonstrated worse outcomes after microfracture treatment. Defect size did not consistently affect autologous chondrocyte implantation or osteochondral autograft transplantation outcomes. Intra-articular lesion location was related to intralesional subchondral bone contact and microfracture outcome. Corrected patellofemoral and tibiofemoral alignment improved clinical outcome when realignment procedures were done concurrently with cartilage repair.

The authors concluded that the choice of the appropriate repair technique for focal knee cartilage defects is multifactorial and suggested a treatment algorithm which should consider frequently used factors such as defect size, location, knee alignment and patient demand. However, patient sex and BMI could also be considered. Patient age was not significantly associated with clinical outcome.

An effective method of promoting scar tissue formation in damaged articular cartilage is by continuous passive motion. Continuous passive motion has been shown to stimulate formation of hyaline-like fibrocartilage in the chondral defect, especially in the immediate postoperative period. This should be supplemented by low load, non weight-bearing exercise such as swimming and cycling. Following articular cartilage injury, the athlete may have to modify his or her training to reduce the amount of weight-bearing activity and substitute activities such as swimming and cycling.

When an injury (e.g. patellar dislocation, ACL or MCL tear) requires a lengthy period of partial or non weight-bearing, particular attention must be paid to preserving the integrity of the articular cartilage. This is done with continuous passive motion, a hydrotherapy program, swimming or cycling.

Other methods of reducing stress on the damaged articular cartilage include correction of biomechanical abnormalities, attention to ensure symmetry of gait and the use of a brace to control any instability. Pool running, mini-trampoline and the AlterG® Anti-Gravity Treadmill® may be used in the early stages of running and agility work to reduce load bearing. Proprioceptive exercises and strength exercises are also important.

## ACUTE PATELLAR TRAUMA

Acute trauma to the patella (e.g. from a hockey stick or from a fall onto the kneecap) can cause a range of injuries from fracture of the patella to osteochondral damage of the patellofemoral joint with persisting patellofemoral joint pain. In some athletes, the pain settles without any long-term sequelae.

If there is suspicion of fracture, a plain radiograph should be obtained. It is important to be able to differentiate between a fracture of the patella and a bipartite patella which is a benign finding present in 1-2% of the population. A skyline view of the patella should be performed in addition to normal views.

If there is no evidence of fracture, the patient can be assumed to be suffering acute patellofemoral pain. This can be a difficult condition to treat. Treatment consists of nonsteroidal anti-inflammatory drugs (NSAIDs), local electrotherapy (e.g. interferential stimulation, TENS) and avoidance of aggravating activities such as squatting or walking down stairs. Taping of the patella may alter the mechanics of patellar tracking and therefore reduce the irritation and pain (Chapter 36). If taping provides symptom relief, rehabilitation and altered loading by strengthened quadriceps could be beneficial.

## Fracture of the patella

Patellar fractures can occur either by direct trauma, in which case the surrounding retinaculum can be intact, or by

indirect injury from quadriceps contraction, in which case the retinaculum and the vastus muscles are usually torn.

Fractures should be described by fracture orientation and position (e.g. transverse, inferior pole), degree of comminution and displacement (especially affecting the articular surface). Vertical fractures are possible but rare. A well-corticated fragment in the superolateral quadrant is more than likely part of a bipartite patella and not an acute fracture. Avulsion fractures are most commonly located at the inferior pole of the patella and often encountered in the paediatric population as patellar sleeve fractures. In the adult population, avulsion fractures occur at the origin of the patellar tendon and often cause disruption of the extensor mechanism.

The goals of treatment are a functional extensor mechanism, articular congruity and full, painless motion of the knee. Undisplaced fractures of the patella with normal function of the extensor mechanism can be managed non-surgically, initially with an extension splint. Over the next weeks as the fracture unites, the range of flexion can be gradually increased and the quadriceps strengthened in the inner range.

Transverse fractures are best treated with a tension-band technique (traditionally two axial Kirschner wires with a figure-of-eight wire anteriorly) which neutralises tension forces anteriorly and converts them into stabilising compressive forces at the articular surface. This technique is stronger than a simple cerclage wire in transverse fractures and can be combined with screw fixation in simple and in more comminuted fractures to increase stability.<sup>226</sup>

Small fragments may be excised or repaired with suture or screw fixation if possible. Every effort should be made to preserve and stabilise as much of the patella as possible to maintain the moment arm and avoid loss or poor outcomes which can occur when greater than 40% of the patella is removed. Removal of the entire patella may be contemplated for patients with massively comminuted fractures. Excision addresses the pain related to the fracture but decreases the mechanical advantage the patella provides to the extensor mechanism. The loss of quadriceps strength after total patellectomy can be as great as 49% and enough loss to preclude climbing stairs or getting out of a chair. Therefore, total patellectomy should be considered only after all techniques for salvage have been exhausted.<sup>226</sup>

## Patella dislocation

Mean annual incidence of patellar dislocation varies with age group: it is between 5.8 and 7.0 per 100 000 person-years in the general population, but 29 per 100 000 in 10-17 year olds. Women are at greater risk than men, as are young subjects; the risk decreases with age. Patellar dislocation may have long-term consequences: instability of patellar origin, pain, recurrent dislocation and patellofemoral osteoarthritis.

## Anatomy

Normally, the two patellar joint surfaces, medial and lateral, are symmetric and congruent with the femoral trochlea. Trochlear morphology remains relatively constant but, with growth, the thick trochlear cartilage thins in the middle, creating an illusion of a trochlear 'hollow'. The peripatellar soft tissue and particularly the medial patellofemoral ligament (MPFL) and vastus medialis obliquus (VMO) muscle contribute significantly to joint stability. The MPFL inserts to the femur between the medial epicondyle and the adductor tubercle and to the superomedial edge of the patella (Fig. 35.17).<sup>227</sup>

The MPFL provides 50-80% of the mechanisms counteracting lateral patellar glide.<sup>228</sup> Lateral patellar dislocation renders it incompetent, promoting recurrence

of dislocation.<sup>229</sup> Neighbouring structures, such as the patellomeniscal or patellotibial ligaments and the superficial medial retinaculum, make lesser contributions to patellar stability. The VMO muscle is very important, acting as a dynamic stabiliser, and is intimately related to the MPFL.<sup>227</sup>

Patella dislocation occurs when the patella is displaced laterally (Fig. 35.18a), leaving its confines within the trochlea groove of the femoral condyle. Acute patellar dislocation may be either traumatic with a history of a traumatic force, followed by development of a haemarthrosis or atraumatic, which usually occurs in young girls with associated ligamentous laxity. Often the latter do not have a history of significant trauma and the dislocation is accompanied by mild-to-moderate swelling.

The typical mechanism underlying patellar dislocation is a movement of the knee in flexion and valgus without direct contact, accounting for 93% of traumatic patellar dislocations.<sup>230</sup> Most patients report a sensation of slippage, intense pain and secondary effusion, often suggestive of knee sprain. True traumatic dislocation, caused by direct tangential force dislocating the patella laterally, also occurs. Almost all patients with traumatic patellar dislocation show haemarthrosis, MPFL lesion and medial patellar wing fracture. Osteochondral fracture occurs in 25% of traumatic patellar dislocations. The recurrence risk is increased 6-fold in the case of history of ipsi- or contralateral patellar dislocation.<sup>227</sup>

## Predisposing factors

Predisposing factors for patellar dislocation are either primary or secondary.<sup>227</sup> Primary predisposing factors are:

- trochlear dysplasia
- elevated distance between the tibial tubercle (TT) and the trochlear groove (TG)
- patella alta (high patella)
- patellar tilt.

Secondary predisposing factors are:

- elevated Q angle with TT lateralisation and genu valgum
- elevated femoral anteversion with compensatory lateral tibial torsion
- vastus medialis hypoplasia
- ligament hyperlaxity with genu recurvatum
- patella dysplasia.

## Clinical features

Patients with traumatic patellar dislocation usually complain that, on twisting or jumping, the knee suddenly gave way with the development of severe pain. Often the patient will describe a feeling of something 'moving' or 'popping out'. Swelling develops almost immediately. The dislocation usually reduces spontaneously with knee

**Figure 35.17** Anatomy showing the MPFL

extension; however, in some cases this may require some assistance or regional anaesthesia (e.g. femoral nerve block).

The main differential diagnosis of an acute patella dislocation is an ACL rupture. Both conditions have similar histories of twisting, an audible 'pop', a feeling of something 'going out' and subsequent development of haemarthrosis.

On examination, there is usually a gross effusion, marked tenderness over the medial border of the patella and a positive lateral apprehension test (Fig. 35.2q) when attempts are made to push the patella in a lateral direction. Any attempt to contract the quadriceps muscle

aggravates the pain and the patient often finds a painless rest in full extension.

Radiographs, including anteroposterior, lateral, skyline and intercondylar views, should be performed to rule out osteochondral fracture or a loose body.

The Merchant view may reveal bone avulsion of the medial facet of the patella and enables analysis of patellofemoral centring. The avulsion involves either the patellar insertion of the MPFL or the more distal patelomeniscal ligament insertion. Osteochondral fractures of the inferomedial pole of the patella are highly suggestive of traumatic patellar dislocation, but are overlooked on 30–40% of initial radiographs.

Computed tomography (CT) scan can assess osseous risk factors such as patellofemoral malalignment, osteochondral defects, patellar tilt and lateral subluxation, elevated TT-TG distance and trochlear dysplasia.

MRI is more specific in precisely determining involved structures and thus guiding treatment decision making. It assesses the patellofemoral joint cartilage surfaces and also the medial patellar stabilising structures (medial retinaculum, MPFL and VMO).<sup>231</sup> In patellar dislocation, MRI reveals: haemarthrosis; osteochondral lesions and bone oedema of the medial patellar facet (Fig. 35.18b); and bone oedema of the lateral femoral condyle (Fig. 35.18c). Concave deformity of the inferomedial patella, due to impaction, is a specific sign of lateral patellar dislocation. Figure 35.18d illustrates the three components of the injury: rupture of the MPFL; injury to the inferomedial pole of the patella; and bone bruising to the femoral lateral condyle.

**Figure 35.18** (a) The patella dislocates laterally tearing the MPFL (b) Axial fat-suppressed T2 MRI of the left knee. Blue arrow shows patellar chondral injury. (c) The torn MPFL is highlighted with the green arrow. Abnormal high signal represents oedema at the site of MPFL tear. Purple arrow at right of image shows bone marrow oedema at the lateral femoral condyle, the impact zone when the patella dislocates (d) Diagram demonstrating the three components of the injury—the torn MPFL, the articular damage at the inferomedial corner of the patella and the bone oedema at the lateral condyle

## Treatment

The initial management of a first-time traumatic patellar dislocation is controversial, with no evidence-based consensus to guide decision making. Most first-time traumatic patellar dislocations have been traditionally treated non-operatively; however, there has been a recent trend towards initial surgical management.

Following a systematic review of 70 level I-IV studies looking at study design, mean follow-up, subjective and validated outcome measures, re-dislocation rates and long-term symptoms, the authors recommended initial non-operative management of a traumatic dislocation except in several specific circumstances.<sup>232</sup> These include:

- the presence of an osteochondral fracture
- substantial disruption of the medial patellar stabilisers
- a laterally subluxated patella with normal alignment of the contralateral knee
- a second dislocation
- in patients not improving with appropriate rehabilitation.

Arthroscopy should be performed in case of an intra-articular loose body secondary to a chondral lesion or osteochondral fracture. When an osteochondral fracture involves more than 10% of the patellar joint surface or involves the weight-bearing surface of the lateral femoral condyle, the osteochondral fragment should so far as possible be fixed by open surgery, for instance using resorbable pins; if this is not possible, micro-fracturing may stimulate cartilage regrowth. As the MPFL and medial retinaculum tend to be torn in acute traumatic patellar dislocation, stabilisation surgery may be required.

According to Duthon, surgery for patellar dislocation patients can be classified under three categories according to whether there are predisposing factors and whether the dislocation is inaugural or recurrent.<sup>227</sup>

1. Inaugural dislocation without predisposing factors. Immediate surgical repair of the patellar stabilising structures (VMO, MPFL, medial retinaculum) is recommended in athletic patients. Bone avulsion at the patellar insertion of the MPFL is known not to show consolidation even with proper immobilisation; functional results of non-operative treatment are unsatisfactory and fixation is recommended.
2. Inaugural dislocation with predisposing factors. Surgical repair of the patellar stabilising structures (VMO, MPFL, medial retinaculum) is recommended when risk factors for recurrence such as trochlear dysplasia, patella alta, elevated TT-TG distance, are present.
3. Recurrent dislocation. In recurrent patellar dislocation, surgery is recommended due to severe apprehension constituting a disability in everyday life, and to prevent chondral lesions which, in the long term, would cause

patellofemoral osteoarthritis. The type of surgery is determined by the presence of one or more risk factors and therefore may involve:

- lowering the tibial tubercle
- patellar tenodesis
- tibial tubercle medialisation
- sulcus-deepening trochleoplasty
- vastus medialis plasty.

While patellar dislocations are increasingly being managed with surgery, there is no good evidence of a benefit over conservative management. Hing et al. performed a literature review of five studies for the Cochrane Database.<sup>233</sup> No significant difference emerged for risk of recurrent dislocation, Kujala patellofemoral score or need for surgical revision.

The most important aim of rehabilitation after patellofemoral dislocation is to reduce the chances of a recurrence of the injury. The therapist should aim to restore normal range of knee motion (full flexion and extension) and to reinforce the quadriceps to restore dynamic patellar balance.

As a result, the rehabilitation program is lengthy and emphasises core stability, pelvic positioning, vastus medialis obliquus strength and stretching of the lateral structures when tight. Similar to ACL intervention exercises, rotational control of the limb under the pelvis is critical to knee and kneecap stability. A suggested rehabilitation program is shown in Table 35.14.

Bracing could be helpful for these patients in combination with extensive rehabilitation. The patella brace usually has a hole for the patella and a lateral rim to prevent lateral dislocation. Bracing does not prevent recurrent instability but may be helpful for those with symptomatic instability.

## LESS COMMON CAUSES

### Patellar tendon rupture

The patellar tendon occasionally ruptures spontaneously. This is usually in association with a sudden severe eccentric contraction of the quadriceps muscle, which may occur when an athlete stumbles or when attempting a powerful take off manoeuvre (e.g. long jump event in track and field competition). There may have been a history of previous corticosteroid injection into the tendon. A previous history of patellar tendinopathy is uncommon.

Patients complain of a sudden acute onset of pain over the patellar tendon accompanied by a tearing sensation and are unable to stand. On examination, there is a visible loss of fullness at the front of the knee as the patella is retracted proximally. The knee extensor mechanism is no longer intact and knee extension with a straight leg cannot be initiated.

Table 35.14 Rehabilitation program following patellar dislocation (see Figs 35.6 and 35.7)

Phase	Goal of phase	Time post-injury	Physiotherapy treatment	Exercise program	Functional/sport-related activity
Phase 1	Control swelling Maintain knee extension Isometric quadriceps strength	0–2 weeks	Extension splint (removal dependent on surgeon/physician) Cryotherapy Electrotherapy PFJ taping Manual therapy	Quadriceps drills (supine) Bilateral calf raises Foot and ankle Hip abduction	Progress to FWB
Phase 2	No swelling Full extension Flexion to 100° 4+/5 quadriceps strength 5/5 hamstring strength	2–6 weeks	Cryotherapy Electrotherapy Compression Manual therapy Gait re-education Exercise modification	ROM drills Quadriceps/VMO setting Mini-squats and lunges Bridges (double, then single-leg) Hip abduction and extension with rubber tubing Single-leg calf raises Gait re-education drills Balance and proprioceptive drills (single-leg)	Walking Exercise bike
Phase 3	Full ROM Full strength and power Return to jogging, running, and agility Return to restricted sport-specific drills	6–8 weeks	Manual therapy Exercise/activity modification and supervision	As above—Increase difficulty, repetitions and weight, where appropriate Single-leg squats Single-leg press Jump and land drills Agility drills	Straight-line jogging Swimming (light kick) Road bike Straight-line running Progressing to sport-specific running and agility (progressively sequenced) (e.g. running forwards, sideways, backwards, sprinting, jumping, hopping, changing directions, kicking)
Phase 4	Return to sport	8–12 weeks	As above	High-level sport-specific strengthening as required	Progressive return to sport (e.g. restricted training, unrestricted training, match play, competitive match play)

FWB = full weight-bearing; PFJ = patellofemoral joint; ROM = range of motion; VMO = vastus medialis obliquus

Surgical repair of the tendon is needed and must be followed by intensive rehabilitation. Full recovery takes 6–9 months and there is often some residual disability.

### Bursal haematoma

Occasionally, an acute bursal haematoma or acute pre-patellar bursitis occurs as a result of a fall onto the knee. This causes bleeding into the pre-patellar bursa and subsequent inflammation. This usually settles spontaneously with firm compression bandaging. If not, the haematoma should be aspirated and the bloodstained fluid removed. Anti-inflammatory medication may also be appropriate. This injury is often associated with a skin wound (e.g. abrasion) and therefore may become infected. Adequate skin care is essential. If the bursa recurs, then aspiration followed by injection of a corticosteroid agent may be required. If conservative treatment fails, arthroscopic excision of the bursa is indicated.

### Fat pad impingement

Acute fat pad impingement (often incorrectly referred to as 'Hoffa's syndrome') usually occurs as a result of a hyperextension injury. As the fat pad is the most sensitive part of the knee, this condition may be extremely painful.<sup>234</sup> There may be an inferiorly tilted lower pole of the patella predisposing to injury. On examination, tenderness is distal to the patella but beyond the margin of the patellar tendon. A haemarthrosis may be present.

This can be an extremely difficult condition to treat. The basic principles of treatment are a reduction of aggravating activities, electrotherapeutic modalities to settle inflammation and resumption of range of movement exercises as soon as possible. Taping of the patella may help in reducing the amount of tilt and impingement (Chapter 36). If conservative management is not successful, arthroscopic joint lavage and resection of the fat pad can be helpful.

### Fracture of the tibial plateau

Tibial plateau fracture is seen in high-speed injuries such as falls while skiing, wave-jumping or horseriding. This condition needs to be excluded when diagnosing collateral ligament damage with instability. The patient complains of severe pain and inability to weight-bear. Fractures are associated with a lipohaemarthrosis, which can be detected on a horizontal lateral X-ray by the presence of a fat fluid level. CT scan is helpful in defining the fracture.

Minimally displaced fractures should be treated by 6 weeks of non weight-bearing in a hinged knee brace (Fig. 35.5a). Displaced fractures (Fig 35.19) or fractures with unstable fragment/s require internal surgical fixation. Displaced vertical split fractures may be fixed percutaneously during arthroscopy.

Tibial plateau fractures are commonly associated with meniscal or ACL injuries. In these cases, arthroscopic assessment is required. Following recovery from a tibial plateau fracture, weight-bearing activity may need to be reduced as the irregular joint surface predisposes to the development of osteoarthritis.

### Superior tibiofibular joint injury

Acute dislocation of the superior tibiofibular joint occurs occasionally as a result of a direct blow. The patient complains of pain in the area of the joint and may be aware of obvious deformity. The common peroneal nerve may be damaged with this injury.

Sprain of the tibiofibular joint is more common. The patient complains of local pain aggravated by movement and, on examination, there is local tenderness and some anteroposterior instability. Treatment consists of rest and local electrotherapeutic modalities. Rarely, a chronic instability of the superior tibiofibular joint develops, but these cases may need surgical stabilisation.

### Ruptured hamstring tendon

Spontaneous rupture of one of the distal hamstring tendons at the knee occurs occasionally during sprinting. Sudden onset of pain is localised to either the biceps femoris tendon or the semitendinosus tendon. Pain and weakness is present with resisted hamstring contraction. When these injuries involve the tendon portion of the hamstring unit, it may be amenable to surgical exploration and repair, followed by protection in a limited-motion brace.

**Figure 35.19** X-ray of a tibial plateau fracture

# Anterior knee pain

by KAY CROSSLEY and JILL COOK with SALLIE COWAN, ADAM CULVENOR,  
SEAN DOCKING, MICHAEL RATHLEFF and EBONIE RIO

*The New York Knicks announced today that Carmelo Anthony will have season-ending left knee surgery. The procedure, which will be performed by Team Orthopedist Dr. Answorth Allen, includes a left knee patella tendon debridement and repair.*

www.NBA.com, 18 February 2015

Anterior knee pain is the most common presenting symptom in many physiotherapy and sports physician practices.<sup>1, 2</sup> It contributes substantially to the 20–40% of family practice consultations that relate to the musculoskeletal system.<sup>3</sup> Anterior knee anatomy is shown in Figure 36.1.

In this chapter, we:

- outline the clinical approach to assessing the patient with anterior knee pain, particularly with a view to

distinguishing the common conditions—patellofemoral pain (PFP) and patellar tendinopathy

- detail contemporary management integrating high level evidence (Chapter 2) with the best of clinical experience
- discuss less common causes of anterior knee pain such as fat pad impingement, which may mimic features of both PFP and patellar tendinopathy
- highlight new research investigating PFP in adolescents, patellar tendinopathy and patellofemoral osteoarthritis (OA).

(a)

(b)

**Figure 36.1** Anterior knee (a) Surface anatomy (b) Anatomy

## CLINICAL APPROACH

Distinguishing between PFP and patellar tendinopathy as a cause of anterior knee pain can be difficult. Rarely, both conditions may be present. Causes of anterior knee pain are listed in Table 36.1.

### History

A number of important factors can be elicited from the history of a athlete presenting with anterior knee pain. These include the specific location of the pain, the nature of aggravating activities, the history of the onset and behaviour of the pain, as well as any associated clicking, giving way or swelling.

Although it may be difficult for the patient with anterior knee pain to be specific about the location of pain, this symptom provides an important clue as to the likely diagnosis. For example, retropatellar or peripatellar pain suggests that the patellofemoral joint (PFJ) is a likely culprit, lateral pain localised to the lateral femoral epicondyle increases the likelihood of iliotibial band syndrome as the diagnosis (Chapter 37). Patellar tendon pain will be localised to the inferior pole of the patella and the patient can point to it with a single finger. The pain remains localised both at rest and on loading with the decline squat. The location of pain (and source) appear to be associated with different changes to motor drive, indicating that the rehabilitation approaches are likely to be different.<sup>4</sup>

The onset of PFP is typically insidious and unrelated to an acute injury. However, it may present secondary to an acute traumatic episode (e.g. falling on the knee) or consequent to another knee injury (e.g. meniscal, anterior cruciate ligament) or knee surgery. The patient presents with a diffuse ache, which is usually exacerbated by

PFJ-loaded activities, such as ascending/descending stairs or running. Sometimes PFP is aggravated by prolonged sitting ('movie-goer's knee'), but sitting also tends to aggravate patellar tendinopathy symptoms and therefore is not diagnostic of PFP. Pain during running that gradually worsens is more likely to be of patellofemoral origin, whereas pain that occurs at the start of activity, settles after warm-up and returns after activity is more likely to be patellar tendinopathy. While the pathologies of patellar tendinopathy and PFP may co-exist, in practice they rarely present as co-existing clinical entities. Table 36.2 is an aid to differentiate PFP and patellar tendinopathy based on clinical history and presentation.

The type of activity that aggravates the anterior knee pain also aids diagnosis. Consider two contrasting scenarios that a patient may report as causing pain at the infrapatellar region. In one case, precipitating activities, such as basketball, volleyball, high, long or triple jumps, that involve repetitive loading (specifically energy storage and release) of the patellar tendon suggest the diagnosis of patellar tendinopathy. On the other hand, if a freestyle swimmer reported pain following tumble turning or vigorous kicking in the pool, where there had been no energy storage and release load on the tendon but a forceful extension of the knee, the practitioner should suspect an irritated fat pad. The mechanism of injury and the aggravating features are critical to an accurate diagnosis.

A history of crepitus may suggest PFP. A feeling that the patella moves laterally at certain times suggests patellofemoral instability. An imminent feeling of giving way may be associated with patellar subluxation, PFP or meniscal abnormality. Although frank, dramatic giving way is usually associated with anterior cruciate ligament

**Table 36.1 Causes of anterior knee pain**

Common	Less common	Not to be missed
Patellofemoral pain Patellar tendinopathy	Synovial plica Pre-patellar bursitis Quadriceps tendinopathy Infrapatellar bursitis Patellofemoral instability Fat pad impingement Sinding-Larsen-Johansson lesion in adolescents (Chapter 44) Tenoperiostitis of upper tibia Stress fracture of the patella Osgood-Schlatter lesion in adolescents (Chapter 44)	Referred pain from the hip Osteochondritis dissecans Slipped capital femoral epiphysis Perthes' disease Tumour (especially in the young)

**Table 36.2 Comparison of the clinical features of patellofemoral pain and patellar tendinopathy**

Signs	Patellofemoral pain	Patellar tendinopathy
Onset	Running, steps/stairs, hills, any weight-bearing activities involving knee flexion	Activities involving jumping and/or changing direction
Pain	Non-specific or vague; may be medial, lateral or infrapatellar; aggravated by activities that load the PFJ	At the inferior pole of patella, aggravated by energy storage loads such as jumping
Tenderness	Usually medial or lateral facets of patella but may be tender in infrapatellar region; may have no pain on palpation due to areas of patella being inaccessible	Localised to inferior pole of patella; this tenderness can exist in jumping athletes without patellar tendinopathy
Swelling	May have small effusion, swelling, suprapatellar or infrapatellar	Tendon may be increased in thickness; no joint swelling
Clicks/clunks	Occasional	No
Crepitus	Occasionally under patella	No
Giving way	Rarely, due to quadriceps weakness/inhibition or subluxation	Rarely, due to quadriceps weakness/inhibition
Knee range of motion	May be decreased in severe cases but usually normal	Normal
Quadriceps contraction in extension	Can be painful, often normal	Often painful
PFJ movement	May be restricted in any direction. Commonly restricted medial glide due to tight lateral structures	Normal PFJ biomechanics
Functional testing	Squats, stairs may aggravate. PFJ taping should decrease pain	Decline squats aggravate pain; PFJ taping has less effect

(ACL) instability (Chapter 35), giving way resulting from pain-induced muscle inhibition is not uncommon in people with various types of anterior knee pain.

A history of previous knee injury or surgery may be important; PFP is a well-recognised complication of posterior cruciate ligament injury and following anterior cruciate ligament reconstruction (Chapter 35). Patellar tendinopathy may be present after ACL reconstruction using bone-patellar tendon-bone grafts.

Knee pain and/or effusion may result in inhibition of the quadriceps (reduced magnitude and delayed timing of electromyography (EMG) onset) commonly termed 'pain-induced muscle inhibition'. This inhibition appears to be more profound in the vastus medialis obliquus (VMO), especially at smaller knee effusion volumes.<sup>5, 6</sup> Preferential inhibition of the VMO has potential to set up an imbalance in the medial and lateral forces on the patella, predisposing to PFP.<sup>7</sup> Significant knee swelling is rare in atraumatic anterior knee pain and generally suggests additional intra-articular abnormality. However, a small effusion may be present with PFP.

Previous treatment and the patient's response to it should be noted. If treatment was unsuccessful, it is essential to determine whether the failure was due to

incorrect diagnosis, inappropriate treatment or poor patient adherence.

### Physical examination

The primary aim of the clinical assessment is to determine the most likely cause of the patient's pain. It is critical to reproduce the patient's anterior knee pain as location of tenderness and aggravating factors are key to the differential diagnosis. This is usually done with either a double or single leg squat (Fig. 36.2c). A squat done on a decline board (Fig. 36.2d).<sup>8</sup> is very painful in people with patellar tendinopathy. It is essential to palpate the anterior knee carefully to determine the site of maximal tenderness, although palpation soreness by itself is not diagnostic; for example, the patellar tendon can be tender on palpation in asymptomatic athletes.<sup>9</sup>

Many clinical tests outlined below have not been evaluated for their clinical utility. Those that have been evaluated for PFP and patellar tendinopathy are outlined in Tables 36.3 and 36.4. The best tests to identify people with PFP are pain during activities (squatting, stairs, prolonged sitting) and pain during an isometric quadriceps contraction, although these tests fall well below the recommended cut offs for a diagnostic test (LR + >10).<sup>10</sup> A combination of these tests may provide greater diagnostic accuracy.<sup>10</sup>

Examination includes the following.

1. Observation
  - a. standing (Fig. 36.2a)
  - b. walking
  - c. supine (Fig. 36.2b)
2. Functional tests
  - a. double then single-leg squat (Fig. 36.2c)
  - b. step-up/step-down
  - c. jump/hop
  - d. lunge
  - e. single-leg decline squat (Fig. 36.2d)

(a)

**Figure 36.2** Examination of the anterior knee

(a) Observation—standing. Observe the patient from the front to examine lower limb alignment including femoral torsion, patellar alignment and any signs of muscle wasting  
(b) Observation—supine. Observe for lower limb alignment, effusion, position of the patella, and any evidence of patella tilt or rotation (c) Functional test—double/single-leg squat  
If the patient's pain has not already been reproduced, functional tests such as squat, lunge, hop, step-up, step-down or eccentric drop squat should be performed

(b)

(c)

(d)

(f)

(e)

**Figure 36.2 (cont.)** (d) Functional test—single-leg squat on decline board (e) Palpation—patella, and medial and lateral facets are palpated for tenderness (f) Patellofemoral joint assessment—mobility of the patella—medial glide

### 3. Palpation

- a. patella—medial and lateral facets (Fig. 36.2e)
- b. medial/lateral retinaculum
- c. patellar tendon
- d. tibial tubercle
- e. effusion—swipe test, ballotment test

### 4. PFJ assessment

- a. quadriceps function
- b. mobility of patella
  - i. superior glide
  - ii. inferior glide
  - iii. medial glide (Fig. 36.2f)
  - iv. lateral glide—look for apprehension
- c. tracking of patella in passive knee flexion/extension

### 5. Flexibility and range of motion

- a. lateral soft tissue structures
- b. quadriceps
- c. hamstring
- d. iliotibial band
- e. gastrocnemius
- f. soleus

  - b. examination of hip joint (Chapter 31)
  - c. examination of lumbar spine (Chapter 29)
  - d. neurodynamic tests (neural Thomas test, slump test, prone bent knee test-Chapter 9)

### Patient-reported outcome measures

Patient reported outcome measures (PROMs) are considered gold standard to evaluate outcomes in a clinical population. When choosing a PROM, the psychometric properties of all possible PROMs should be considered, specific to the patient. For PFP, three scales (the anterior knee pain scale, and visual analogue scales for usual and worst pain) have adequate psychometric properties for use (Table 36.5). The patient specific functional scale<sup>14</sup> is also a useful clinical PROM, but has not been

**Table 36.5 Patient-reported outcome measures for patellofemoral pain**

Anterior knee pain scale (AKPS), also known as Kujala scale
<ul style="list-style-type: none"><li>• Self-administered questionnaire that evaluates pain and function in anterior knee pain<sup>15</sup></li><li>• 13 items</li><li>• Score range 0–100 (100 is best score)</li><li>• Test-retest reliability: 0.81–0.90<sup>16</sup></li><li>• MDC95%: 19.7<sup>16</sup>–9.7<sup>17</sup></li><li>• MCID: 8–10<sup>17</sup></li></ul>
Visual analogue pain scale when usual pain (VAS-U)
<ul style="list-style-type: none"><li>• Self-administered questionnaire to evaluate pain on a 100 mm visual analogue scale during usual activities in the past week<sup>17</sup></li><li>• Score range 0–100 (100 is worst imaginable pain)</li><li>• Test-retest reliability: 0.56–0.77<sup>16</sup></li><li>• MDC95%: 33<sup>16</sup>–17<sup>17</sup></li><li>• MCID: 15–20<sup>17</sup></li></ul>
Visual analogue pain scale when worst pain (VAS-W)
<ul style="list-style-type: none"><li>• Self-administered questionnaire to evaluate pain on a 100 mm visual analogue scale during worst (most aggravating) activities in the past week<sup>17</sup></li><li>• Score range 0–100 (100 is worst imaginable pain)</li><li>• Test-retest reliability: 0.56–0.79<sup>16</sup></li><li>• MDC95%: 30<sup>16</sup>–17<sup>17</sup></li><li>• MCID: 20<sup>17</sup></li></ul>

specifically validated for PFP. For each scale, the patient needs to improve by more than the Minimal Detectable Change (MDC), to be greater than the error associated with the measurement and greater than the Minimal Clinically Important Difference (MCID), to have a clinically meaningful change. See Chapter 16 for more details on PROMS and how to use them in clinical practice.

Investigations

Imaging may be used to confirm a clinical impression obtained from the history and examination. Structural imaging includes plain radiography, ultrasound, CT, and MRI. Occasionally, radionuclide bone scan is indicated to evaluate the ‘metabolic’ status of the knee (e.g. after trauma, or in suspected stress fracture).

Most patients with PFP will require either no imaging or plain radiography consisting of a standard AP view, a true lateral view with the knee in 30° of flexion and an axial view through the knee in 30–40° of flexion. Plain radiography can detect bipartite patella, apophyseal changes at the patellar tendon attachments and osteoarthritis, as well as rule out potentially serious complications such as tumour or infection. Although CT and three-dimensional CT can assess the PFJ morphology, MRI is gaining increasing popularity as an investigation of

PFP and the unstable patella.<sup>18</sup> These imaging techniques can identify features including bone lesions, chondral lesions, tendinopathy and synovitis. However, the importance of such features to symptoms or progression of disease remains unknown.<sup>19</sup> MRI displays high signal abnormality in patellar tendinopathy. Ultrasound hypoechogenicity and excessive vascularity also indicate a potential diagnosis of patellar tendinopathy.<sup>20</sup> However, in asymptomatic athletes or those with symptoms from another source in the anterior knee, the patellar tendon can be abnormal on imaging,<sup>21, 22, 23</sup> and the clinician should be wary of using imaging findings diagnostically.

PATELLOFEMORAL PAIN

In this section we:

- define the condition and underscore its significance
- review clinically relevant functional anatomy
- alert the clinician to predisposing factors and how to identify them—this may prove critical for effective long-term treatment
- summarise the results of RCTs that have added high-quality evidence (Chapter 2) to guide clinical treatment.

## What is patellofemoral pain?

### PRACTICE PEARL

**Patellofemoral pain is the preferred term used to describe pain in and around the patella.**

Synonyms include patellofemoral pain syndrome, anterior knee pain and chondromalacia patellae. Patellofemoral pain (PFP) is an 'umbrella' term used to embrace all peripatellar or retropatellar pain in the absence of other pathologies.<sup>24</sup> Since the cause of the pain may differ between patients, it is appropriate to review the potential sources of PFP.<sup>25</sup>

Numerous structures in the PFJ are susceptible to overload. A number of extra- and intra-articular components of the knee can generate neurosensory signals that ultimately result in the patient feeling pain (see box

below). Patellofemoral articular cartilage is avascular and aneural. However, a cartilage lesion may lead to chemical or mechanical synovial irritation, bone oedema or erosion, all of which can result in pain.<sup>26, 27</sup>

Peripatellar synovitis, in the absence of obvious cartilage damage, must be considered as a primary cause of PFP.<sup>28</sup> Soft tissues such as the lateral retinaculum are also implicated as a potent source of PFP.<sup>29, 30-32</sup> Other important sources of pain are the synovium and infrapatellar fat pad.<sup>33-36</sup>

So how does an increase in PFJ load result in PFP? Dye and Vaupel<sup>37</sup> described a concept whereby injury to the PFJ musculoskeletal tissues results from supraphysiological loads—either a single maximal load or lower magnitude repetitive load. Injury to these tissues initiates a cascade of events encompassing inflammation of the peripatellar synovium through to bone stress. Thus, a number of different pain-sensitive structures can give rise to the conscious sensation of PFP (Chapters 5 and 6).<sup>37</sup>

## The 'pain' in patellofemoral pain

### Local and central contributors to PFP

Pain is a complex protective mechanism (Chapters 5 and 6). Although nociception is an input to the brain that may result in the output of pain, the brain considers many other inputs before deciding to create pain, some of which may be far more decisive than the level of nociception. The experience of knee pain is modulated at different sites in the body, both locally and centrally within the brain and spinal cord. This means that both local peripheral nociceptors and facilitated central pain pathways, may influence the pain that is experienced by the patient. Current thinking in the field of pain science teaches us that pain reflects the perception of threat more so than the state of injury to tissues. Pain, such as perceived in the PFJ, is considered a driver of behaviour to protect tissues.

### Do people with PFP have hyperalgesia?

The pathways involved in PFP are starting to be evaluated. Compared with pain-free controls, female adolescents presenting with longstanding PFP have hypersensitivity highlighted by reduced pressure pain thresholds (PPTs) around the knee and more distally around the tibialis anterior muscle.<sup>38</sup> The distal hyperalgesia may reflect segmental spreading of hyperalgesia.<sup>39</sup> Identification of pressure pain hyperalgesia (decreased PPT) may be clinically important and associated with poorer recovery as previously shown in adult patients with acute whiplash injury and after total knee replacement. However, early reports indicate that low PPTs around the knee or tibialis anterior are not associated with

a worse prognosis and PPTs tend to increase when patients recover.<sup>40</sup> This implies a nociceptive contribution to PFP.

### How does facilitated central pain mechanism affect the pain experience in PFP?

Conditioned pain modulation (CPM) (primarily a descending inhibitory mechanism) is also impaired in young female adults with longstanding PFP.<sup>40</sup> Less efficient CPM mechanisms are evident in patients with musculoskeletal pain conditions, such as myofascial temporomandibular disorders, chronic low back pain and fibromyalgia. A reduced potency of the descending control can make the entire neuroaxis more vulnerable to pain. However, in the study of female adolescents with PFP, the CPM mechanisms were highly variable, ranging from an efficient CPM system to severely impaired CPM. This suggests that central pain mechanisms may be a factor we need to consider in some, but not all, patients with PFP. Furthermore, there is emerging evidence that some people may be more vulnerable to pain due to genetic and other factors.

### Clinical signs that may suggest facilitated central pain mechanisms

In a clinical setting the following signs may suggest facilitated central pain mechanisms:

- disproportionate pain, implying that the severity of pain and related reported or perceived disability are disproportionate to the nature and extent of the injury
- presence of diffuse pain distribution, allodynia and hyperalgesia.

If this fits with your patient with longstanding PFP and he or she does not respond to your normal exercise protocol, you might want to consider the following items.

**Guidelines for clinical management of longstanding PFP in respect to a heightened/hypersensitive central pain presentation**  
(adapted from Nijs et al<sup>41</sup>)

- Be conservative when estimating the initial training load; prefer a lower baseline and then progress from there depending on symptom flaring.

- Monitor symptom flares after exercise and progress exercises depending on response.
- Let the patient know that minor symptom flares are natural during the initial stages of exercise therapy, but should cease once an exercise routine is established.
- Allow increased pain during and shortly following exercise but avoid continuously increasing pain intensity over time.
- Use aerobic exercise as well as motor control training.
- Include exercise of non-painful parts of the body (including cross-education and strength training of the other limb).
- Use multiple and long recovery breaks in between exercises.

### What is patellofemoral osteoarthritis?

Patellofemoral osteoarthritis (OA) can be a considerable source of anterior knee symptoms and functional limitations,<sup>42</sup> with a growing body of evidence indicating that patellofemoral OA occurs before tibiofemoral disease<sup>43</sup> and can affect young to middle-aged adults.<sup>44</sup>

Specific risk factors for early-onset patellofemoral OA development include a history of patellofemoral dysfunction (i.e. pain, dislocation, cartilage lesions), ACL rupture, and meniscal tears. Evidence updates, to highlight the importance of patellofemoral OA, are outlined in the box below.

### Patellofemoral osteoarthritis as a source of anterior knee pain in active young adults

#### Is patellofemoral OA related to PFP?

The best available evidence suggests that PFP and patellofemoral OA may exist on a continuum;<sup>45</sup> retrospective recall of PFP is associated with radiographic<sup>46</sup> and MRI<sup>47</sup> features of patellofemoral OA. While not all patients with PFP will develop patellofemoral OA, PFP should be considered to be more than simply a benign, self-limiting condition and therefore be managed with appropriate evidence-based interventions.

#### Is patellofemoral OA a consequence of acute knee injuries?

Anterior cruciate ligament injury increases the risk of tibiofemoral and patellofemoral OA.<sup>48</sup> Five years after ACL injury, radiographic patellofemoral OA is evident in 19% of knees, regardless of conservative or surgical management or graft type used,<sup>49</sup> while MRI evidence of patellofemoral OA is observed in 17% of individuals at 1 year following ACL reconstruction.<sup>50</sup> By 10 years after ACL reconstruction, almost 50% of people will demonstrate radiographic patellofemoral OA.<sup>51</sup> Meniscal tears requiring partial meniscectomy, either in association with ACLR<sup>52</sup> or in isolation,<sup>53</sup> are associated with 2–5 times greater odds of patellofemoral OA development than knees without meniscal pathology over the following 8–20 years.

The mechanisms driving the development of post-traumatic patellofemoral OA following ACL and meniscal injury are not well understood, but may relate to concomitant damage to the PFJ at the time of initial trauma, or inherent

biomechanics that are risk factors for both PFP and ACL injury (e.g. high knee abduction moments).<sup>54</sup>

Patellofemoral trauma, such as patellar dislocation, doubles the risk of patellofemoral OA at 13 years post-injury (22% vs 11%), irrespective of non-operative or surgical management.<sup>55</sup>

The onset of post-traumatic patellofemoral OA may be mediated by the presence of a patellofemoral articular cartilage lesion—a particularly common finding in the unstable PFJ (97%),<sup>56</sup> which predicts future cartilage loss<sup>57</sup> and the development of radiographic patellofemoral OA.<sup>51</sup>

#### Can we identify people with or at high risk for patellofemoral OA?

The presence of knee crepitus and history of patellar pain are associated with patellofemoral joint OA (but not tibiofemoral joint OA) in women.<sup>58</sup> However, clinical examination findings and knee pain location have limited ability to discriminate those with patellofemoral OA from those with tibiofemoral OA.<sup>24</sup> Future studies may shed some light on diagnostic tests to recognise or predict patellofemoral OA in people with PFP.

#### Where to now for research and clinical practice?

The sensitivity of MRI to detect joint changes in the earliest stages of disease and recently proposed MRI-OA criteria<sup>59</sup> offer promise for early OA diagnosis, enabling studies of risk factors for early onset patellofemoral OA and evaluating interventions to be tested early in the disease process.

## Functional anatomy

At full extension, the patella sits lateral to the trochlea. During flexion, the patella moves medially and comes to lie within the intercondylar notch until 130° of flexion, when it starts to move laterally again.<sup>35</sup> With increasing knee flexion, a greater area of patellar articular surface comes into contact with the femur, thus offsetting the increased contact load that occurs with flexion. Loaded knee flexion activities subject the PFJ to loads ranging from 0.5 times body weight for level walking to seven to eight times body weight for stair climbing.<sup>36</sup>

## Factors that may contribute to patellofemoral pain

Patellofemoral pain is likely to be initiated by increased or unaccustomed PFJ loads. Factors that influence PFJ load can be considered in two categories: extrinsic and intrinsic. During physical activities the extrinsic load is created by the body's contact with the ground (ground reaction force) and is therefore moderated by body mass, speed of gait, surfaces and footwear. The number of loading cycles and frequency of loading are also important. During weight-bearing activities, any increase in the amount of knee flexion will increase the PFJ load. Therefore, when an individual experiences an increase in the magnitude of the PFJ load (e.g. higher training volume, increased speed of running), this may overload the PFJ structures sufficiently to initiate pain. Note that activities with a high eccentric component, such as bounding, will overload the PFJ structures but are more likely to lead to patellar tendon pain.

Intrinsic factors can influence both the magnitude and the distribution of the PFJ load. Distribution of load is influenced by the alignment of the patella within the femoral trochlea, also known as patella tracking. Intrinsic factors that can influence patella tracking may be considered as 'remote' or 'local'. Considering the patient as a whole, 'remote' factors that affect patella tracking include femoral and tibial rotations. These factors can in turn be influenced by hip muscle strength, trunk kinematics, subtalar pronation and muscle flexibility (discussed below).<sup>60</sup> Local factors that influence patella movement include bony shape of the patella and trochlea, soft tissue tension and neuromuscular control of the medial and lateral components of the vasti.<sup>61</sup>

Therefore, when the initial subjective and objective examinations are completed and the diagnosis of PFP is confirmed, the clinician should assess the contribution of various extrinsic and intrinsic factors to the development of PFP.

## PRACTICE PEARL

Although the history provides valuable information pertaining to extrinsic factors, clinical examination is usually required to evaluate the key intrinsic contributing factors ('remote' and 'local'). This comprehensive assessment is crucial in the planning treatment.

## 'Remote' intrinsic factors

The following 'remote' intrinsic factors may contribute to PFP developing (see also Chapter 8):

- increased hip/femoral internal rotation
- Increased hip adduction
- increased apparent knee valgus/external tibial rotation
- poor trunk and pelvic control
- pronated foot type
- sagittal plane motions.

It is important to assess the patient in static postures and during functional activities. Some factors may become more obvious during specific functional tasks, such as the step-down or single-leg squat and hopping or landing from a jump, where the postural demands are high. Once a potential contributing factor has been identified, the clinician must investigate the mechanisms that may require intervention (Table 36.6a-d).

## Increased femoral/hip internal rotation

Increased femoral/hip internal rotation motions are associated with PFP<sup>62-65</sup> and may contribute to its development.<sup>66</sup> Clinical observation of the patient in standing reveals internally rotated femurs, often manifesting as 'squinting patellae'—the patellae both face medially. During tasks of increasing load, further internal rotation of the thigh can often be observed and may be visualised as an apparent knee valgus.

## Increased hip adduction motions

Increased hip adduction motion may increase valgus load on the knee during dynamic tasks<sup>62</sup> and has been associated with PFP.<sup>63-68</sup> Clinical observation of the patient in standing may not reveal any abnormality. During functional tasks such as a single-leg squat, adduction of the thigh can often be observed and is usually associated with a pelvic drop towards the non weight-bearing leg.

## Increased apparent knee valgus and/or increased tibial external rotation

Genu valgum (knee valgus or abduction) may be associated with PFP and observed in standing. This

**Table 36.6a Remote factors that can contribute to patellofemoral pain syndrome and their possible mechanisms—increased femoral internal rotation**

Increased femoral/hip rotation	Possible contributing factors	Confirmatory assessments
	Structural: • femoral anteversion	Imaging—MRI, radiography
	Inadequate strength/control: • hip external rotators • hip abductors • hip extensors • lumbopelvic muscles	Clinical assessment: • manual muscle test (Figs 28.3a, b) • hand-held dynamometer • biofeedback
	Range of motion deficits: • inadequate ankle dorsiflexion range • inadequate hip external rotation range	Range of motion tests: • clinical inclinometer (Chapter 8) • figure '4' or FABER test (Fig. 31.6c)
	Altered movement patterns	Biomechanical/gait assessment (Chapter 8): • can the patient correct the movement pattern when asked to focus on it?

**Table 36.6b Remote factors that can contribute to patellofemoral pain syndrome and their possible mechanisms—increased hip adduction**

Increased hip adduction	Possible contributing factors	Confirmatory assessments
	Inadequate strength/control: • hip external rotators • hip abductors • hip extensors • lumbopelvic muscles • trunk muscles	Clinical assessment: • manual muscle test • hand-held dynamometer • side-bridge tests • biofeedback
	Altered movement patterns	Biomechanical/gait assessment (Chapter 8): • can the patient correct the movement pattern when asked to focus on it?

may be exaggerated during gait, possibly associated with a midstance valgus thrust. Additionally, increased hip adduction/internal rotation or a lateral pelvic drop during the step-down and single-leg squats (potentially owing to weakness of the gluteus medius) may be observed as an increase in apparent knee valgus posture. Knee abduction is associated with PFP.<sup>63,65, 67, 69, 70</sup> Increased structural or functional tibial rotations can

affect PFJ loads directly and also through transferred rotations to the femur. Importantly, tibial rotations are strongly coupled with the motion of the subtalar joint. Although there is little data on the assessment or treatment of structural tibial rotation in isolation, experienced clinicians often address functional rotation in association with femoral or subtalar rotations (see treatment outline later).

**Table 36.6c Remote factors that can contribute to patellofemoral pain syndrome and their possible mechanisms—increased knee valgus/tibial external rotation**

### Trunk and pelvic motions

The trunk represents the largest proportion of body mass and hence any alterations to trunk and pelvic motions can influence lower limb loads, including those of the PFJ. Although not studied as frequently as other segments, recent studies have focused on trunk and pelvic motions and their influence on PFJ loads.<sup>71</sup> Increased trunk

flexion is associated with lower PFJ stress.<sup>71</sup> Furthermore, people with PFP exhibited greater anterior (forward) and ipsilateral trunk lean and contralateral trunk drop, compared to controls.<sup>63, 65, 72, 73</sup> Clinical observation of the patient in standing may not reveal any abnormality. During functional activities such as a single leg squat, ipsilateral trunk lean may be observed, often in association

with contralateral pelvic drop. Observing the patient from the side may reveal inadequacies in sagittal plane motion (i.e. too much or too little forward trunk lean or anterior pelvic tilt).

### Dynamic foot function

Dynamic foot function (e.g. plantar loading) and static foot posture (e.g. increased pronation, navicular drop, arch height mobility) are associated with PFP and may contribute to its development.<sup>63, 65, 66, 74-78</sup> Static foot posture can be observed clinically in standing and during gait (Chapter 8).

### Sagittal plane

Recently, studies have focused on frontal plane and transverse plane motions when evaluating people with PFP. Sagittal plane impairments should also be considered. In particular, loss of knee flexion<sup>79-81</sup> and greater trunk flexion<sup>72, 73, 82</sup> are

features of people with PFP. While some of these adaptations may serve to reduce PFJ reaction force and hence joint stress, over time they may be associated with atrophy of key muscle groups (especially quadriceps) or increased frontal plane knee loads<sup>83</sup> with potential for further damage to the PFJ.<sup>84</sup> Hence, all patients should be observed from the side, to check for loss of sagittal plane motions.

### Local contributing factors

Local factors that can contribute to the development of PFP are in three main categories (Table 36.7):

- patella position
- soft tissue contributions
- quadriceps (vasti) dysfunction.

#### Patella position

Clinical examination provides valuable information on the structural and functional relationships of the PFJ

**Table 36.7 Local factors that can contribute to patellofemoral pain**

Factor	Structural observations	Functional observations (with quadriceps contraction)
<b>Patella position</b>		
Lateral displacement	<ul style="list-style-type: none"> <li>• Patella displaced laterally, closer to the lateral than medial femoral condyle</li> <li>• Restricted medial glide (Fig. 36.2f)</li> </ul>	<ul style="list-style-type: none"> <li>• Patella moves laterally</li> </ul>
Lateral tilt	<ul style="list-style-type: none"> <li>• Difficult to palpate lateral border, high medial border</li> <li>• Lateral tilt increases with passive medial glide</li> </ul>	<ul style="list-style-type: none"> <li>• Patella tilts laterally</li> </ul>
Posterior tilt	<ul style="list-style-type: none"> <li>• Inferior patella pole displaced posteriorly, often difficult to palpate due to infrapatellar fat pad</li> </ul>	<ul style="list-style-type: none"> <li>• Inferior pole moves further posteriorly. A 'dimple' may appear in the infrapatellar fat pad</li> </ul>
Patella alta	<ul style="list-style-type: none"> <li>• High-riding patella</li> </ul>	<ul style="list-style-type: none"> <li>• NA</li> </ul>
<b>Soft tissue contributions</b>		
Tight lateral structures	<ul style="list-style-type: none"> <li>• Lateral patella displacement or tilt</li> <li>• Palpation of lateral structures (Fig. 36.3)</li> </ul>	<ul style="list-style-type: none"> <li>• Lateral patella displacement or tilt</li> </ul>
Compliant medial structures	<ul style="list-style-type: none"> <li>• Lateral patella displacement or tilt</li> </ul>	<ul style="list-style-type: none"> <li>• Lateral patella displacement or tilt</li> </ul>
General hypermobility	<ul style="list-style-type: none"> <li>• NA</li> </ul>	<ul style="list-style-type: none"> <li>• Increased patellar mobility in all directions</li> </ul>
<b>Quadriceps (vasti) dysfunction</b>		
Reduced activity of quadriceps (general)	<ul style="list-style-type: none"> <li>• Reduced muscle bulk of quadriceps</li> </ul>	<ul style="list-style-type: none"> <li>• Reduced muscle strength</li> </ul>
Delayed onset or reduced magnitude of VMO relative to VL	<ul style="list-style-type: none"> <li>• Reduced muscle bulk of VMO</li> </ul>	<ul style="list-style-type: none"> <li>• Poor quantity/quality of VMO</li> <li>• Assess in functional positions</li> <li>• Biofeedback can assist (Fig. 36.4)</li> </ul>

(Table 36.7). The clinician should carefully assess passive and active movement of the patella in all directions: medial (Fig. 36.2f), lateral, superior, and inferior glides, as well as rotations. Although the tests for patella position are not functional and may not be repeatable,<sup>85, 86</sup> clinical examination of the patella position remains a useful tool for clinical decision making.

### Soft tissue contributions

The contribution of the superficial and deep soft tissues to the PFJ mechanics can, in part, be obtained from the structural and functional assessments of patella position. Palpation around the thigh, knee and lower leg allows the clinician to ascertain the compliance of soft tissues which may be contributing to PFP (Fig. 36.3).

### Quadriceps (vasti) dysfunction

Individuals with PFP produce less quadriceps torque<sup>87-89</sup> and have smaller quadriceps size<sup>90</sup> than those without pain, and quadriceps weakness increases the risk of PFP development.<sup>91</sup>

There is controversy in the literature regarding an imbalance in vasti activation in PFP.<sup>92-101</sup> Inadequate vasti motor control could increase lateral patellar shift<sup>102</sup> or patellofemoral pressure.<sup>103</sup> Balanced activation of VMO and VL has long been believed to be disrupted in people with PFP, but the literature is inconsistent regarding imbalances in vasti activation or size and PFP pain.<sup>99-101, 104-107</sup> These inconsistencies may in part be accounted for by a wide variation in methodology and also by inherent heterogeneity in the PFP population, meaning that some, but not all, may have delayed VMO onset. Furthermore, the role of delayed EMG onset on medial vasti force production remains unknown.

Clinical examination of the vasti (medial and lateral components) provides some insight into their role in a patient's presentation (Table 36.7, Fig. 36.4). Frank muscle wasting and weakness may be obvious, but seemingly normal muscle bulk does not ensure normal function. If VMO dysfunction is suspected, then its ability to contract synchronously with the rest of the quadriceps should be evaluated. The vasti function should be assessed in a number of positions or activities, including those that are functionally relevant to the patient.

### Treatment of PFP

Effective treatments usually integrate several different treatment techniques that target the local PFJ factors, in addition to the more remote (distal and proximal) factors. Different techniques, including exercise, manual therapy, taping, bracing and foot orthoses can be used in isolation or in combination, depending on the patient's presentation, the clinician's expertise and the preferences

**Figure 36.3** Clinical assessment of lateral soft tissue contribution. The iliotibial band and lateral retinacular structures are palpated for any reduced compliance

of both patient and clinician.<sup>108</sup> An integrated approach to management of a patient with PFP generally includes the following components:

- exercise
- taping
- manual therapy
- foot orthoses
- bracing.

#### PRACTICE PEARL

The first priority of treatment is to reduce pain. Rest from aggravating activity usually suffices but it may require ice, a short course of oral analgesics (rarely) or techniques such as mobilisation (Fig. 36.7). Taping should have an immediate pain-relieving effect; when it does, this strongly suggests that the diagnosis is PFP (Fig. 36.6).

**Figure 36.4** Clinical examination of neuromotor control of the vasti. The quality (amount and timing) of the vastus medialis obliquus and vastus lateralis component of the quadriceps can be assessed in a number of positions, including supine, sitting and standing. In these positions the patient is asked to contract the quadriceps. The clinician can either observe or palpate the quality of the contraction in these positions. A surface EMG biofeedback (illustrated) may be used to provide useful information to the clinician on the relative contribution of the vasti during quadriceps contractions across the various positions

### Exercise

Exercise is a cornerstone of PFP management. Usual components include:

- quadriceps retraining
- hip muscle retraining
- strengthening/endurance building for lower limb and trunk muscles
- coordination and balance training
- retraining of functional activities (including sports- or work-related).

Not all patients will require all components. Using a pain monitoring system<sup>109</sup> (where pain levels scoring 0-3

on a 10 cm numerical pain scale are considered acceptable during exercise) may avoid pain-induced muscle inhibition and enhance adherence to an exercise program. Pain levels up to 5 (out of 10), momentarily during exercise or immediate following exercise are acceptable, but not extending to the following morning. Patellar taping may be required to ensure pain-free exercise.

### Quadriceps retraining programs

Retraining the quadriceps can reduce PFP and symptoms,<sup>108, 110-113</sup> as well as enhance VMO activation relative to VL.<sup>114</sup> Patients cannot activate the VMO in isolation and no exercise appears to be preferential for activation of the VMO. Most people will not require a specific focus or emphasis on their VMO. However, for those who appear to have difficulty with VMO activation, it may be necessary to find and use training positions where the patient can attain a consistent VMO activation.

It may be necessary for the patient to learn to contract the VMO. By palpating the VMO while contracting their quadriceps in various degrees of knee flexion, hip abduction or knee rotation and/or in different activities the patient can receive feedback on the contraction. A dual-channel biofeedback machine may also be used (Fig. 36.4). The patient should attempt to recruit the VMO during all quadriceps contractions. Other strategies may assist VMO activation, including imagery or visual cues, facilitation techniques (e.g. palpation, dry needles/acupuncture), other forms of feedback (e.g. real-time ultrasound, tactile or visual) or inhibitory techniques to reduce over-activity in the VL or lateral hamstrings (e.g. inhibitory taping, feedback).

Initially, quadriceps exercises may commence in sitting with the knee at 90°, the foot on the floor and in this position, the patient may palpate the VMO to facilitate muscle activation (Fig. 36.5a). To ensure the quadriceps are trained in positions where they are required to function, the patient should begin training in a weight-bearing position and perform functional exercises with steadily increasing load and difficulty as soon as possible.

Progression is based on their ability to maintain control and the absence of significant pain (2-3 out of 10). Lower load exercises may include lunges, squats and step-ups. Further progressions can be made from minimal weight-bearing (using hand rails or other supports) to full weight-bearing (eventually including added loading) and through various knee flexion ranges.

The final aim of quadriceps training is to achieve a carry-over from functional exercises to functional activities. The patient should perform small numbers of exercises frequently throughout the day. A series of graded quadriceps exercises is demonstrated in Figure 36.5.

### Hip retraining programs

Retraining the hip abductors, external rotators and extensors is thought to stabilise the lateral pelvis and to control internal hip rotation and adduction. Such strengthening programs have been associated with pain reduction in patients with PFP.<sup>115</sup> Indeed, evidence suggests that hip retraining is an essential component to any PFP rehabilitation. The principles for retraining hip muscle function are the same as above, with exercises performed initially in non weight-bearing positions and then progressed to weight-bearing positions (Fig. 36.5). It is critical to ensure that the targeted muscles are being activated during the retraining program. For example, if your assessment reveals that hip external rotator retraining is required then the retraining programs must be activating the hip external rotators. More detail on hip retraining exercises is available in Chapter 31. The focus of all retraining exercises is on quality, then quantity.

As soon as it is possible and practical, the patient must be taught to activate the hip abductors, extensors and

external rotators, in combination with other lower limb muscles during functional exercises. The emphasis of all retraining exercises will be on maintaining the activation of these muscles and correct alignment of the hip (i.e. neutral rotation) during weight-bearing flexion tasks (e.g. lunge, step up and step down). Some patients may require retraining of their movement patterns during functional or potentially aggravating activities.<sup>116</sup>

#### Lower limb strengthening/endurance-building exercises

Adequate strength and endurance, especially in the quadriceps, hip, trunk and calf muscles, is likely to be important for all patients. Strengthening programs can be commenced early (see above for maintaining control and monitoring pain) in the patient's treatment, and progressed according to patient response and American College of Sports Medicine guidelines.<sup>117</sup> A generalised quadriceps strengthening program can effectively relieve patellofemoral pain and improve function.<sup>112</sup> However,

patients with poor vasti or hip coordination may first need to address their motor control deficits. The available evidence does not support the effectiveness of one exercise regimen over another.

#### Movement retraining

This is required in the final stage of the exercise-based interventions in order to return to high loaded activities involving knee flexion during full weight-bearing (e.g. stair descent, deep squats), or higher intensity activities such as running. Patients need additional training to facilitate progression to these high PFJ loading activities. Motor control, strength and endurance in the quadriceps and global muscles (e.g. calf, hip and trunk muscles), balance and coordination should be trained in these higher loading tasks. Exercise choice and progression decisions are based on the patient's needs, their ability to maintain control and the absence of significant pain. More detail on movement (and running) retraining is available in Chapter 8.

### Patellar taping

The aim of taping is to correct the abnormal position of the patella in relation to the femur. Although patellar taping reduces PFP substantially and immediately,<sup>118</sup> the precise mechanism of the effect is still being investigated. It is possible that pain relief following patella taping could be due to subtle changes in patella position and PFJ contact area<sup>119</sup> and/or changes in motor control or proprioceptive input.<sup>120</sup> Regardless of the mechanism, patella taping is an effective interim measure to relieve PFP and can increase adherence to an exercise program and/or enable pain-free activities of daily living.

A commonly used technique involves taping the patella with a medial glide (Fig. 36.6a). It may also require correction of abnormal lateral tilt (Fig. 36.6b), rotation (Fig. 36.6c) or inferior tilt (Fig. 36.6d). The taping is performed with rigid strapping tape. It is important that the clinician recognises a posteriorly displaced inferior pole of the patella, as taping the patella too low will increase the patient's symptoms. Taping to 'unload' the fat pad (effectively to 'lift' the patella away from

(a)

**Figure 36.6** Patellar taping techniques (a) Patellar taping (medial glide). Tape is applied to the lateral aspect of the patella. The patella is glided medially and the tape is anchored to the skin over the medial aspect of the knee. When taping is completed, skin creases should be evident on the inside of the knee, indicating adequate tension on the patella

(b)

(c)

(d)

**Figure 36.6 (cont.)** (b) Patellar taping (correction of lateral tilt). Tape is applied to the medial aspect of the patella and secured to the soft tissue on the inner aspect of the knee (c) Patellar taping (correction of rotation). Tape is applied to the inferior pole of the patella and taken medially and superiorly to rotate the patella (d) Patellar taping (correction of inferior tilt). Tape is applied across the superior pole of the patella with sufficient firmness to elevate the inferior pole

the fat pad) can also be used, either alone or in conjunction with the above techniques (see below, 'Fat pad irritation/impingement' for more details; Fig. 36.15).

Patella taping effects should be assessed immediately using a pain-provoking activity such as a single- or double-leg squat. If the tape has been applied correctly and is going to be a useful treatment option, the post-taping squat will be less painful. If all or some pain persists, the tape should be altered, possibly including a component for tilt or rotation or both. Note that if patella tape does not make a substantial (at least 50%) reduction in the patient's pain, the initial diagnosis should be revisited.

If patients are able to perform strengthening exercises pain-free without tape, then exercises should be performed

*continued*

tape free. Some people, however, require tape to perform the exercises and, initially, to continue their sporting activities. Acute cases of PFP may initially need tape applied 24 hours a day until the condition settles. The tape time is then gradually reduced.

Adverse skin reactions can occur beneath the rigid tape. Therefore, the area to be taped should be shaved and a protective barrier applied beneath the rigid strapping tape to reduce both the reaction to the zinc oxide in the tape

adhesive and the reaction to shearing stresses on the skin. This can be achieved with adhesive gauze tape (Hypafix® or Fixomull®) applied to the area to be taped. A protective barrier or plastic skin can also be used in patients with extremely sensitive skin. If skin irritation still occurs, the patient must be advised to remove the tape. Treatment with a hydrocortisone cream may be necessary. Patients with fair skin seem to have particularly sensitive skin and need to be monitored closely.

## Manual therapies

Manual therapies, such as joint and soft tissue mobilisation, manipulation and massage may relieve symptoms associated with PFP. Joint mobilisations can include patellofemoral or tibiofemoral joint glides, whereas soft tissue therapies might involve massage of tight lateral retinacular structures or the fascia/muscles of the thigh (predominantly anterolateral). Applied passively by either the patient or clinician, these techniques are designed to optimise movement and facilitate the exercise program. When applied by the clinician, the patient may be in a side-lying position with the knee flexed. The therapist glides the patella medially using the heel of the hand for a sustained stretch (Fig. 36.7). Other simple stretching techniques can be performed by the patient, usually in sitting, with the knee flexed approximately 30–90°. Studies evaluating efficacy of such techniques applied in isolation do not show benefit,<sup>121</sup> supporting the clinical practice to include manual therapy as part of a combined approach to management and not performed in isolation.

Attention must also be paid to improving the compliance of the hip flexors, quadriceps, hamstring and calf muscles as well as the iliotibial band if required, through stretches, soft tissue techniques (Fig. 36.8) or dry needling. Restoration of optimal muscle and fascial length is the goal. Further detail on soft tissue techniques including dry needling are available in Chapter 17.

## In-shoe foot orthoses

Prefabricated in-shoe foot orthoses, combined with active retraining of the extrinsic muscles of the foot, improve pain and physical function in people with PFP.<sup>111</sup> Although the mechanisms underpinning the clinical effects are unclear, it appears both neuromuscular and mechanical factors need to be considered when prescribing in-shoe foot orthoses.<sup>122</sup> A clinical decision-making paradigm has been proposed to assist with orthosis prescription for people with PFP<sup>123</sup> (see also Chapter 8).

Pain reduction during aggravating activities with either anti-pronation taping or an orthosis, may indicate

**Figure 36.7** Mobilisation of the patella (supine or side-lying)

**Figure 36.8** Soft tissue therapy—myofascial tension of the iliotibial band

which patients are more likely to have a favourable response to orthoses.<sup>124, 125</sup> Older people with less severe pain and a more mobile midfoot are more likely to experience success with orthosis intervention.<sup>123</sup> Additionally, the clinician might consider customised foot orthoses or changing footwear, although the efficacy of these interventions is unknown. These interventions are discussed in Chapter 8.

### Braces

Some braces (Fig. 36.9) are commercially available to maintain medial glide. Patella braces reduce patella displacement, increase patella contact area<sup>126</sup> and reduce PFJ stress<sup>127</sup> in individuals with PFP. However, an RCT of such a brace did not find any benefit of the brace over a 'sham' knee sleeve or a general quadriceps strengthening program.<sup>128</sup> Braces are less specific than taping and do not specifically address tilt or rotation; but they may have a role in those patients who are unable to wear tape or who suffer recurrent patella subluxation or dislocation.

### Evidence base for physical and exercise interventions

A number of systematic reviews and meta-analyses of randomised clinical trials have assessed the efficacy of physical interventions for PFP (Table 36.8). Level I evidence supports the use of multimodal interventions (combination of retraining, strengthening, balance/coordination, functional retraining, taping and manual therapy)<sup>112</sup> and also for individual treatments in isolation.<sup>112, 129, 130</sup> Proximal (mostly hip) rehabilitation programs, when combined with a quadriceps program, decreases pain in the short and medium term, and emerging evidence suggests that proximal retraining, either combined with quadriceps retraining or in isolation, may be superior to quadriceps retraining alone.<sup>115</sup> While tailored patellar taping produces immediate pain reduction, other techniques result in only small (untailored medial patellar taping) or negligible (kinesiotape) pain reductions in the immediate term.

Limited evidence supports better short-term outcomes with foot orthoses versus flat inserts,<sup>112, 129</sup> versus 'wait and see',<sup>131</sup> and beneficial effects for exercise (versus

**Figure 36.9** Patella stabilising brace

control), closed chain exercises (versus open chain exercises) and acupuncture (versus control).<sup>112</sup> However, there is moderate evidence for no additive effectiveness of knee braces to exercise therapy on pain and conflicting evidence on function.<sup>132</sup>

Blue = supported by meta-analyses (systematic reviews)

Black = expert opinion, clinical guidelines

Orange = insufficient evidence

Red = no evidence supporting its use

**Bold text** = reviews considered to be moderate or high quality

Although the interventions tested in clinical trials reflect some aspects of clinical practice, in many studies the interventions are not individualised to the patient's needs. Furthermore, some studies have evaluated one aspect of intervention in isolation. These studies have enabled the assessment of a single treatment strategy, but the study results may not be generalised to clinical scenarios. Therefore, while the evidence base for different combinations of physical or exercise therapies for PFP is increasing in quality and quantity, clinicians need to individualise their treatment approaches, thus targeting the treatment to their patient's presentations and requirements and clinician preferences and expertise.<sup>108</sup>

### Addressing extrinsic contributing factors

Although the patient should reduce the load on the PFJ initially, it is essential that as rehabilitation progresses, any extrinsic factors that may have been placing excessive load on the PFJ (e.g. training, shoes, surfaces) be addressed.

### Surgery: to be avoided

Experienced clinicians will have observed that surgery is now much less common for PFP than it was 30 years ago. This is likely to be due to the availability of evidence-based, exercise-based, physical interventions. To date, no surgical RCT has demonstrated the effectiveness of treatments such as chondroplasty or lateral release for PFP. Surgery should only be an option for athletes/patients whom have failed a number of attempts of conservative interventions. Poor surgical outcomes have been reported in the literature.<sup>142</sup>

#### PRACTICE PEARL

Patient education is an important element of effective treatment. A number of resources exist, including Barton and Rathleff [www.patelofemoral.com/completeportscare.com.au/wp-content/uploads/2014/11/Managing-my-patelofemoral-pain\\_education\\_single-sheets.pdf](http://www.patelofemoral.com/completeportscare.com.au/wp-content/uploads/2014/11/Managing-my-patelofemoral-pain_education_single-sheets.pdf).

## Patellofemoral osteoarthritis can be managed using an approach similar to patellofemoral pain

### Can we prevent patellofemoral OA in people with patellofemoral pain or ACL injury?

Strategies targeting prevention of PFP and traumatic knee injuries are vital to prevent patellofemoral OA in active adults. Following knee injury or PFP, treatments to optimise patellofemoral biomechanics may reduce the risk of patellofemoral OA.

Until more research can determine which features of an individual makes them more likely to develop OA after PFP or knee injuries such as ACL or meniscal, interventions with potential to reduce PFJ stress (e.g. patellofemoral malalignment, low quadriceps strength, higher body mass, valgus knee malalignment) should be included as part of a treatment package. Furthermore, it is probably never too early to discuss the possibility of chronic knee pain, and the need for ongoing management of the knee.

### How do we treat people with established radiographic patellofemoral OA?

Once patellofemoral OA has developed, non-surgical management is the preferred primary treatment. Although few clinical trials exist to inform best-practice management, multimodal physiotherapy treatment (i.e. exercise, education, manual therapy and taping)<sup>143</sup> and knee braces<sup>144</sup> may be efficacious. Patellar bracing may improve PFJ kinematics and knee pain, and shrink BMLs in those with patellofemoral OA.<sup>145, 146</sup> Although tibiofemoral and patellofemoral OA frequently coexist, it is inappropriate to assume that treatments designed for tibiofemoral OA are optimal for patellofemoral OA.

### Can we optimise treatments for patellofemoral OA?

To improve treatments for those with patellofemoral OA, we need to recognise the clinical findings that identify and discriminate them from tibiofemoral OA.<sup>24</sup>

A number of factors associated with patellofemoral OA may alter the mechanics of the patellofemoral joint and increase joint stress, leading to OA. Identification of these impairments in patients with patellofemoral OA may lead to targeted and personalised interventions, with capacity to not only reduce the symptoms but have potential to slow disease progression. Such factors include:

- **Abnormal patellofemoral joint alignment and trochlear morphology** These are associated with patellofemoral OA (both radiographic and MRI features).
- **Muscle weakness** Quadriceps function, such as muscle size,<sup>147</sup> strength<sup>148, 149</sup> and muscle force,<sup>150</sup> is impaired in people with patellofemoral OA, and quadriceps weakness is a risk factor for patellofemoral OA.<sup>151, 152</sup> Impairment in proximal muscle function is also evident on patellofemoral OA.
- **Abnormal biomechanics** Abnormal movement patterns during functional activities may affect PFJ loading and stress,<sup>153–155</sup> which can lead to OA and pain<sup>156–158</sup> and are, therefore, potential targets for rehabilitation interventions. There is recent evidence that individuals with patellofemoral OA also demonstrate abnormal biomechanics during gait.<sup>150, 152, 159–161</sup> In the only longitudinal study to date, Teng et al. found that peak knee flexion moment and flexion moment impulse at baseline lead to progression of PFJ cartilage damage over 2 years.<sup>162</sup>

*Note:* Patellofemoral pain may predispose to the development of patellofemoral osteoarthritis and hence treatments should aim to not only reduce pain and symptoms but to address potential contributing factors.

## How does our treatment need to change for adolescents with patellofemoral pain?

### Patellofemoral pain is common in adolescents

Chances are that if you work in clinical setting you will see a lot of young patients with knee complaints. Up to 7% of the adolescent population may be affected (in varying severities) by PFP, making it one of the most common knee conditions among adolescents. Fifty percent of the adolescents with

knee pain will, at some point, seek medical treatment, often through their general practitioner (in a Danish context).<sup>163</sup> This means that at some point, we are likely to meet them (and their parents) in the clinic. So how should we treat adolescents with PFP? Do they need to be treated differently to adults with PFP?

*continued*

### Education and exercises

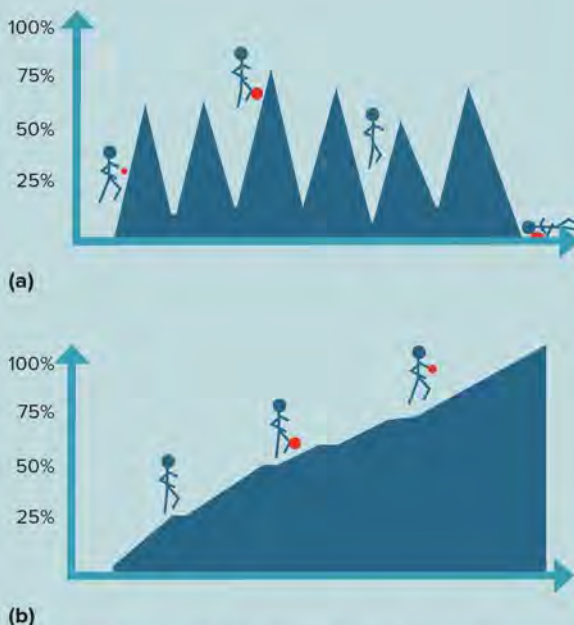

Combining exercise therapy and patient education is more effective than patient education alone in adolescents aged 15–19 with PFP.<sup>164</sup> Adding exercise therapy to patient education improves recovery rates in both the short term (3 months) and long term (24 months). However, not all adolescents respond favourably to the exercise therapy, and the overall recovery rate is lower than for adults. This suggests that exercise therapy is effective for some adolescents but not all. How can we improve the effect of exercise therapy among adolescents to ensure good outcomes?

### Adherence and modifying the activity level are crucial

Two issues seem to be particularly important when treating adolescents with PFP. One is adherence to exercise therapy, and the second is sports participation.<sup>165</sup> For highly active young adolescents, frequent sports participation is a risk factor for persistent knee pain and failure to modify sports participation may hinder recovery.<sup>166, 167</sup> This suggests that, in the group of highly active adolescents, PFP may result from excessive loading of the PFJ during sport and physical activity.<sup>165</sup> The clinical implication is that we need to educate both the adolescents and their parents to modify the adolescents' activity levels and make a gradual return to sport that is guided by symptoms.

The second important issue is adherence to exercise therapy. Adolescents with poor adherence (less than 1 exercise session per week) were 4 times less likely to be recovered after 12 months compared to those with good adherence (at least 3 exercise sessions per week).<sup>164</sup>

To improve adherence, it is essential that the adolescent and the parent are educated about the importance of adherence and understand why the exercises are important. If you suspect that the adolescent may not perform the prescribed home exercises, it might be relevant to focus on supervised exercises to improve outcomes.

**Figure 36.10 a and b** Modifying the physical activity level may be key to successful treatment and to avoid recurrence of knee pain.

## PATELLOFEMORAL INSTABILITY

Before discussing the causes of and treatments for, patellofemoral instability we need to clearly define the term. As is also the case at shoulder, 'instability', is not a synonym for 'dislocation'. Instability refers to excessive joint range of motion (and is often referred to as 'subluxation'). Patellofemoral instability may be primary (referred to as patellar subluxation) or secondary (meaning that the instability is due to previous acute patella dislocation) (see Chapter 35).

### Primary patellofemoral instability

Factors that predispose to this condition include patella alta (a patella that is located more superiorly than normal), trochlear dysplasia and generalised ligamentous laxity. Patients usually describe sensations of instability (patella moving or slipping) and the pattern of tenderness around the patella may be similar to PFP or more generally

distributed. Examination reveals patella hypermobility with apprehension and pain when the patella is pushed laterally by the clinician.

### Treatment

Treatment of patellofemoral instability parallels that of PFP. The aim of acute management is to reduce pain and swelling. Patellar taping in combination with a knee extension brace may provide temporary immobilisation after an initial episode. The patient may use crutches for either partial or

#### PRACTICE PEARL

Rehabilitation to improve active support for the PFJ is paramount as dominant predisposing factors cannot be addressed easily (bony morphology and ligamentous laxity).

non weight-bearing in that instance. Rehabilitation requires a comprehensive multimodal approach, as outlined earlier for PFP to be commenced as soon as possible.

In acute situations, biofeedback and/or electrical stimulation may be required as an adjunct to vasti retraining. Taping (and/or bracing) may be part of long-term management. It is also vital to address any proximal and distal contributing factors (see above), maximise trunk and lower limb muscle strength and/or endurance and provide advice regarding avoiding aggravating activities.

Surgery is rarely indicated. Surgical approaches aim to correct the structural/anatomical predisposing factors, and techniques used include arthroscopic medial plication. Bony realignment procedures including 'trochleaplasties' have largely lost popularity in Scandinavia and Australia, but are performed in a limited number of countries including the United States. These interventions often do not have favourable outcomes, thus they should only be considered if a properly managed non-surgical program fails. An intensive rehabilitation program should be trialled prior to the athlete considering surgical options.

### Secondary patellofemoral instability

Secondary instability results from a primary dislocation episode (see Chapter 35 for acute management) that is likely to have arisen because of rupture of the medial patellofemoral ligament. This ligament is the main static restraint to lateral patella translation (Fig. 35.17). It acts like a guy rope on a tent. Individuals with persistent patellofemoral instability after an acute dislocation may require additional investigations. Imaging (Fig. 35.18) may reveal evidence of osteochondral damage to the articular surface of the patella and femur as well as predisposing anatomical abnormalities.

Arthroscopy may be required to remove a loose osteochondral fragment, and, if appropriate, the medial patellofemoral ligament may need reconstruction.<sup>168</sup> As with surgery for primary instability, surgery for secondary instability also requires aggressive rehabilitation. Rehabilitation for secondary patellofemoral instability follows the same guidelines as primary patellofemoral instability. At the current time, there is limited evidence to suggest that surgical management of primary patella dislocation decreases the risk of recurrent dislocation.<sup>169</sup>

### PATELLAR TENDINOPATHY

There have been substantial advances in understanding the management of this condition in the past decade. Successful management of the athlete with patellar tendinopathy requires thorough clinical and functional assessment and then appropriate load management.

### Nomenclature

Patellar tendinopathy is otherwise known as 'jumper's knee' due to its frequency in jumping sports (e.g. basketball, volleyball and high, long and triple jumps).<sup>170</sup> However, the condition also occurs in athletes who change direction, as well as those who put large energy storage loads on their tendon, such as running downhill. The term 'patellar tendinitis' is a misnomer as the pathology underlying this condition is degenerative tendinosis rather than a purely inflammatory condition (see Chapter 4).<sup>171</sup> On balance, patellar tendinopathy is probably the most appropriate general label for this condition as it describes the clinical condition of pain and loss of function, independent of the underlying pathology.<sup>172</sup>

### Clinical features

The clinical features of patellar tendinopathy are outlined in Table 36.2. The key to making an accurate clinical diagnosis is that the patient complains of well-localised (focal) pain at the attachment of the patellar tendon to the patella (Fig. 36.11). The tendon is frequently thickened. The pain is aggravated by jumping, changing direction and decelerating. Distal lesions are less common and midsubstance lesions are rarely reported.<sup>173</sup>

Clinicians should assess factors such as weakness of the lower limb musculature, including calf, quadriceps and gluteal muscles. This loss in muscle strength often results in dysfunction of the kinetic chain, especially in its ability to function as a spring. These deficits may predispose or be a consequence of pain, but either way are important to assess so that they may be addressed in rehabilitation.

#### PRACTICE PEARL

**Pain on palpation (i.e. tenderness) is not a useful test to diagnose tendinopathy in general (Chapter 14); it is not a helpful diagnostic test in patellar tendinopathy as pain at this site is common and does not indicate the pain is from the tendon. Most importantly, it is not a reliable outcome measure to assess response to rehabilitation.**

Note that the proximal patellar tendon is often tender in jumping athletes with normal tendons therefore palpation has poor specificity for patellar tendinopathy. Also, some athletes with patellar tendon pathology are not tender at the junction of patellar tendon and the patella—hence the test does not have perfect sensitivity. Note that palpation is also not a useful test of recovery (outcome measure)—this is discussed later.

To make the diagnosis of patellar tendinopathy, the clinician must be able to reproduce the patient's focal

**Figure 36.11** Sites of tendon pathology in the knee extensor mechanism. The most common presentation is patellar tendonopathy. Quadriceps tendonopathy is discussed later. Pain at the distal tendon (tibial tuberosity) can be associated with Osgood–Schlatter disease (Chapter 44)

pain when placing high loads on the tendon. The clinician should progressively increase the tendon load with functional activities, such as a squat, then progressing to a hop, to test the patient's ability to complete the task well and to reproduce the pain. In patellar tendonopathy the pain remains localised. If the pain becomes diffuse with loading, consider other diagnoses.

#### PRACTICE PEARL

Knee pain that is described as being diffuse with loading does not represent a clinical diagnosis of patellar tendonopathy (or tendon pain). Patients can perceive pain from the PFJ in the region of the patellar tendon.

In patellar tendonopathy, a useful outcome measure (Chapter 16) is pain on the decline squat (Fig. 36.2d). Document the amount of pain and the range when it occurs. An additional method to monitor the clinical progress of patellar tendonopathy is the VISA-P questionnaire (Table 36.9).<sup>174, 175</sup> This simple patient-completed questionnaire takes less than 5 minutes to complete.

### Investigations

Ultrasound and MRI can image patellar tendon pathology. These imaging modalities have low sensitivity with better specificity for patellar tendonopathy (Fig. 36.12). Imaging findings need to be placed within the context of the clinical presentation and the loading history of the patient. Up to 50% of asymptomatic players in patellar tendon loading sports (e.g. volleyball, basketball) have imaging abnormalities.<sup>22</sup> These changes are best described as load-appropriate changes and do not contribute to making a clinical diagnosis.

### Management: is the athlete still competing?

After making the diagnosis of patellar tendonopathy, the approach to management will vary if the player can keep competing or if the tendonopathy is at a level where the player needs to withdraw from competition and complete rehabilitation.

Factors that determine whether a player should keep playing or withdraw from competition are: the levels of (i) pain, (ii) function and (iii) effect on performance (Table 36.10). Players always want to keep playing and the clinician will support this where appropriate, but there are also times when the quality shared decision is for the player to withdraw from training and competition and undergo comprehensive rehabilitation.

As the player will want to keep competing in most cases, we address that scenario first. We discuss out-of-competition rehabilitation below.

### The approach to 'in-season' treatment of the player with patellar tendonopathy

When the player presents with pain in-season, the clinician should discuss the key elements of treatment and explain that there is unlikely to be complete relief of pain during the season.

In-season management of patellar tendonopathy requires maintenance (or improvement) of strength in the affected muscle-tendon unit and the rest of the kinetic chain. Load reduction, correcting biomechanical factors and adjunct therapies such as soft tissue therapy to the affected muscle (not the tendon) are also appropriate in this scenario (detailed below).

**Table 36.9 Victorian Institute of Sport Assessment (VISA-P) questionnaire (English version, this is available in numerous languages)<sup>150</sup>**

1. For how many minutes can you sit pain-free? POINTS

0 min												100 min	
	0	1	2	3	4	5	6	7	8	9	10		

2. Do you have pain walking downstairs with a normal gait cycle? POINTS

Strong severe pain												No pain	
	0	1	2	3	4	5	6	7	8	9	10		

3. Do you have pain at the knee with full active non-weight-bearing knee extension? POINTS

Strong severe pain												No pain	
	0	1	2	3	4	5	6	7	8	9	10		

4. Do you have pain when doing a full weight-bearing lunge? POINTS

Strong severe pain												No pain	
	0	1	2	3	4	5	6	7	8	9	10		

5. Do you have problems squatting? POINTS

Unable												No problems	
	0	1	2	3	4	5	6	7	8	9	10		

6. Do you have pain during or immediately after doing 10 single-leg hops? POINTS

Strong severe pain												No pain	
	0	1	2	3	4	5	6	7	8	9	10		

7. Are you currently undertaking sport or other physical activity? POINTS

0 ☐ Not at all

4 ☐ Modified training ± modified competition

7 ☐ Full training ± competition but not at same level as when symptoms began

10 ☐ Competing at the same or higher level as when symptoms began

8. Please complete EITHER A, B, or C in this question.

- If you have no pain while undertaking sport please complete Q8A only.
- If you have pain while undertaking sport but it does not stop you from completing the activity, complete Q8B only.
- If you have pain that stops you from completing sporting activities, please complete Q8C only.

A. If you have no pain while undertaking sport, for how long can you train/practice? POINTS

	Nil		1–5 min		6–10 min		11–15 min		>15 min	
	0		7		14		21		30	

OR

B. If you have some pain while undertaking sport, but it does not stop you from completing your training/practice, for how long can you train/practice? POINTS

	Nil		1–5 min		6–10 min		11–15 min		>15 min	
	0		4		10		14		20	

OR

C. If you have pain that stops you from completing your training/practice, for how long can you train/practice? POINTS

	Nil		1–5 min		6–10 min		11–15 min		>15 min	
	0		2		5		7		10

(c) Sagittal slice MRI appearance of patellar tendinopathy

In-season treatment *does not include* heavy eccentric loading, power, and energy storage and release exercises, as the tendon is subjected to these frequently during training and competition. Injection therapies are contraindicated in-season because they require around 2–3 weeks out of sport after injection.

**Table 36.10** Factors to take into account when making the decision about whether a player should keep competing or stop playing because of patellar tendinopathy. The decision should be shared between player and clinician

	Pain?	How limited is function?	Player's performance level	Likely clinical decision	Management strategy
Scenario 1 (often long-term)	Severe	Severely limited	Poor	Unable to compete—player understands he/she cannot play	Begin comprehensive out-of-competition rehabilitation program
Scenario 2 (often medium-term)	Tolerable	Moderate to severely limited	Adequate	Continue to compete but player is at risk of aggravating the tendon or suffering other injury	Maintain or improve function (see below)
Scenario 3 (more recent onset of symptoms)	Severe	Moderately limited	Adequate	Continue to compete but modify training/games to lower load	Use pain-relieving strategies (isometric exercise, medication)

This section outlines the physiotherapy approach to in-season management.

### Relative load reduction: modified activity and biomechanical correction

There are numerous ways of reducing the load on the patellar tendon. The player must modify his or her training and perhaps game time, with reduction in the amount of jumping or sprinting in a session, the number of high load days each week or the total weekly training hours. Absolute rest is contraindicated and some continued lower limb load that does not include excessive energy storage loads (i.e. jumping, changes of direction, deceleration) on the tendon is critical to maintain tendon integrity, kinetic chain function and cardiovascular fitness.

Optimising biomechanics to improve the energy-absorbing capacity of the limb should be directed at both the affected musculotendinous unit and the hip and ankle. The ankle and calf are critical in absorbing the initial landing load and reduces the load transmitted to the knee.<sup>176</sup> Biomechanical studies reveal that only about 40% of landing energy is transmitted proximally.<sup>177</sup> Thus, the calf complex, and especially the soleus, must function well to prevent more load than necessary being placed on the patellar tendon.

Biomechanical correction should include assessment of both anatomy and function. Better landing techniques can decrease patellar tendon load. Compared with flat-foot landing, forefoot landing generates lower ground reaction forces and, if this technique is combined with a large range of hip or knee flexion, vertical ground reaction forces can be reduced by a further 25%.<sup>177</sup> Landing with weight further forward that uses all available dorsiflexion may also decrease patellar tendon load.<sup>178, 179</sup> Anatomical variants that may contribute to persistent patellar tendinopathy include limited ankle dorsiflexion and hallux rigidus. Tight hamstrings, quadriceps and calf muscles may increase the load on the patellar tendon. However, solely focusing on biomechanical correction without addressing kinetic chain strength and capacity will ultimately deliver an undesired outcome.

### Isometrics for pain relief

Isometric exercises reduce pain and improve motor drive by reducing cortical inhibition.<sup>4</sup> (See also Chapter 4, Fig. 4.14) These exercises are best performed on weighted machines (Fig. 36.13) with single-leg isolated knee joint movement. Isometric exercise also is as effective as isotonic exercise in reducing pain in-season.<sup>180, 181</sup>

The specific parameters for isometric exercise are 45-second holds at 70% maximal voluntary isometric quadriceps contraction (MVC) with 2 minutes between each of the 5 repetitions. Long holds at mid-range with heavy weights are essential to the protocol but individual variations may be required.

**Figure 36.13** Isometric holds on a knee extension machine. Hold the highest weight possible for up to 45 seconds with good control

### Strengthening

Strategies that maintain or improve strength of the entire kinetic chain are critical when managing a player during the season. Slow heavy-resistance training to maximise muscle strength prevents unloading weakness and atrophy, but may not improve performance or pain when competing.<sup>182, 183</sup>

Particular attention can be paid to the calf and gluteal muscles as these attenuate landing forces as well as improving quadriceps strength on the unaffected side. Cross-education means that quadriceps strength on the unaffected side can improve the strength of affected quadriceps by up to 20%.

The effect on cortical inhibition suggests that isometric exercises should also be used prior to quadriceps strength training throughout the four-stage program (Table 36.11) to improve the motor drive to the quadriceps.

Decline squat exercises (Fig. 36.14a) have traditionally been widely used, but are painful and can be detrimental when used during the season.<sup>184, 185</sup>

### Soft tissue therapy

The use of friction to treat patellar tendinopathy remains a popular treatment, but lacks a logical theoretical construct and can further irritate the tendon. Studies that compared soft tissue therapy/transverse friction to other treatments demonstrated little benefit in reducing pain.<sup>186, 187</sup> Digital ischaemic pressure and sustained myofascial tension to tight muscles or trigger points in the quadriceps, hamstrings and calf muscles can be performed.

### Pain reduction

Several strategies exist for reducing pain aside from the isometrics discussed earlier, all have to be considered against their potential to further irritate the tendon.

**Table 36.11** Four-stage strengthening program for treatment of patellar tendinopathy

Stage	Type of overload	Timing	Purpose	Activity	Maintain/kinetic chain exercise
1	Heavy load isometric exercise	0–1 months	Reduce pain	Weight-machine-based isolated quadriceps exercise	Begin isotonic exercise for calf and gluteals as well as quadriceps exercise for the other leg
2	Heavy load isotonic exercise	1–3 months	Improve strength, regain muscle bulk	Weight-machine-based heavy isotonic exercise	Isometrics before strength to reduce cortical inhibition Kinetic chain exercises
3	Energy storage exercises	3–4 months	Progressive high tendon load	Fast, body-weight-only knee flexion exercise to load the patellar tendon spring	Maintain isotonic exercise
4	Energy storage and release exercises	4–6 months	Sport-specific high tendon load	Jumping and change-of-direction exercises	Stop stage 3 exercise, maintain heavy load isotonic exercise
Return to training and competition	Sport-specific training	6+ months	Controlled-load return to sports activity	Sports drills with attention to frequency (2–3 times a week), volume and intensity	Maintain isotonic exercise

**(a)****(b)****Figure 36.14** Patellar tendon eccentric strength training exercises (a) Single-leg squat on decline board (may aggravate pain and thus be detrimental in-season) (b) Lunge

(c)

**Figure 36.14 (cont.)** (c) Lunge with weights**Cryotherapy**

Cryotherapy (e.g. ice) is a popular adjunct to treatment but if the athlete finds no clinical benefit from this modality, there is no rationale for persisting.

**Pharmacotherapy**

Studies of pharmacotherapy in the treatment of patellar tendinopathy are limited to phoresis as few studies have investigated oral medications. The use of aprotinin in tendinopathy has some evidence, but is not recommended due to the risk of anaphylaxis after injection. Iontophoresis with corticosteroid improved outcome compared to phonophoresis, suggesting it may introduce corticosteroid into target tissue more effectively than phonophoresis.<sup>188</sup>

The model for tendinopathy proposed by Cook and Purdam suggests that early stage (reactive) tendinopathy could respond to medications that reduce cell activity and protein production.<sup>189</sup> Ibuprofen, doxycycline and green tea are hypothesised to improve pain and pathology in tendinopathy.<sup>190</sup>

**Taping**

Inferior patellar tendon taping reduced pain minimally and no more than placebo taping.<sup>191</sup>

**Extracorporeal shock wave therapy**

Extracorporeal shock wave therapy has been used to treat tendon pain. A systematic review including two RCTs

showed variable results of randomised controlled studies; one RCT showed no benefit and the other showed better outcomes versus placebo in long-term tendon pain.<sup>192</sup>

Extracorporeal shock wave therapy may cause a neuropraxia to the nociceptive nerves resulting in decreased pain for several weeks. There is some animal evidence that it can have a negative effect on normal tendon structure within hours that remains for several weeks.<sup>193</sup>

**The approach to out-of-competition treatment of the player with patellar tendinopathy**

If the player needs to stop competing (see Table 36.10) an extensive out-of-competition exercise program is required to restore tendon, muscle and kinetic chain function. Resolution of the pathology is not required for recovery and good clinical outcomes can arise with limited changes in tendon structure.<sup>194-196</sup>

Another important concept that supports load-based rehabilitation is that a pathological tendon has adapted and has more aligned tendon structure than a structurally normal tendon.<sup>197</sup> This suggests that directing treatments at the area of pathology may be unnecessary and positive clinical outcomes may be due to improving the capacity of already present normal tendon structure.

The clinician will discuss the key elements of management and time frames for recovery/eventual return to play with the athlete, emphasising that there are no short cuts to recovery of function.

Conservative quadriceps rehabilitation of patellar tendinopathy requires appropriate strengthening, power, energy storage and release exercises, load reduction, and correction of biomechanical errors, along with adjunct therapies such as soft tissue therapy to the affected muscle (not the tendon). More invasive treatments, such as injection with substances that either affect the vessels (sclerotherapy with polidocanol), theoretically promote tendon repair (platelet rich plasma [PRP] injections) or augment matrix structure (prolotherapy), lack evidence.<sup>198-200</sup>

**Relative load reduction**

There are numerous ways of reducing the load on the patellar tendon without resorting to complete rest or immobilisation. Absolute rest is contraindicated; early rehabilitation with isometric and resistance training not only recovers muscle strength but reduces pain, so can be used immediately in the rehabilitation process. Variations on the isometric protocol outlined above may be required for individuals with high levels of pain. Although it is clear that long holds with heavy weights are required, it is unknown what is the most important (i.e. length of hold or external weight).

### When and how should patellar tendon strengthening begin?

Therapists often have concerns as to when and how they should begin a strengthening program. Even athletes with the most severe cases of patellar tendinopathy should be able to begin some weight-based strength and other exercises (such as calf strength and isometric quadriceps work) in standing. However, the athlete who has not lost a lot of knee strength and bulk can progress quickly to the speed part of the program.

Both pain and the ability of the musculotendinous unit to do the work should guide the amount of strengthening to be done. If pain is a limiting factor, then the program must be modified so that the majority of the work occurs without aggravating symptoms within 24 hours of the exercise. A subjective clinical rating system, such as the VISA questionnaire (Table 36.9), administered at about monthly intervals, will help both the therapist and the patient measure progress.

If pain is under control, it is essential to monitor the ability of the limb to complete the exercises with control and quality. Exercises should only be progressed if the previous work load is easily managed, pain is controlled, and function is satisfactory.

Athletes with patellar tendinopathy tend to 'unload' the affected limb to avoid pain, so they commonly have not only weakness but also abnormal motor patterns that must be reversed. Strength training must graduate quickly to incorporate single-leg exercises (Fig. 36.14) as the athlete

can continue to unload the affected tendon when exercising using both legs. Thus, exercises that target the quadriceps specifically (such as single-leg extensions) may have a place in the rehabilitation of patellar tendinopathy. Similarly, when the athlete is ready, increase the load on the quadriceps by having the patient stand on a 25° decline board to do squats. Compared with squatting on a flat surface, this reduces the calf contribution during the squat.

The therapist should progress the regimen by adding load and speed and then endurance to each of those levels of exercise. Combinations such as load and speed, or height and load, then follow. These end-stage exercises can provoke tendon pain, and are only recommended after a prolonged rehabilitation period, and when the sport demands intense loading. In several sports, it may not be necessary to add potentially aggravating activities such as jump training to the rehabilitation program, whereas in volleyball, for example, it is vital.

Finally, the overall exercise program must correct aberrant motor patterns such as stiff landing mechanics (discussed above) and pelvic instability. For example, weight-bearing exercises must be in a functionally required range, and the pelvis position must be monitored and controlled at all times. The common errors in rehabilitation strength programs are listed in Table 36.12.

**Table 36.12** Why rehabilitation programs fail at various stages

Early failure	Late failure
Insufficient strength training	Failure to monitor the patient's symptoms
Progression of rehabilitation program too rapid	Rehabilitation and strength training end on return to training, instead of continuing throughout the return to sport
Inappropriate loads during rehabilitation (too little, too much)	No speed rehabilitation
	Plyometrics training performed inappropriately, not tolerated, or unnecessary

### Restoring function

Strength, power and energy storage and release capacity are required for all the muscles, especially the anti-gravity muscles—the calf, quadriceps and gluteal muscles. An effective rehabilitation program embraces the principles outlined in Table 36.11. Commonly prescribed exercises are illustrated in Figure 36.14. When and how a strengthening program should begin is outlined in the box.

Several papers have documented the effectiveness of quadriceps strengthening exercises on patellar tendinopathy.<sup>8, 201–205</sup> These can be divided into two groups: those studies that investigated eccentric exercises on a decline board and those using other exercises.

The studies that have investigated the effectiveness of exercise on a 25° decline board—a method specifically loading the extensor mechanism of the knee by increasing the moment arm of the knee<sup>203</sup>—include two randomised trials which reported improvements in pain, function and return to sport with exercise, although time frames for improvement varied.<sup>8, 204</sup> In another study, compared to surgery, eccentric exercise on a decline board provided similar outcomes at 12 months.<sup>205</sup> Care with these exercises is required in the early painful stages as they can be provocative.

Other studies have investigated heavy load strengthening and report equally good results.<sup>206</sup> Three papers

have suggested that exercise-based interventions such as squatting, isokinetics and weights reduced the pain of patellar tendinopathy.<sup>186, 201, 202</sup>

#### Soft tissue therapy, cryotherapy, pharmacotherapy, taping

Massage can be used for muscle soreness resulting from resistance training. Ice is of little benefit during rehabilitation, and medications and taping also have no place in this phase.

#### Biomechanical correction

Ongoing management of any range of movement deficits in the ankle and foot can be continued early in the rehabilitation program. Formal correction of running and jumping techniques, if required, are commenced once kinetic chain function has been mostly restored. However, solely focusing on biomechanical correction without addressing kinetic chain strength and capacity will ultimately deliver an undesired outcome.

#### Injection therapy

Neovascularisation is a cornerstone of degenerative tendon pathology and is the target of treatment by Alfredson and Ohberg's sclerosing injection.<sup>207</sup> In a high-quality RCT of elite athletes with patellar tendinopathy, investigators found that sclerosing injections with polidocanol resulted in a significant improvement in knee function and reduced pain in patients with patellar tendinopathy.<sup>208</sup> However, polidocanol has a neurotoxic effect that may underpin its effectiveness, rather than altering the vascularity.<sup>209</sup> This is supported by research that shows tendons that have substantial vascularity can remain pain-free.

Corticosteroid injections (CSI) have been compared to placebo and CSI improved symptoms so much so that all 12 athletes who had placebo injection subsequently had CSI. It is worthwhile noting that after initial improvement, 50% of athletes in the CSI group failed to return to sport and were referred to surgery.<sup>210</sup> Blood injection therapy (autologous blood, platelet rich plasma [PRP]) is being used clinically, but controlled trials show no additional benefit over placebo injection.<sup>211</sup> High volume injections and the addition of tendon cells are being used clinically with little or no quality research to show their efficacy.

#### Surgery

The only randomised trial to date that compared surgical treatment and conservative management of patellar tendinopathy was published in 2006.<sup>212</sup> There was no significant difference in outcome between groups; thus, surgical intervention provided no benefit over conservative

management. Thus, the clinical implication is that surgery is not a 'quick fix' for patellar tendinopathy.<sup>212</sup>

A number of different surgical techniques have been proposed. There has been some enthusiasm for arthroscopic debridement of the anterior portion of the fat pad adjacent to the patellar tendon and results published to date appear similar to those of patients undergoing open surgery.<sup>213, 214</sup> Open surgery aims to remove the region of tendinosis from the proximal patellar tendon. A systematic review of 17 studies of surgery for patellar tendinopathy reported that outcomes were reasonable after both open and arthroscopic surgery, but that return to sport was faster with the arthroscopic surgery.<sup>215</sup>

We recommend surgery only after a thorough, high-quality rehabilitation program has failed. Surgeons must advise patients that while symptomatic benefit is very likely, return to sport at the previous level cannot be guaranteed (60-80% likelihood).<sup>213, 216</sup> Time to return to the previous level of sport, if achieved, is likely to take between 6 and 12 months.<sup>213, 216</sup>

#### Sudden, acute patellar tendon pain

The term 'partial tear' is often used when the player has a sudden painful episode, which may be associated with disability. A small partial tear of the patellar tendon is often diagnosed by ultrasonography following an event like this or as an incidental finding on ultrasound examination, and it is difficult to differentiate a tear from an area of tendinosis.<sup>217, 218</sup> Based on surgical specimens in the Achilles tendon, the ability of ultrasound to differentiate degenerative changes and partial tears are limited.

This type of partial tear occurs in degenerative tendinopathy and can be managed conservatively. There are few consequences in the patellar tendon as the tissue trauma is likely to be in an area of pathology of the patellar tendon and not in the normal, load-bearing tissue. If the pain and dysfunction after acute onset pain persists, further imaging and possible intervention may be justified to stimulate some healing response in the tendon.

### LESS COMMON CAUSES OF ANTERIOR KNEE PAIN

#### Fat pad irritation/impingement

Fat pad syndrome was first described by Hoffa in 1903 to describe a condition where the infrapatellar fat pad was impinged between the patella and the femoral condyle due to a direct blow to the knee. More commonly, fat pad irritation occurs with repeated or uncontrolled hyperextension of the knee where it is impinged between the femur and tibia. The condition can be extremely painful and debilitating, as the fat pad is one of the most pain-sensitive structures in the knee.<sup>25</sup>

Chronic fat pad irritation is relatively common and often goes unrecognised. The pain is often exacerbated by extension manoeuvres, such as straight leg raises and prolonged standing, so it needs to be recognised early so that appropriate management can be implemented.

Clinical findings include localised tenderness (at the inferior pole of the patella, deep to the tendon) and puffiness in the fat pad with the inferior pole of the patella appearing to be (or actually being) displaced posteriorly. Pain may be reproduced with active knee extension and passive overpressure in extension. Contracting the quadriceps with the knee extended may aggravate the pain during the acute phase. There may be quadriceps weakness. Patients often have hyperextension of the knees (*genu recurvatum*) associated with increased anterior pelvic tilt.

Thus, treatments should be directed to improve the control, strength and endurance of local (*vasti*), proximal and distal muscles as well as retraining to avoid uncontrolled and excessive terminal knee extension manoeuvres.

A popular clinical approach consists of treating the inferiorly tilted patella by taping across the superior surface of the patella to lever the inferior pole forward and relieve impingement of the fat pad (Fig. 36.6d). Unloading of the fat pad may be required to relieve the symptoms further.

To unload the fat pad, a 'V' tape is placed below the fat pad, with the point of the 'V' at the tibial tubercle coming wide to the medial and lateral joint lines. As the tape is being pulled towards the joint line, the skin is lifted towards the patella, thus shortening the fat pad (Fig. 36.15). Improving lower limb biomechanics is often helpful. Surgery should be avoided if possible. To date, there have been no RCTs of surgery for this condition.<sup>219</sup>

### Osgood–Schlatter lesion

Osgood–Schlatter lesion is an osteochondrosis (Chapter 44) that occurs at the tibial tuberosity in children as they progress through puberty. It is much more common among boys of about 13–15 years (but these ages vary) than girls (age about 10–12) and results from excessive traction on the soft apophysis of the tibial tuberosity by the powerful patellar tendon. It occurs in association with high levels of activity during a period of rapid growth and is associated with a change in the tendon. Longitudinal imaging of the tendon in adolescents without pain shows that the attachment transitions to a normal attachment through a process that can be interpreted as osteochondritic.<sup>220</sup> As with all tendon-related pain, the clinician must be careful not to diagnose based on imaging findings.

Treatment consists of reassurance that the condition is self-limiting and muscle strength exercises. Whether or not to play sport depends on the severity of symptoms. Children with mild symptoms may wish to continue

to play some or all sport; others may choose some modification of their programs. If the child prefers to cease sport because of pain, that decision should be supported. However, the amount of sport played does not seem to affect the time taken for the pain to disappear.

### Sinding–Larsen–Johansson lesion

This rare lesion is one of the group of osteochondroses found in adolescents (Chapter 44). It is a clinically unimportant differential diagnosis in young patients with pain at the inferior pole of the patella, who can actually have patellar tendinopathy at a young age.

### Quadriceps tendinopathy

Pain arising at the quadriceps tendon at its attachment to the patella occurs mainly in the older athlete and in weightlifters as the quadriceps tendon is loaded more in a deeper squat. It is characterised by tenderness at the superior margin of the patella and pain on resisted quadriceps contraction. Treatment follows the same principles as treatment of patellar tendinopathy. Differential diagnosis is suprapatellar pain of PFJ origin, plica and bipartite patella. Ruptures of the entire quadriceps attachment to the patella are not uncommon in middle-aged men and require surgery and extensive rehabilitation.

### Bursitis

There are a number of bursae around the knee joint (Fig. 36.16). The most commonly affected bursa is the pre-patellar bursa. Pre-patellar bursitis ('housemaid's knee') presents as a superficial swelling on the anterior aspect of the knee. This must be differentiated from an effusion of the

**Figure 36.15** Fat pad unloading tape. Tape is applied in a 'V' from the tibial tuberosity to the joint lines. The fat pad region is pinched to unload the fat pad while applying the tape. This tape is often combined with taping of the superior pole of the patella (Fig. 36.6d) in the treatment of fat pad impingement

**Figure 36.16** Bursae around the knee joint

knee joint. Acute infective pre-patellar bursitis, common in those who kneel a lot, should be identified and treated quickly. Infrapatellar bursitis can also cause anterior knee pain that may mimic patellar tendinopathy; this bursa forms part of an enthesis organ of the distal insertion and, thus, can be challenging to treat. Pes anserinus bursitis is often associated with an underlying rheumatological condition.

Treatment of mild cases of bursitis includes non-steroidal anti-inflammatory drugs (NSAIDs). More severe cases require aspiration and infiltration with a corticosteroid agent and local anaesthesia, followed by appropriate treatment of the enthesis if appropriate.

### Synovial plica

The importance of the synovial plica, a synovial fold found along the supero-medial edge of the patella (see Fig. 36.17), has been a matter of considerable debate. An inflamed plica may cause variable sharp pain located anteriorly, medially or posteriorly. The patient may complain of sharp pain on squatting and it can mimic quadriceps tendinopathy. On examination, the plica is sometimes palpable as a thickened band under the medial border of the patella. It should only be considered as the primary cause of the patient's symptoms when the patient fails to respond to appropriate management of PFP. In this case and in the presence of a tender thickened band, arthroscopy should be performed and the synovial plica removed.

(a)

(b)

# Lateral, medial and posterior knee pain

with MARK HUTCHINSON

*When I listened to other people—who seemed to have trouble even though their [knee replacements] went well—[I learned that] they didn't make the commitment to rehab . . . I can walk forever now—pain-free . . . I can hit a tennis ball again.*

Billie Jean King, six years after her 2010 knee replacements

Although acute knee injuries and anterior knee pain are very common presentations in sports and exercise medicine practice, patients presenting with lateral, medial or posterior knee pain are not uncommon and can provide the clinician with both diagnosis and treatment challenges.

### LATERAL KNEE PAIN

Athletes can present with the chief complaint of lateral knee pain for a number of underlying problems, including: lateral meniscus tears and cysts; bone bruises or cartilage injuries of the lateral compartment; patellofemoral syndrome or patellar instability; injuries of the posterolateral corner structures (popliteus, lateral collateral ligament, mid third capsular ligament anterolateral ligament); biceps insertional tendinopathy and injuries; tibiofibular joint instability; and iliotibial band syndrome at the knee.

Lateral knee pain (Fig. 37.1) is a particularly common problem among distance runners and cyclists, the most common cause of lateral knee pain being iliotibial band friction syndrome (ITBFS). Training errors as well as alignment and biomechanical abnormalities can precipitate ITBFS. Patellofemoral syndrome (Chapter 36) or instability may also present as lateral knee pain. In the older active person, lateral meniscus degeneration or lateral compartment osteoarthritis should be more strongly considered as part of the differential diagnosis. For sprinters and footballers, overuse injuries of the biceps femoris tendon and its insertion onto the fibula should be considered more highly in the differential diagnosis. The biceps femoris tendon may suffer compression and irritation as it passes posterolaterally to the knee and inserts into the head of the fibula, likely as a result of the repetitive flexion

and rotation demands on the knee. Injuries of the superior tibiofibular joint may also cause lateral knee pain.

The astute clinician should always be conscious of the potential of associated injuries or referred pain involving the lateral aspect of the knee. Ligamentous injuries of the posterolateral corner are rarely isolated and frequently involve injury to the ACL or PCL. Lateral knee pain may also occur as a result of referred pain from the lumbar spine. The causes and differential diagnoses of lateral knee pain are shown in Table 37.1.

(a)

**Figure 37.1** Lateral aspect of the knee (a) Surface anatomy

(b)

**Figure 37.1 (cont.)** (b) Anatomy of lateral aspect of the knee

### Clinical approach

As with acute knee injuries (Chapter 35) and most musculoskeletal injuries, history and physical examination are key to an accurate diagnosis.

### History

Most complaints involving the lateral aspect of the knee can be classified as either chronic, with no specific traumatic episode, or acute, where the athlete can recall a single event that initiated the complaint. A history of overuse or pain related to a change in training intensity suggests ITBFS or

biceps femoris tendinopathy. ITBFS has been associated with acute ramping up of training period or distance, excessive downhill running and running on an uneven surface (particularly the downside leg on a canted/sloped road). Biceps femoris strains and tendinopathy have been correlated with sprinting or kicking activities.

The pain associated with biceps femoris tendinopathy flares up on initial activity and then starts to settle after warming up, usually recurring following cessation of activity or the next day. When left untreated, pain persists during exercise and the athlete may not be able to continue with sporting activity. ITB pain usually does not settle with ongoing activity and can be associated with a snapping sensation as well as swelling and pain localised proximal to the lateral joint line.

If the athlete can remember a single episode or event, then the clinician should consider such diagnoses as a bone bruise (bone marrow lesion [BML] posterolateral corner ligament injury, proximal fibular subluxation, patellar instability or a lateral meniscus tear (Chapter 35). Lateral joint line pain associated with a sudden twisting event, accompanied by episodes of locking, is highly suggestive of a meniscus tear. The sensation of giving way may be secondary to intra-articular pathology such as a loose body, bucket-handle meniscus tear, or more commonly related to true ligamentous instability of the patella or posterolateral corner of the knee. As the population of active individuals who are over 50 years old increases, the diagnosis of lateral compartment osteoarthritis should be considered and it is possible for them to have an acute or chronic injury to a degenerative meniscus.

A complete history is necessary to avoid missing radicular or associated diagnoses. The presence of back pain may suggest referred pain from the lumbar spine. Associated neurological symptoms such as weakness and paraesthesia in the lower leg may indicate common peroneal nerve entrapment. Acute ankle injuries with

**Table 37.1 Causes of lateral knee pain**

(e)

**Figure 37.2 (cont.)** (e) Resisted movement—knee flexion. Concentric or eccentric contractions may reproduce the pain of biceps femoris tendinopathy (f) Palpation—lateral femoral epicondyle (g) Special test—knee effusion. Manually drain the medial subpatellar pouch by stroking the fluid in a superior direction. (1) Then 'milk' the fluid back into the knee from above (2) while observing the pouch for reaccumulating fluid (h) Special tests—McMurray's test. The knee is flexed and, at various stages of flexion, internal and external rotation of the tibia are performed (arrow). The presence of pain and a palpable 'clunk' are a positive McMurray's test and are consistent with meniscal injury. If there is no 'clunk' but the patient's pain is reproduced, then the meniscus may be damaged or there may be patellofemoral joint abnormality

### Investigations

Although the majority of patients with lateral knee pain do not require investigations, MR imaging can be useful in cases of persistent lateral knee pain when a degenerative lateral meniscus is suspected. Weight-bearing radiographs with the knee slightly flexed have an improved sensitivity for osteoarthritis when compared to standard radiographs obtained in a supine position. Full-length tibia/fibula films should be obtained when associated ankle injuries are present. When imaging is not readily available, a diagnostic local anaesthetic injection can be used to differentiate local soft tissue pain (e.g. ITBFS) from intra-articular or referred pain. If the clinician is concerned for the possibility of radiculopathy from the lumbar spine, electromyography or lumbar spine imaging may be indicated.

### Iliotibial band friction syndrome

Iliotibial band friction syndrome (ITBFS) is an overuse injury presenting as lateral knee pain that is exacerbated by sporting activity. It is more commonly seen in runners, cyclists, defence force recruits and endurance athletes.<sup>1-4</sup> Incidence rates in running range from 1.6% to 12% and 1% to 5.5% in military populations.<sup>3</sup> In cycling ITBFS accounts for 15% to 24% of overuse injuries.<sup>3</sup>

### Anatomy

Traditionally, ITBFS was considered to be the result of friction between the iliotibial band (ITB) and the underlying lateral epicondyle of the femur (Fig. 37.3) as the ITB switched from an extensor at 0–20° to a flexor at 20–90°. This friction was thought to contribute to local inflammation and irritation of an anatomical bursa lying between the tendon and the lateral femoral epicondyle (LFE).<sup>5</sup> However, anatomical studies have questioned or negated this theory.<sup>2,4</sup>

While both ultrasound and MRI can show thickening of the ITB over the lateral femoral condyle and often a fluid collection deep to the ITB at the same site,<sup>6</sup> studies do not support the presence of an anatomical bursa around the LFE.<sup>2,4</sup> Instead of a bursa, the authors claim that a richly innervated and vascularised layer of fat and connective tissue separates the ITB from the LFE and is the likely source of pain in ITBFS.<sup>2,4</sup>

It is important to note that the ITB is not a discrete band but a lateral thickening of the circumferential fascia lata that envelops the whole thigh like a stocking

**Figure 37.2 (cont.)** (i) Special tests—slump test

(j) Special tests—biomechanical assessment Full lower limb biomechanical assessment should be performed while standing, walking and lying. Abnormal pelvic movements (e.g. excessive lateral tilt) should be noted

**Figure 37.3** Anatomy of the iliotibial band insertion  
FROM FRANKLYN-MILLER A. ET AL. *CLINICAL SPORTS ANATOMY*.  
MELBOURNE: MCGRAW-HILL, 2010; P.269

(Fig. 37.3).<sup>1,2,4</sup> The ITB inserts along the length of the femur down the linea aspera via the lateral intermuscular septum.<sup>1,2,4</sup> Proximally, the tensor fascia lata muscle (TFL) inserts into the ITB, as does a substantial portion of the gluteus maximus muscle (GMax). The remaining portion inserts directly into the greater trochanter. Distally, the ITB crosses the LFE and is connected to the LFE by strong fibrous bands. The ITB continues, acting like a lateral ligament, from the LFE to insert onto the patella and Gerdy's tubercle on the tibia. The ITB can also project onto the fibula. This orientation demonstrates the close relationship between the ITB and the knee and hip complex and its role in lateral stability.

### Clinical features

Typically, an athlete with ITBFS complains of an ache over the lateral aspect of the knee which is aggravated by running or cycling. The pain often develops at about the same distance/time during activity. Longer training sessions, downhill running or cambered courses are often aggravating factors.

On examination, tenderness is elicited over the LFE 2-3 cm above the lateral joint line (Fig. 37.2f). Crepitus and local swelling may also be felt. Repeated flexion/extension of the knee may reproduce the patient's

symptoms. Ober's test (Fig. 37.2d) often reveals ITB tightness and may produce a burning sensation. Tightness may be secondary to shortening of the TFL and/or GMax muscles proximally or excessive development of the vastus lateralis, placing increased tensile load on the ITB. Imaging is not usually required to confirm the diagnosis of ITBFS.

### Biomechanics

Understanding the anatomy and pathomechanics of the ITB should assist in better targeting therapeutic interventions. Movement of the ITB around the LFE is restricted by its strong fibrous band attachments. Traditional approaches involving the alteration of tension of the fascia lata and hip musculature may not achieve the intended outcomes and can result in an increase in compressive forces around the LFE,<sup>2,4</sup> leading to increased pain related to compression rather than a reduction in transverse frictional forces. The ITB clearly plays a role in stability around the hip through its tensioning effect. In hip adduction and flexion, an increase in pressure around the greater trochanter has been reported.<sup>1</sup> This pressure is further increased by knee flexion. The same pressure is reduced in hip abduction and knee extension. This is supported by surgical studies which have shown that ITB lengthening can lead to favourable outcomes in trochanteric bursitis presentations.<sup>1</sup>

It was originally thought that ITBFS was associated with repetitive knee flexion and extension movement. A biomechanical study found no significant difference in sagittal knee movements between an ITBFS population and matched controls.<sup>5</sup> This suggests that other planes of motion may be more relevant. For example, an increase in tibial internal rotation can augment compressive forces around the LFE by moving the ITB's distal attachment to the tibia more medially.<sup>7</sup>

### PRACTICE PEARL

It is clear that the pathomechanics of ITBFS is complex and involves various segments along the kinetic chain. Tibial internal rotation may result from poor proximal control (increased hip adduction/internal rotation), a genu valgus strain and/or poor rearfoot mechanics.

An increase in hip adduction, especially during the loading phase of running, increases the eccentric demand on the hip abductors.<sup>7</sup>

Runners with ITBFS can have significant weakness of their hip abductors in the affected limb,<sup>8</sup> and decreased ability of the hip abductors to eccentrically control

adduction.<sup>9</sup> There is also often weakness in knee flexion and knee extension, with decreased braking forces.<sup>10</sup> Weakness and fatigue can result in increased compressive forces around the LFE and therefore lead to ITBFS.

Neural feedback from the richly innervated fat and connective tissue between the ITB and LFE may result in decreased tension in the hip abductors to reduce these compressive loads.<sup>2</sup> This can lead to hip muscle imbalances and altered biomechanics.

### Treatment

Treatment of ITBFS should address not only local symptoms, but also each segment along the kinetic chain including foot alignment and hip biomechanics to assure more favourable long-term results. A guiding philosophy is that while the pathology is felt distally, treatment should be focused proximally.

Local treatment includes cryotherapy, topical non-steroidals and modalities such as shock wave therapy<sup>11</sup> applied to the area around the LFE. Oral NSAIDs may be helpful in the initial stages to reduce pain and allow therapy.<sup>12</sup> Corticosteroid injection (Fig. 37.4) has traditionally been used to inject the 'bursa'.<sup>13</sup> The inconsistent results from these injections can be attributed to a misunderstanding of the pathology. Whether there is a role for corticosteroid injections into the area of pain-sensitive tissue between the ITB and lateral femoral epicondyle is presently unclear. It is unlikely that they provide a cure; however, they may play a temporary role in relieving pain to allow rehabilitation. Caution should always be used when injecting steroids about ligaments for fear of weakening them.

Soft tissue treatment to the proximal ITB (Fig. 37.5a and b), dry needling (Fig. 37.5c) and self-massage with a foam roll (Fig. 37.5d) all help to reduce muscle tension

and tone on the ITB. Stretching (Fig. 37.6) is routinely proposed as a treatment technique for ITBFS. However, because the ITB inserts into the entire length of the femur via the lateral intermuscular septum, stretching exercises may have a limited effect on the ITB itself. Stretching may have some effect on reducing the tension in the tensor fascia lata (TFL).<sup>2, 4</sup> Stretching of the gluteus maximus muscle may prove more beneficial because of its close relationship to the ITB.

(a)

(b)

**Figure 37.4** Corticosteroid injection, if used, is aimed deep to the ITB tendon—between it and the underlying LFE

**Figure 37.5** Treating tight myofascial structures  
(a) Sustained myofascial tension to the proximal ITB  
(b) Ischaemic pressure to the body of the ITB

(c)

(e)

(d)

**Figure 37.5 (cont.)** (c) Dry needling to ITB trigger points (d) Foam roll self-massage to the ITB (e) Dry needling to gluteal trigger points

Tightness of the gluteal muscles and TFL are commonly associated with ITBFS. The presence of trigger points in the TFL, gluteus minimus and gluteus medius may contribute to ITBFS. Gluteal trigger point dry needling (Fig. 37.5e) and ischaemic pressure can reduce the tension and relieve local pressure around the LFE. Strengthening of the hip external rotators (Fig. 37.7a) and abductors

(Fig. 37.7b) is an important component of the treatment of ITBFS in order to correct the underlying weakness and fatiguability of these muscles.

In rare and resistant cases, surgery may be considered. Surgery may be targeted proximally or distally. If the athlete has associated pain over both the greater trochanter and lateral aspect of the knee, then decompression/release of the ITB and excision of the 'bursa' or abnormal tissue can be done at either location or both. In patients with isolated distal pain over the lateral epicondyle, most surgeons will target the abnormal tissue by working arthroscopically beneath the ITB or via direct approach, splitting the ITB to address the abnormal tissue that lies beneath. It is essential to work aggressively with rehabilitation postoperatively as recurrence or residual pain is not uncommon.

**Figure 37.6** ITB stretch—the ITB on the left side is being stretched. The symptomatic leg is extended and adducted across the uninvolvement leg. The patient exhales and slowly flexes the trunk laterally to the opposite side until a stretch is felt on the side of the hip

### Lateral meniscus abnormality

When athletes present with lateral knee pain that is focused on the lateral joint line, lateral meniscus injury or pathology must be considered. The lateral meniscus is more circular than the C-shaped medial meniscus. It is loosely connected to the lateral joint capsule, has an unattached region through which the popliteus tendon passes and communicates with the PCL via the menisco-femoral ligaments. It is inherently more mobile than the medial meniscus. Acute meniscal injuries are discussed in Chapter 34.

#### PRACTICE PEARL

In children and early adolescents, diagnosing meniscal injury can be difficult due to vague subjective findings and difficulty in localising pain.<sup>14</sup> Meniscal injury in children is more common than previously thought and is underdiagnosed.<sup>14</sup>

A discoid (disc-shaped) lateral meniscus is an anatomical abnormality that has been reported in children. Most

(a)

(b)

**Figure 37.7** Strengthening exercises for the external hip rotators and abductors (a) Exercise involves the patient standing on one leg and slowly performing a squat, maintaining pelvic stability (b) Hip abduction is side-lying

commonly asymptomatic and presenting as an incidental finding on an MRI scan,<sup>15</sup> a discoid meniscus can also present as chronic 'snapping knee syndrome'. It is more common in the Asian population and may be bilateral. When symptomatic (i.e. painful, presence of joint effusion, symptoms of clicking and locking), it is either grossly unstable or associated with a degenerative meniscal tear, and treated arthroscopically with partial resection.<sup>15</sup>

Tenderness along the lateral joint line (2–3 cm below the lateral epicondyle and site of ITBFS) and a positive McMurray's test (pain with popping) is indicative of meniscal injury (Fig. 37.2h). Chronic degenerative meniscus tears can create a meniscus cyst which can be palpated as a soft, usually painful, bump over the lateral joint line. Radiographs can assist in ruling out other concerns, such as degenerative arthritis, osteochondritis dissecans, osteochondral loose bodies and tibial plateau fractures, within the differential diagnosis.<sup>14, 15</sup> MRI is over 90% accurate for intra-articular pathology but can be associated with false positives.<sup>14</sup>

Treatment of lateral meniscus pathology is based on the athlete's age, duration of symptoms, area of meniscal pathology (vascular areas compared with non vascular) and number of associated injuries such as cruciate ligament tear. Surgeons are more likely to repair meniscus injuries that appear in young athletes or that are large and in the peripheral vascular zone. Degenerative tears in older patients are usually less repairable. The outcomes of surgical repairs have a 90% success rate when performed with a concomitant cruciate reconstruction, compared with only 60–70% success rate when the meniscus tear is an isolated injury. Symptomatic meniscus cysts are usually treated by arthroscopically debriding the intra-articular pathology.

### Less common causes of lateral knee pain

#### Osteoarthritis of the lateral compartment of the knee

Degenerative changes in the lateral compartment of the knee may also be the source of lateral knee pain, especially in older athletes. The pain can be caused by degeneration of the articular surface of lateral tibial plateau or femoral chondyle with or without degenerative changes of the meniscus. Contributing factors include functional demand, size and depth of the lesion, varus or valgus knee malalignment and obesity.<sup>16, 17</sup>

Early in the disease, the patient may give a history of increasing knee pain with activity, swelling, a grinding sensation and stiffness after a period of rest. As the disease progresses, the patient may start to experience more pain with activity, reduced function, morning stiffness or pain at night that may disturb sleep. In the early stages, examination may only reveal a small effusion or lateral joint line tenderness. McMurray's manoeuvre or varus and valgus stressing may exacerbate pain or create the sensation of grinding. A painful McMurray's is not specific for a meniscus tear unless associated popping or clicking occurs. In late stages, the grinding sensation becomes more obvious and the patient may have progressive alterations in their alignment.

The best imaging study is a weight-bearing plain radiograph in the plane of the tibial plateau with the knee slightly flexed. This has greater sensitivity than views taken with the patient supine. Other cartilage injuries that

should be considered include osteochondritis dissecans in young patients, osteochondral injuries or loose bodies following acute trauma, and spontaneous osteonecrosis of the knee (SONK) in older patients.

Initial treatment of knee osteoarthritis targets symptom relief with cryotherapy, analgesia and NSAIDs. Modification of activity and exercise prescription are helpful, particularly when combined with weight loss in overweight patients. The efficacy of oral glucosamine and chondroitin sulphate and intra-articular hyaluronic acid injections (viscosupplementation) have been debated and in some reports have a similar efficacy to NSAIDs with very little risk of serious adverse effects (Chapter 17).<sup>18, 19</sup> Another alternative is the use of a deloader brace. Functional motor control assessment focusing on load distribution, such as single-leg squat, stair negotiation and gait, can identify biomechanical contributing factors.

Athletes may modify their activities to choose lower impact training (cycling and swimming rather than running) or reduced sporting challenges (doubles rather than singles tennis). Early identification of these factors may help delay further degeneration.

#### PRACTICE PEARL

Over the past decade, the efficacy of arthroscopic 'wash-outs' in the absence of mechanical pathology has shown no significant benefit over placebo.

Patients with severe clinical symptoms and joint space narrowing on radiographs may require unicompartmental<sup>20</sup> or, eventually, total knee replacement.

### Excessive lateral pressure syndrome

Excessive lateral pressure syndrome (lateral patellar compression syndrome) occurs when there is excessive pressure on the lateral patellofemoral joint resulting from a tight lateral retinaculum. The lateral retinaculum is not one distinct anatomical structure but comprises several layers. A recent cadaveric study suggests there are three layers: a deep fascia layer (not attached to the patella), an intermediate layer (composed of the ITB and the quadriceps aponeurosis and their attachments to the patella) and the deepest layer consisting of the joint capsule.<sup>21</sup> Therefore, an increase in pressure around the lateral retinaculum will affect the joint capsule, the patellofemoral joint, the ITB and the quadriceps muscles. This can lead to bone strain on the lateral patella, inflammation of the lateral retinaculum and ITBFS.

Eventually the increased strain on the lateral patella may lead to chondral degeneration or the development of a vertical stress fracture. The stress fracture can be differentiated radiologically from a congenital bipartite patella by its sharper edges with no evidence of marginal sclerosis. MRI is useful to distinguish the two as a stress injury should have associated

bone oedema.<sup>22</sup> Chronic changes and malalignment related to chronic cartilage degeneration of the lateral patellar facet are best seen on a tangential patellar view such as a sunrise view, which allows the clinician to assess patellar tracking, patellar tilt and patellar joint space narrowing.

Initial treatment consists of patellofemoral mobilisation and soft tissue therapy to the lateral retinaculum. Taping techniques rarely help. Surgical lateral retinacular release is reserved for patients with increased, uncorrectable, lateral patellar tilt with no patellar instability. If a lateral fragment is present, removal of fragment is occasionally required.<sup>23</sup>

### Biceps femoris tendinopathy

Biceps femoris tendinopathy occurs with excessive acceleration and deceleration activities and is often associated with running and cycling. As with most tendinopathies it does not initially restrict sporting activity and therefore has a high risk of chronicity when not recognised early. Pain is described at the posterolateral corner knee, near and just proximal to the biceps insertion onto the fibular head. The pain usually settles after activity and post exercise; morning stiffness is common.

The pain is reproduced with resisted flexion, especially with eccentric contractions (Fig. 37.2e). The pain may be associated with tightness of the hamstring and gluteal muscles. Stiffness of the lumbar spine and poor core stability may also be contributing factors. The diagnosis is usually made clinically but ultrasound examination may reveal synovitis or tendinopathy.

Treatment is based on the general principles of the treatment of tendinopathy: a few days of relative rest and soft tissue therapy (Fig. 37.8) followed by progressive loading (Chapters 4 and 17). Strengthening of the hamstrings (Fig. 37.9) and the hip muscles, specifically the gluteus maximus, may also prove useful.<sup>24</sup> (See also Chapter 31 for the management of lateral hip pain.)

If prolonged pain and reduced function affect sporting activity despite quality conservative measures, surgical approaches may be considered. These include stripping of the paratenon, removal of degenerative tissue and other repair techniques for torn tendons.<sup>25</sup>

### Superior tibiofibular joint injury

Injury to the superior tibiofibular joint (STFJ) is a rare but commonly missed cause of lateral knee pain. The STFJ is comprised of the articulation between the lateral condyle of the tibia and the fibular head. The joint capsule is strengthened by superior, anterior and posterior ligaments.<sup>26, 27</sup> The STFJ plays a role in tibiofemoral joint stability through its surrounding anatomical structures, which include the lateral collateral ligament, arcuate ligament, popliteofibular ligament, biceps femoris tendon and popliteus muscle.<sup>27</sup> The STFJ externally rotates

**Figure 37.8** Soft tissue therapy in the treatment of biceps femoris tendinopathy. Ischaemic pressure at the musculotendinous junction (shown) and muscle belly can be effective

**Figure 37.9** Eccentric strengthening exercises in the treatment of biceps femoris tendinopathy. Drop-and-catch is performed in prone positions. This may be progressed to include hip flexion (i.e. patient lying over the end of the bed)

during ankle dorsiflexion and is thought to dissipate torsional stresses from the ankle.<sup>27</sup> When injured, the STFJ can affect knee and ankle function and can be a source of lateral knee pain.

### Clinical assessment

STFJ injury may result from twisting injuries or direct trauma resulting in capsuloligamentous sprains, subluxation or dislocation of the fibula. The mechanism of injury is often described as a combination of rotation and knee flexion (e.g. pivoting, cutting) and has been reported in sports such as rugby, soccer, skiing and the various forms of martial arts.<sup>25</sup> Additionally, STFJ injuries can be secondary to severe ankle injuries (a Maisonneuve variant) (Chapter 41). In the older athlete, osteoarthritis of the STFJ can accompany knee arthritis and can be confirmed by careful review of radiographic imaging.<sup>26</sup>

In the presence of an acute dislocation, the athlete may present with a prominent head of fibula, lateral knee pain and swelling around the STFJ. The athlete may report popping or clicking. Pain may be exacerbated by ankle movements and weight-bearing activities. It is important to immediately assess and rule out a peroneal nerve injury. STFJ injuries can be associated with popliteus tendon injury and injuries to the posterolateral corner of the knee.<sup>26</sup> Early recognition of posterolateral corner injuries is essential to optimising clinical and surgical outcomes for the patient (Chapter 35).<sup>26</sup>

In the presence of a sprain, pain may be local or may refer distally along the lateral calf. The STFJ is often tender, especially directly over the head of the fibula, and passive movement of the joint may be restricted by hamstring (biceps femoris) and peroneal muscle spasm. With these muscles relaxed, excessive movement may be detected on passive gliding (Fig. 37.2c).

### Treatment

Acute and painful subluxations of the tibiofibular joint can be managed conservatively with immobilisation (approximately 2–3 weeks), followed by a progressive strengthening program of the hamstring and calf muscles.<sup>25</sup> Excessively mobile joints are more difficult to treat and can be associated with generalised hypermobility, especially in the female athlete. Predisposing factors, such as excessive pronation, which place greater torsional forces through the joint, should be assessed and may require correction. Dislocated joints require reduction with possible stabilising fixation.

Manual mobilisation can be an effective treatment for the stiff tibiofibular joint. Local electrotherapy may help relieve pain, but care must be taken as the peroneal nerve is quite close. Strengthening of the muscles around the knee, especially the tibial rotators (Fig. 37.15), may help stabilise the joint, reduce pain and improve function.

Occasionally a corticosteroid injection may be used. For patients with chronic pain or instability which impairs function, surgical options include arthrodesis and fibular head resection.<sup>28</sup> Proximal tibiofibular joint capsule reconstruction using a gracilis autograft can lead to subjective improvements and could aid return to sport.<sup>25</sup> However, strength may continue to be reduced.

### Referred pain

Pain may refer from the lumbar spine to the lateral aspect of the knee. Referred pain is usually a dull ache and is poorly localised. The slump test may be positive. The lumbar spine should be examined in athletes presenting with atypical lateral knee pain.

### MEDIAL KNEE PAIN

Like the lateral aspect of the knee, being able to evaluate and treat medial knee pain begins with an understanding of the basic anatomy and function of the structures on the medial aspect of the knee (Fig. 37.10). The medial collateral ligament (MCL) provides stability versus valgus stress of the knee and originates at the medial epicondyle and travels beneath the pes tendons to insert 10–15 cm distal to the medial joint line on the tibia. The sartorius, semitendinosus and gracilis tendons (pes anserine) serve to flex the knee and insert just anterior and proximal to the tibial insertion of the MCL. The medial patellofemoral ligament (MPFL)

(a)

**Figure 37.10** Medial aspect of the knee (a) Surface anatomy

(b)

**Figure 37.10 (cont.)** (b) Anatomy

ADAPTED FROM THE CIBA COLLECTION OF MEDICAL ILLUSTRATIONS, REPRODUCED BY COURTESY OF CIBA-GEIGY LIMITED, BASEL, SWITZERLAND. ALL RIGHTS RESERVED

is a key stabilising structure for patellar stability and runs from the supero-medial border of the patella via the medial retinaculum to a point posterior to the femoral insertion of the MCL (Fig. 35.17). The medial meniscus is intimately attached to the MCL and may be injured with MCL injuries. Ultimately, injury to any of these structures can cause acute or chronic medial knee complaints in athletes. The causes of medial knee pain are shown in Table 37.2.

## Patellofemoral syndrome

Anteromedial knee pain is common and is usually associated with patellofemoral syndrome or patellar mal-tracking. Patellofemoral syndrome is discussed in Chapter 36; however, some discussion is included here as it relates to the differential diagnosis of medial knee pain. Indeed, recent studies suggest that the MPFL may play a significant role in medial knee pain associated with patellofemoral syndrome.<sup>29, 30</sup>

When an athlete dislocates his or her patella, he or she will invariably injure the medial retinaculum and MPFL. Most of these will be injured in their mid-substance or off the femur; therefore, in addition to the sensation of apprehension and palpable effusion, the most common finding on examination is pain to palpation over the MPFL and medial retinaculum.

In chronic cases, pain over the MPFL and medial retinaculum may persist due to recurrent instability. Chronic inflammation of the medial retinaculum due to recurrent instability or repetitive irritation from knee flexion may present as a symptomatic plica (Chapter 36). Non-surgical treatments may include cryotherapy, taping, patellofemoral bracing and steroid injections. Surgical options can include arthroscopic resection of a resistant medial plica or medial patellofemoral ligament reconstruction targeting both pain and recurrent instability.<sup>30</sup>

## Medial meniscus abnormality

Pain that is localised over the medial joint line is usually secondary to either meniscus tear or degeneration, or a cartilage injury in the medial compartment of the knee. In the young adult patient, a small tear of the medial meniscus may cause a synovial reaction and medial knee pain (Fig. 37.11). In the older patient, gradual degeneration of the medial meniscus can present as gradual-onset medial knee pain. The clinical scenario is similar to that described earlier for a lateral meniscal abnormality.

**Table 37.2 Causes of medial knee pain**

Common	Less common	Not to be missed
Patellofemoral syndrome Medial meniscus <ul style="list-style-type: none"> <li>• Minor tear</li> <li>• Degenerative change</li> <li>• Cyst</li> </ul> Osteoarthritis of the medial compartment of the knee	Synovial plica (Chapter 36) Pes anserinus <ul style="list-style-type: none"> <li>• Tendinopathy</li> <li>• Bursitis</li> </ul> Medial collateral ligament <ul style="list-style-type: none"> <li>• Grade 1 sprain/bursitis</li> <li>• Pellegrini-Stieda lesion</li> </ul> Referred pain <ul style="list-style-type: none"> <li>• Lumbar spine</li> <li>• Hip joint</li> <li>• Neural mechanosensitivity</li> </ul>	Tumour (in the young) Slipped capital femoral epiphysis Referred pain from the hip Perthes' disease

The athlete is generally aged over 35 years and complains of clicking and pain with certain twisting activities, such as getting out of a car, rolling over in bed, changing direction, and cutting and pivoting movements during sporting activity. Examination reveals joint line tenderness and a positive McMurray's test, that is, pain with a pop (Fig. 37.2h). MRI is the investigation of choice.

Like the lateral meniscus, treatment for medial meniscal injuries depends on the patient's age, chronicity, tear pattern, functional demands and associated ligamentous injuries (see Chapter 35). Conservative management is warranted for non-displaced or degenerative tears; however, if this fails, surgical intervention may be required. Complete meniscectomies are contraindicated as the remaining uninjured portion of the medial meniscus can continue to contribute to shock absorption.<sup>31</sup> Complete

meniscectomies are associated with osteoarthritis. Assuming an appropriate tear pattern, meniscus repair is preferred, especially in younger athletes.

### Osteoarthritis and chondral injuries of the medial compartment of the knee

Osteoarthritis (OA) of the knee generally affects older athletes (over the age of 50 years), but has been reported in adolescents and young adults.<sup>32, 33</sup> It is important to remember that OA affects not only articular cartilage, but also subchondral bone and synovium. Ligamentous, meniscal and chondral injury, as well as repetitive joint loading, can predispose the knee joint to OA.<sup>32, 33</sup>

### Epidemiology

Risk factors for developing premature arthritis include obesity, sports participation, previous knee injury and genetic predisposition.<sup>32, 33</sup> Increasing obesity rates in children, specifically a body mass index (BMI) above the 95<sup>th</sup> percentile for height and weight ratios (for 2-19 year olds), has been linked to increased risk of musculoskeletal injury.<sup>32, 33</sup> Athletes participating in power sports, such as wrestling, boxing, weightlifting, and team sports, such as soccer, basketball and football, have a higher incidence of premature knee arthritis.<sup>32, 33</sup> However, some sports have a lower incidence of OA. These sports include cross-country skiing, walking and swimming.<sup>32</sup>

#### PRACTICE PEARL

In the early stages, it is very difficult to distinguish medial compartment OA clinically from medial meniscal injury.

**Figure 37.11** Medial meniscus tear—a common cause of medial knee pain

A painful McMurray's manoeuvre may be present in either case. The sensation of grinding is consistent with arthritis while a palpable clunk during the McMurray's manoeuvre is more indicative of a meniscus tear. If weight-bearing radiographs are normal, MRI can distinguish the two conditions using specific articular cartilage sequences, including the technique of delayed gadolinium-enhanced MRI of cartilage (dGEMRIC), which estimates cartilage quality.<sup>34</sup>

Identifying and monitoring athletes at a high risk of OA can allow the opportunity for prevention and disease modifying interventions. Assessment of family history, previous knee injuries, muscle imbalances (specifically quadriceps weakness), lower limb biomechanics and body weight can be incorporated into a screening assessment. Preventive lower-limb-specific rehabilitation programs reduce the risk of lower limb injuries.<sup>35-37</sup>

## Treatment

Initial management of osteoarthritis includes symptomatic relief with cryotherapy, analgesia and NSAIDs.<sup>19</sup> A randomised clinical trial found that a custom-made, valgus-producing functional knee (unloader) brace provided significant benefit in this population of patients aged in their 60s.<sup>38</sup> Biomechanical studies have shown that these braces maintain condylar separation.<sup>39</sup> The benefits of glucosamine and chondroitin sulfate supplementation and viscosupplementation injections have been debated but do not appear to have a deleterious effect other than cost (Chapter 17).<sup>18, 40</sup> Modification of activity and exercise prescription, together with weight loss, should be addressed early.

If clinical symptoms are persistent and severe, referral to an orthopaedic surgeon is warranted. Arthroscopic 'clean out' procedures for patients with arthritis but no mechanical pathology have fallen into disfavour but may be effective if mechanical symptoms are present. Surgical intervention may include high tibial osteotomy, unicompartmental replacement and total knee replacement. Interestingly, early surgical intervention to prevent OA has not been shown to be superior to non-surgical treatments;<sup>32</sup> indeed, some surgeries have been linked to the development of early degenerative changes in young adults, for example, ACL reconstruction.<sup>41, 42</sup>

## Less common causes of medial knee pain

### Pes anserinus tendinopathy/bursitis

Athletes who present with pain over the anteromedial aspect of the knee distal to the joint line should be evaluated for a stress fracture or pes anserine bursitis. A stress fracture would present with focal pain and pain with impact. Pes anserine bursitis is characterised by localised tenderness and swelling three fingerbreadths distal to the medial joint line but it can mimic medial meniscus pathology. Active contraction or stretching of the medial hamstring muscles can reproduce pain.

The pes anserinus ('goose's foot') is the combined tendinous insertion of the sartorius, gracilis and semitendinosus tendons at their attachment to the tibia (Fig. 37.10b). The area is richly innervated as each muscle (sartorius, gracilis, semitendinosus) is supplied by a different nerve (femoral, obturator and tibial respectively). The primary action of these muscles is to flex the knee; however, they play an important stability role by resisting valgus strain.<sup>43, 44</sup> The risk of injury to the pes anserinus is increased with excessive valgus stress. Excessive valgus stress can be the result of collateral ligament instability, meniscal pathology, muscle imbalances or valgus knee deformity.<sup>44</sup> The pes anserinus bursa lies between the pes anserinus insertion and the periosteum and may become inflamed as a result of overuse. The pes anserinus tendons themselves can also be compressed or irritated, resulting

in a tendinopathy. Pes anserinus tendinopathy/bursitis is uncommon but may occur in swimmers (particularly breaststrokers), cyclists or runners.

Initial treatment follows the general principles of tendinopathy/bursitis management including cryotherapy, NSAIDs, electrotherapeutic modalities and eccentric stretching/strengthening. Ultrasound-guided corticosteroid injection into the bursa can be effective in reducing pain.<sup>45</sup> Advanced imaging such as MRI is rarely necessary, but may clarify the diagnosis or identify concomitant pathology in resistant cases.<sup>45</sup> For long-term results, biomechanical factors including the core, foot alignment and muscle imbalances, which can influence valgus forces, need to be addressed.

### Chronic MCL injuries and Pellegrini–Stieda syndrome

Due to its excellent vascularity and multiple-layered anatomy, the medial aspect of the knee and in particular the MCL has an excellent healing potential with conservative treatment. Nonetheless, a few factors correlate with chronic medial knee pain due to resistant healing of the MCL.

Chronic repetitive valgus loading of the knee has been correlated with medial knee pain in breaststrokers. The repetitive whip kick can stress the MCL or nearby bursa. Treatment is usually symptomatic with rest, kick modifications, cryotherapy, NSAIDs followed by a gradual return when asymptomatic. Steroid injections are discouraged as they may weaken the MCL.

Pellegrini–Stieda syndrome is a disruption of the femoral origin of the MCL with calcification at the site of injury. It can be a difficult lesion to assess before radiological changes become evident. It may follow direct trauma or, less frequently, a grade 2 or 3 sprain of the MCL. Note that imaging abnormalities exist in asymptomatic individuals.<sup>46</sup>

#### PRACTICE PEARL

**Pellegrini–Stieda syndrome is an important cause of knee stiffness. The patient complains of difficulty straightening the leg and twisting.**

Examination reveals marked restriction in joint range of motion with a tender lump in the proximal portion of the MCL. Treatment consists of active mobilisation of the knee joint and infiltration of a corticosteroid agent to the tender MCL attachment if pain persists. Surgery may be indicated in the presence of significant bone formation and persistent symptoms (pain and stiffness).<sup>47</sup>

Injuries of the distal insertion of the MCL can be difficult to distinguish between the pes anserine insertion and a chronic MCL injury. In rare cases, the distal MCL is avulsed as a sleeve off its tibial insertion, leading to persistent pain and instability. Clinically, the patient

will have pain 3–4 fingerbreadths distal to the joint line on the medial aspect of the knee. The key to clarifying the diagnosis with pes anserine bursitis is that a chronic injury of the MCL will be accompanied by valgus knee instability. If symptoms have been present for longer than 2 months, the potential for healing is poor and surgical repair is usually required.

### Other causes of medial knee pain

Perhaps the most important thing to consider in an athlete with medial knee pain is not the knee at all. The most important thing is to consider the pathologies that can radiate to the knee and, if missed, lead to catastrophic outcomes.

For the skeletally immature athlete with medial knee pain, the clinician should always consider the possibility of a hip pathology such as slipped capital femoral epiphysis or Legg-Calvé-Perthes' disease (Chapter 44). For skeletally mature athletes, one must be aware that a femoral neck stress fracture (Chapter 32) can radiate pain to the medial knee. Since missing these diagnoses has potential catastrophic long-term implication on hip function, every athlete with medial knee pain should be screened with a simple hip examination assessing range of motion, looking for these associated pathologies. Radicular pain to the medial knee may also be caused by lumbar spine pathology such as a herniated disc but any potential catastrophic implication is usually more obvious, with associated paraesthesias or motor weakness.

### POSTERIOR KNEE PAIN

The posterior knee is the most difficult and challenging region of the knee in which to make an accurate and specific diagnosis (Fig. 37.12). The anatomy is complex, there are multiple possible pathologies, structures are less superficial and the posterior knee pain is a common site of referred pain from the lumbar spine and from the patellofemoral joint. Reactive changes from other pathologies such as a knee effusion related to a meniscus tear may lead to pain and tightness of the back of the knee. The causes of posterior knee pain are shown in Table 37.3.

### Clinical evaluation

Posterior knee pain precipitated by acceleration or deceleration (e.g. downhill running, kicking, sprinting) may trigger symptoms related to biceps femoris or popliteus tendinopathy.

### History

Pain described as a poorly localised, dull ache that does not directly relate to activity is more suggestive of referred pain. The presence of low back pain, patellofemoral symptoms or other knee pathology may provide diagnostic clues.

### Examination

In the examination of the posterior aspect of the knee, it is important to differentiate between local and referred causes of pain. The slump test may indicate whether the pain is referred from the lumbar spine or neural structures. It is also important to detect the presence of an effusion as this may be the cause of the posterior knee pain.

**Figure 37.13 (cont.)** (c) Resisted movement—popliteus. With the patient supine, hips and knees flexed to 90° and the leg internally rotated, the patient is asked to 'hold it there' while the examiner applies an external rotation force (d) Palpation. This should be performed with the knee in flexion. Tenderness can be elicited over the hamstring tendons (shown), gastrocnemius origin or popliteus. It is helpful for the patient to gently contract and relax individual muscles that are being palpated in order for the examiner to precisely pinpoint the site of pain

### Investigations

Ideally, a good history and physical examination should lead to a confident diagnosis and obviate the need for additional investigations or advanced imaging. Nonetheless, it must be acknowledged that the anatomy and potential pathologies in the posterior aspect of the knee are

complex and additional studies may be prudent to clarify the diagnosis. Since many patients with deep venous thrombosis are asymptomatic, the clinician should be readily willing to order venous Doppler studies if history and symptoms dictate. Radiographs may be reserved for resistant cases, but may reveal loose bodies in the posterior compartment of the knee. Diagnostic ultrasound may be used to confirm the presence of a Baker's cyst or identify a tendinopathy, and is a valid tool to guide targeted injections. In most cases, MRI is the investigation of choice if the initial diagnosis does not respond to treatment.

### Baker's cyst

A Baker's cyst (popliteal cyst) is a synovial fluid filled mass located in the popliteal fossa.<sup>48</sup> The mass is often an enlarged bursa located beneath the medial gastrocnemius or semimembranosus muscles or both. It can be thought of as a chronic knee joint effusion (Fig. 37.14) that herniates between the two heads of the gastrocnemius.

In children the mass is often isolated and asymptomatic and resolves spontaneously. In adults the mass almost

**Figure 37.14** Baker's cyst (arrowed)—knee joint effusion herniating posteriorly; usually secondary to degenerative or meniscal pathology

always communicates with the knee joint and is secondary to intra-articular pathology.<sup>48</sup> Intra-articular pathology includes meniscal tears (most common), ACL deficiencies, cartilage degeneration and arthritis. The size of the mass may fluctuate.

Observation of an athlete's knee in standing often reveals a palpable, swollen, tender mass over the posteromedial joint line. End-of-range knee flexion can be restricted and painful. Deep squats and kneeling may also produce posterior knee pain. Due to its high association with intra-articular pathologies, a full assessment of the knee is warranted.

Radiographs may be of little use in the assessment of Baker's cyst, but may rule out other pathologies (e.g. calcification, loose bodies). Ultrasound can visualise the cyst but cannot assess intra-articular structures, which may be the underlying cause.<sup>48</sup> MRI will confirm the presence of the cyst and may identify the underlying intra-articular cause—it is considered the gold standard.<sup>48, 49</sup> Finally, aspiration can differentiate between inflammatory, infectious and mechanical aetiologies. Occasionally the cyst may rupture, leading to lower leg swelling that simulates venous thrombosis. A ruptured cyst usually displays a 'crescent sign'—an ecchymotic (bruised) area around the malleoli.

Initial treatment should involve addressing the underlying cause, (e.g. meniscal tear). Aspiration, together with steroid injection may be useful in the short term.<sup>48, 50</sup> Surgery may be indicated in symptomatic athletes presenting with a large, symptomatic mass. However, unless the underlying pathology is addressed, it is likely the mass will reform.

### Biceps femoris tendinopathy

Biceps femoris tendinopathy has been described earlier under lateral knee pain.

### Popliteus tendinopathy

The popliteus muscle arises from the posteromedial border of the proximal tibial metaphysis and travels proximally beneath the lateral head of the gastrocnemius to insert onto the lateral femoral condyle. It also has attachments to the fibula and the posterior horn of the lateral meniscus. A recent cadaveric study has confirmed the role of the popliteus tendon in limiting external and internal rotation, knee varus stresses and anterior translation of the femur (acts with the quadriceps and PCL).<sup>51</sup> Additionally, the popliteus has a role in unlocking the knee during initial flexion from an extended position and aids retraction of the posterior horn of the lateral meniscus to minimise compressive forces during knee flexion.

### Clinical features

With its role in knee stability, the popliteal tendon could be thought of as the fifth ligament of the knee.<sup>51</sup> Therefore,

assessment of tibial rotation during a routine knee stability assessment should be considered. Pain associated with the popliteus region may arise from the popliteus muscle, its tendon or the popliteus-arcuate ligament complex. Due to their close proximity, differentiation is difficult.

#### PRACTICE PEARL

Isolated popliteal muscle injuries are rare. Popliteal muscle injuries associated with lateral meniscus and PCL injuries are more common.<sup>51, 52</sup>

Posterior lateral instability is often associated with some degree of popliteal pathology.

Twisting activities can result in popliteal injuries, especially with associated posterior knee pain. Impingement of the popliteus tendon can occur with knee rotational instabilities (e.g. following posterior capsule-arcuate ligament strain) and overuse injuries are often associated with repetitive or prolonged acceleration/deceleration activities (e.g. downhill running).

Athletes typically present with posterior knee pain and may report some instability. The main clinical finding is tenderness on palpation along the proximal aspect of the tendon (Fig. 37.13d). With the athlete prone, palpation should begin near the posterolateral corner medial to the biceps tendon and then progress along the medial joint line. Resisted knee flexion in external tibial rotation may reproduce the athlete's pain (Fig. 37.13b).

Garrick and Webb<sup>53</sup> describe a test for the popliteus with the patient supine, hips and knees flexed to 90° and the leg internally rotated. The patient is asked to 'hold it there' while the examiner applies an external rotation force (Fig. 37.13c). It is important that the clinician assess both active and passive tibial rotation. Excessive rotation may be a result of repeated strain to the area. Knee flexion and extension range of motion at the end of range may be limited and also reproduce pain. Lower limb biomechanics should be assessed in terms of varus, valgus and rotational forces around the knee.

Soft tissue techniques and mobilisation may improve any restriction of tibial rotation or knee flexion/extension. Rehabilitation should focus on strengthening of the tibial rotators (Fig. 37.15) and hamstring muscles. Any weakness or fatigue in the quadriceps can add excessive strain on the popliteus and should be addressed, for example with a progressive strengthening program that includes tibial internal rotation.<sup>54</sup> Patients who fail to respond to initial treatment may benefit from corticosteroid injection posteriorly into the point of maximal tenderness or into the popliteus itself, guided by ultrasound.<sup>55</sup>

**Figure 37.15** Strengthening the tibial rotators. This may be performed against manual resistance (illustrated), with pulleys, rubber tubing resistance or with an isokinetic machine

### Other causes of posterior knee pain

#### Gastrocnemius tendinopathy

The origin of the medial gastrocnemius at the posterior femoral condyle occasionally is susceptible to painful overuse injuries, especially in runners. This may result from excessive hill running or a rapid increase in mileage.

Examination may reveal local tenderness and associated trigger points in the medial gastrocnemius muscle belly.

Pain may be reproduced on resisted knee flexion, calf raises with the knee in extension, jumping and hopping. Occasionally, stretching the gastrocnemius muscle can reproduce the athlete's pain. Possible biomechanical factors should be assessed, including muscle imbalances around the hip, knee and ankle. Knee stability, footwear and foot function should also be assessed.

Initial treatment may consist of activity modification, ice and local and generalised soft tissue therapy. A graduated/strengthening program is key to good long term results (Chapter 39).

#### Deep venous thrombosis

Deep venous thrombosis usually presents as calf pain (Chapter 39), but may occasionally present as posterior knee pain. It usually occurs after surgery or following a period of immobilisation. Due to the relative high incidence of asymptomatic deep venous thrombosis, it is important for the clinician to be liberal in the use of Doppler ultrasound or other vascular testing to rule it out, even with minimal suspicion. Distal swelling and some posterior knee pain or calf pain in an athlete who is on oral contraceptives, obese or post surgical, or who has a history of clotting problems, should be tested.

#### Claudication

Claudication can occasionally present as posterior knee pain. It can occur in young adults, not only in the older person. Popliteal artery entrapment syndrome usually presents as calf pain (Chapter 39).

# Leg pain

with MARK HUTCHINSON, WALTER KIM and MATT HISLOP

*I saw it once like two years ago... And that was it, I didn't need to see any more after that.*

Kevin Ware, commenting on his gruesome complete tibial fracture that occurred while contesting a loose ball in the NCAA in 2013

The leg, defined as the anatomic region below the knee but above the ankle, is a common site of complaints among athletes, particularly distance runners. The term 'shin splints' is commonly used by runners as a non-specific reference to leg pain. The same term is also often used by health professionals to describe pain along the medial tibial border or to describe shin pain in general. Neither use of the term is pathologically precise. There are multiple causes with defined pathophysiology that should lead the clinician to a more specific diagnosis of leg pain in athletes. A more accurate and specific diagnosis allows for targeted treatment. Therefore, the term 'shin splints' should be abandoned in favour of a more specific, anatomic and diagnostic terminology.

This chapter focuses on four major pathologies that cause leg pain:

- medial tibial stress fracture
- anterior tibial cortical stress fracture
- medial tibial stress syndrome
- chronic exertional compartment syndromes.

## CLINICAL APPROACH

Leg pain in athletes generally involves one or more of several pathological, anatomically specific processes.

1. **Bone stress.** A continuum of increased bone damage exists from bone strain to stress reaction and stress fracture.
2. **Vascular insufficiency.** This includes reduction in arterial inflow such as popliteal artery entrapment or vascular outflow due to venous insufficiency, thrombotic disease or vascular collapse due to elevated intracompartmental pressures.

3. **Inflammation.** This develops at the muscle insertions or along the tendons. Periosteal changes at the tibialis posterior and soleus, and fascia to the medial border of the tibia may be due to traction or a variation of the stress injury to bone.
4. **Elevated intracompartmental pressure.** The lower leg has a number of muscle compartments, each enveloped by a thick inelastic fascia. The muscle compartments of the lower leg are shown in Figure 38.1. As a result of overuse or inflammation, these muscle compartments may become swollen and painful, particularly if there is excessive fibrosis of the fascia.
5. **Nerve entrapment.**

The clarification between these processes and the narrowing of the differential diagnosis begins with the

**Figure 38.1** Cross-section of the lower leg (a) The various muscle compartments

**Figure 38.1 (cont.)** (b) The individual muscles, nerves and vessels

history, narrowed by clinical examination findings, and confirmed with specific targeted imaging or clinical tests (Table 38.1). It is important to remember that two or three of these conditions may exist simultaneously. For instance, it is not uncommon to have a stress fracture develop in a patient with chronic periostitis. Periostitis or stress fracture may lead to intracompartmental swelling and tip a patient on the edge of symptomatic exertional compartment syndrome over the edge. This interrelationship is demonstrated in Figure 38.2. These co-existing conditions are usually managed differently and this explains why patients continue to have leg pain when only one condition has been addressed. The less common differential diagnoses for leg pain include tendinopathy, nerve entrapment, vascular claudication, neurogenic claudication, deep venous thrombosis (DVT), infection (osteomyelitis, cellulitis), metabolic bone disease, and tumours of bone and soft tissues, which may in rare cases affect prognosis and outcome of leg pain in athletes.

### Role of biomechanics

Clinical experience suggests that abnormal biomechanics predisposes some individuals to pain on the anterior or medial border of the tibia (shin pain). Both extremes of foot type can contribute to the incidence of shin pain in athletes (Chapter 8). A rigid, cavus foot has limited shock absorption, thus increasing the impact pressure on the bone. In athletes with excessive pronation, the muscles of the superficial (soleus) and deep compartments (tibialis posterior, flexor hallucis longus [FHL], and flexor digitorum longus [FDL]) are placed at a relatively lengthened position and are required to contract eccentrically harder and longer to resist pronation after heel strike.

On toe off, these muscles must contract concentrically over a greater length to complete the transition to a supinated foot, creating a rigid lever for push off. With fatigue, these muscles fail to provide the normal degree of shock absorption. The chronic traction at the muscles' origins can lead to medial tibial stress syndrome. In chronic cases, this mechanism can contribute to the presentation of stress fractures or deep compartment syndromes.

The athlete with excessive pronation may also develop lateral shin pain or stress injuries of the fibula. Pronation of the fixed foot forces internal tibial rotation. With repetitive excessive pronation, the tibia and fibula are exposed to repetitive rotational (torque) stresses. These stresses are transferred across the fibula, tibia, and proximal and distal tibiofibular articulations. Based on these biomechanical stresses, overuse can lead to stress reactions or stress fracture, not only of the tibia but also of the fibula.

Motor imbalance can also lead to stress injuries in the lower extremity. Tight calf muscles, commonly the result of hard training, will restrict ankle dorsiflexion and increase the tendency for excessive pronation, leading to increased internal rotation of the tibia. Posterior tibial tendon weakness or deficiency can likewise contribute to foot pronation. Ankle instability secondary to chronic ankle sprains causes the athlete to overuse the peroneal tendons to compensate for ankle stability. This overuse can be just enough to send a athlete with borderline compartment syndrome over the brink to symptomatic complaints. To clearly understand biomechanics and have a foundation on which to create a differential diagnosis of leg pain, a complete knowledge of lower leg anatomy is essential (Figs. 38.1 and 38.3). When the presentation is atypical, one must expand the possibilities and consider a broad differential diagnosis for potential causes of leg pain in athletes (Table 38.2).

### History

Taking a thorough history is essential for correct diagnosis of athletes with leg pain. Asking the right questions should narrow the diagnosis. Clarifying the pain complaints and assessing mechanism is key to the history. The history should be thorough and assess the presence of associated features with the pain such as paraesthesia or muscle hernia.<sup>1</sup> A complete history should include a broad review of systems to discover other facets such as metabolic issues, prior surgical procedures, developmental problems, contributing medical issues and social issues such as smoking. When the diagnosis does not classically fit the simple pain screen, a broader differential should be considered.

**Table 38.1** The clinical characteristics and imaging features of common causes of shin pain in athletes

Condition	Pain	Effect of exercise	Associated features	Tenderness	Investigations
Bone stress reaction or stress fracture	Localised Acute or sharp Subcutaneous medial tibial surface or fibula	Constant or increasing  Worse with impact	May be exacerbated by vibration with a tuning fork or therapeutic ultrasound (however, neither are a sensitive clinical test)	Subcutaneous medial tibial surface or fibula	Radiographs may be negative • Use magnified views • Look for callous or periosteal reaction  MRI can stage severity and define prognosis but is also non-specific
Medial tibial stress syndrome	Diffuse pain on posteromedial border of tibia  Variable intensity	Decreases as athlete warms up and stretches	Worse in the morning and after exercise  Pes planus	Posteromedial edge of tibia at muscular insertions	Radiographs negative  MRI shows diffuse oedema and periosteal thickening
Chronic exertional compartment syndrome	No pain at rest Ache, tightness, gradually building with exertion	Specific onset variable between athletes; usually 10–15 minutes into exercise  Decreases with rest	Occasional muscle weakness or dysfunction with exercise  Paraesthesia of nerve in affected compartment is possible	None at rest Anterior and lateral more common with exertion  Occasionally related to palpable muscle herniation (superficial peroneal nerve)	Radiographs negative  Bone scans negative  Exertional compartment pressure testing is diagnostic  Exertional MRI or infrared oxygen assessment may also be diagnostic
Popliteal artery entrapment	Pain in calf with exertion; not anterolateral 'Atypical compartment syndrome'	Worse with exertion especially active ankle plantar flexion	Pulses may be diminished with active plantar flexion (assessed by palpation or Doppler ultrasound)	Rarely in proximal calf	Radiographs negative  MRI may reveal hypertrophic or abnormal insertion of medial gastrocnemius  MR arteriography with provocative manoeuvres is diagnostic
Muscle-tendon injuries  Strains  Tendinopathy	Pain at pathologic site with resisted stretch	Pre-participation stretching usually helps	Short-term symptom relief with NSAIDs and ice	Pain can be at muscle belly, muscle-tendon junction, tendon or tendon insertion	Rarely required  Radiographs usually negative  MRI gives best view of soft tissue pathology

**Figure 38.2** Possible interrelationship between the pathological sources of leg pain. These three entities need to be considered within a potentially critical factor—that of workload (represented by the surrounding box)

## Physical examination

In the examination of the patient with leg pain, it is important to palpate the site of maximal tenderness and assess the consistency of soft tissue. At rest, the physical examination for certain diagnoses (specifically chronic exertional compartment syndrome) is often unrewarding and the patient may be completely asymptomatic. The astute clinician will ask the athlete to reproduce the pain or symptoms via exertion or impact. This can be done on the athlete's playing surface, on a treadmill, or in and about the clinician's office by having the athlete run stairs or run around the block. A complete examination should be sequential, repeated the same way with each patient, and include observation, analysis of muscle function and range of motion, anatomically directed palpation, functional testing and diagnosis-specific testing (Fig. 38.4)

1. Observation. Assess lower limb alignment (varus/valgus, tibial torsion, pes planus) swelling, bruising, asymmetry:
  - a. standing (Fig. 38.4a)
  - b. walking—assess gait mechanics (forwards, backwards, on toes, on heels)
  - c. lying

(b)

Table 38.2 Causes of leg pain

Common	Less common	Not to be missed
Stress fracture <ul style="list-style-type: none"> <li>• Medial tibia</li> <li>• Anterior tibia*</li> </ul>	Stress fracture fibula	Tumours <ul style="list-style-type: none"> <li>• Osteosarcoma</li> <li>• Osteoid osteoma</li> </ul>
Acute fracture	Referred pain from spine	Infection (osteomyelitis, cellulitis)
Medial tibial stress syndrome	Chronic compartment syndrome <ul style="list-style-type: none"> <li>• Superficial posterior</li> </ul>	Acute compartment syndrome
Periosteal contusion	Vascular insufficiency/claudication	Chronic transition to acute compartment syndrome
Chronic compartment syndrome <ul style="list-style-type: none"> <li>• Anterior</li> <li>• Lateral (peroneal)</li> <li>• Deep posterior</li> </ul>	DVT (Chapter 39)	Chronic ankle injuries and Maisonneuve fracture
	Popliteal artery entrapment	<b>Rare and unusual</b>
	Femoral endarteritis	Syphilis
	Atherosclerotic disease	Sickle cell anaemia
	Superficial peroneal nerve entrapment	Hyperparathyroidism
	Muscle herniations	Sarcoidosis
	Baker's cysts or ganglion cysts	Rickets
	Osgood–Schlatter's disease (Chapter 44)	Paget's disease
	Pes anserine bursitis	Erythema nodosum
	Proximal tibiofibular subluxation	
	Electrolyte and metabolic dehydration cramping	

\*Anterior tibial cortex stress fractures are less 'common' than medial tibial stress fractures but included here because of their clinical significance and because we discuss the two types of stress fractures in adjacent sections of this chapter.

2. Active movements. Assess motor function and range of motion:
  - a. plantarflexion/dorsiflexion—check pulses in full plantar or dorsiflexion; if diminished, consider popliteal artery entrapment
  - b. inversion/eversion
  - c. flexion and extension of the knee will put the gastrocnemius/soleus complex in a contracted or relaxed position
3. Passive movements. Assess true joint range of motion. May exacerbate pain in compartment syndromes:
  - a. plantarflexion (Fig. 38.4b)
  - b. dorsiflexion (Fig. 38.4c)
  - c. inversion/eversion
4. Resisted movements. Assess motor function. May exacerbate pain in muscle strains and tendinopathy:
  - a. plantarflexion/dorsiflexion
  - b. inversion/eversion
5. Functional tests:
  - a. hopping (Fig. 38.4d)—requires motor strength and landing skills. Rigid landing on heels exacerbates the pain of stress fracture
  - b. jumping
    - c. running—may bring on pain of exertional compartment syndrome or popliteal artery entrapment symptoms. Athletes should always reproduce symptoms
    - d. stair-climbing
6. Palpation. Evaluate pain distribution, warmth, swelling, pitting oedema, posterior cords or the presence of crepitus with motion:
  - a. tibia (Fig. 38.4e)—focal pain indicates stress fracture, diffuse pain over posterior medial border of tibia indicates medial tibial stress syndrome
  - b. fibula—the entire fibula should be palpated to identify focal pain related to a stress fracture. Severe eversion/external rotation ankle sprains may injure the syndesmotic connection between the tibia and fibula and be associated with a proximal fibula fracture (Maisonneuve fracture)
  - c. gastrocnemius, plantaris and soleus muscles (Fig. 38.4f)—look for muscle strains and ruptures. Tennis leg is a partial rupture of the medial head of the gastrocnemius vs plantaris
  - d. gastrocnemius-soleus aponeurosis (Fig. 38.4g)—assess for swelling and focal tenderness. May indicate tendinosis vs bursitis

## Key diagnostic questions

Question	Clinical significance of response
<i>Was there an acute onset of pain?</i>	Fractures and tendon ruptures are usually acute traumatic events. In athletes, the acute onset of pain may be preceded by low-grade chronic pain of a stress fracture or tendinopathy.
<i>Is the pain chronic but stable?</i>	Pain that is getting worse over time should raise concerns of a tumour.
<i>Do you have a history of injury or prior leg pains?</i>	Old fractures or injuries can lead to scar tissue, stiffness and pain.
<i>Is the pain worse with impact?</i>	Stress fractures are normally exacerbated with impact. Medial tibial stress syndrome and muscle strains may also be made worse with loading and resistance.
<i>Is the pain worse with exertion?</i>	Pain absent at rest, that presents with exertion is classic for exertional compartment syndrome. Nonetheless, popliteal artery entrapment can have a similar presentation with posterior rather than anterior/lateral pain.
<i>Does the pain improve with warm-up and stretching?</i>	Medial tibial stress syndrome and muscle strains will frequently improve with pre-participation stretching, while stress fractures and exertional compartment syndrome generally do not.
<i>Does the pain get worse with stretching or resistance?</i>	Providing resistance to the muscle–tendon units including their origins and insertions should exacerbate symptoms related to medial tibial stress syndrome and muscle–tendon strains and tendinopathy.
<i>Where is the pain?</i> <i>Is the pain focal?</i> <i>Is the pain diffuse?</i>	The anatomic site of pain is the best physical clue to diagnosis. Focal pain over bone should raise suspicion of a stress fracture; focal pain over the muscle–tendon is likely a muscle strain or tendinopathy; diffuse pain over the posteromedial border of the tibia is likely medial tibial stress syndrome.
<i>Do you have swelling with the pain?</i> <i>Is it diffuse?</i> <i>Is it focal?</i>	Localised swelling is possible with a contusion, a stress fracture or muscle herniation. Diffuse swelling may indicate more significant injury or vascular problems like a DVT. Medial tibial stress syndrome may have palpable swelling about muscle insertions on the posterior medial border of the tibia.
<i>Do you feel electrical shooting pain?</i> <i>Do you have weakness with the pain?</i> <i>Do you get numbness with the pain?</i>	Electrical shooting pain, dermatomal loss of sensation and sclerotomal loss of motor power usually indicate nerve injury, entrapment or radiculopathy. Always check the lumbar spine.
<i>Does the pain get better with ice or non-steroidal anti-inflammatories (NSAIDs)?</i>	Pathologies associated with inflammation should improve with cold therapy and anti-inflammatories. Osteoid osteomas (a benign bone tumour) are known to have significant response to aspirin.
<i>Do you have pain at night?</i>	Pain that wakes a patient up at night should raise concern about tumours.

- e. superficial and deep posterior compartment (Fig. 38.4h)
- f. anterior and lateral compartment–post-exertion palpation may reveal tenseness in exertional compartment syndrome or palpable localised mass due to muscle herniation

## 7. Special physical examination tests:

- a. stress fracture test (Fig. 38.4i)–vibration may exacerbate pain associated with a stress fracture. Applying a vibrating tuning fork along the subcutaneous border of the tibia is a convenient and inexpensive test easily applied in the training room

(f)

(g)

**Figure 38.4 (cont.)** (e) Palpation—tibia. Palpate for the exact site of focal tenderness. Determine if pain is diffuse, focal or multifocal. Bony irregularity or subtle swelling may occur along the medial tibial border with medial tibial stress syndrome or stress fractures (f) Palpation—soleus muscle belly. A pincer grip is used (g) Palpation—soleus aponeurosis. Palpate for sites of tenderness and associated taut bands that may be a precipitating factor in the development of inflammatory shin pain

or office; however, this test's sensitivity (35–92) and specificity (19–83) is not well established<sup>2</sup>

- b. pain may also be exacerbated when therapeutic ultrasound is applied over a bone stress injury. However, this test has both poor sensitivity (64) and specificity (63),<sup>2</sup> and its use is not recommended.
- c. biomechanical examination (Chapter 8).

### Key outcome measures

The medial tibial stress syndrome score<sup>3</sup> is a valid and reliable outcome measure for medial tibial stress syndrome patients (Table 38.3). As there are few other tools to

monitor leg pain, this questionnaire could also be used for patients with lower leg stress fractures. There are currently no questionnaires to monitor chronic exertional compartment syndrome.

### Investigations

Following the history and physical examination, extended work-up should target the most likely diagnosis. Imaging options included radiographs, MRI, CT scan, angiography, ultrasound and nuclear medicine scans. Routine radiography is rarely obviously positive in the diagnosis of leg pain. Careful inspection may reveal a subtle radiolucent line

(h)

(i)

**Figure 38.4 (cont.)** (h) Palpation—deep posterior compartment. This is palpated through the relaxed overlying muscles. In compartment pressure syndrome, the entire compartment feels tight in contrast to the localised tissue tightness of chronic muscle strain. Muscle or fascial hernias are occasionally found. The superficial posterior compartment should also be palpated (i) Special test—stress fracture. Applying vibration using a tuning fork over the site of tenderness can provoke pain in the presence of a stress fracture

**Table 38.3** Patient-reported outcome measures for leg pain

Medial tibial stress syndrome score
<ul style="list-style-type: none"> <li>• Simple self-administered questionnaire that evaluates pain and function in patients with medial tibial stress syndrome</li> <li>• 4 items</li> <li>• Score range 0–10</li> <li>• Test-retest reliability (1 week): 0.82</li> <li>• Construct validity: moderate to strong correlation with items of RAND-36 and with changes in the volume and intensity of patients' sporting activities</li> <li>• MDC: 0.69</li> <li>• MCID: 0.69</li> <li>• Available online: <a href="http://www.sportsoutcomemeasures.com">www.sportsoutcomemeasures.com</a></li> </ul>

indicating a stress fracture, but radiography has a very low sensitivity for stress fractures generally and that applies particularly at this site (tibia).

Historically, radioisotopic bone scan was the next test in line to confirm the presence of a stress fracture or medial tibial stress syndrome. For stress fractures, a discrete focal area of increased uptake is seen on either the tibia (Fig. 38.5a) or fibula. In chronic medial tibial stress syndrome, the bone scan may show patchy areas of increased uptake along the medial border of the tibia. The absence of uptake does not preclude the diagnosis of medial tibial stress syndrome. No identifiable changes on the bone scan are associated with compartment syndrome.<sup>4</sup>

#### PRACTICE PEARL

**MRI is the investigation of choice in patients with leg pain on the basis of its sensitivity to evaluate bony lesions, marrow changes and soft tissue injuries and correlate these findings with clinical symptoms.<sup>5</sup>**

Typically, a stress fracture will appear on MRI as an area of periosteal oedema (Fig. 38.5b). The severity of injury documented on MRI (bone oedema only, unicortical radiolucent line or bicortical radiolucent line) has been correlated with healing time.<sup>6, 7</sup> Medial tibial stress syndrome will appear with a broader area of oedema with thickening of the posterior medial periosteum or multiple small stress injuries of the bone. The MRI may also confirm the diagnosis of a muscle strain, muscle herniation, as well as benign (lipoma, cysts, osteoid osteoma) and malignant tumours. Magnetic resonance arteriography (MRA) with dynamic plantarflexion is the test of choice to confirm popliteal artery entrapment syndrome (Chapter 39).

(a)

(b)

**Figure 38.5** Characteristic appearances on imaging (a) Bone scan of tibial stress fracture (b) MRI of tibial stress fracture showing fracture line (arrows) in the presence of marrow oedema

### Investigation of chronic exertional compartment syndrome

For many years, it has been desirable to find a non-invasive method to confirm the diagnosis of chronic exertional compartment syndrome (CECS). Pre- and post-exertional MRI scans may reveal intracompartmental oedema confirming the diagnosis of an exertional compartment syndrome, but this is an expensive alternative. The role of MRI in the diagnosis of compartment syndromes is still unclear.<sup>5, 8, 9</sup> Recently, diffusion tensor magnetic resonance imaging (DTI) and ultrasound have emerged as potentially attractive non-invasive alternatives.

Ultrasound provides a non-invasive, cost-effective and readily available tool to diagnose CECS of the anterior compartment of the lower extremity.<sup>10</sup> Originally described by Gershuni et al.,<sup>11</sup> Martinson and Stokes<sup>12</sup> subsequently devised a technique using ultrasound to measure the thickness of the anterior compartment of the lower leg. Birtles et al.<sup>13, 14</sup> expanded upon this technique to measure anterior compartment thickness in patients with CECS versus control subjects when performing eccentric and isometric exercises. Rajasekaran et al. measured anterior compartment thickness in patients at pre- and post-exertion periods, defined as running for at least 5 minutes up to 7 mph on a 20% incline on a treadmill. Patients with CECS had a significant difference and percentage change in anterior compartment thickness at all post-exertional time points versus resting levels when compared to control subjects.<sup>10</sup>

The use of ultrasonography may also contribute to understanding the pathophysiology behind CECS. In CECS patients, a convexity in the anterior fascial layer was noted during the post-exertional period. The combined effect of fascial bowing with a significant increase in anterior compartment thickness among CECS patients appears to offer an alternative explanation to the fascial non-compliance theory secondary to repetitive overuse and inflammation in the causation of CECS. In addition, recent studies show no significant difference in fascial elasticity in patients with CECS versus control subjects in the anterior leg compartment, which lie in stark contrast to previous findings.<sup>15</sup>

DTI is a non-invasive MRI marker that can serve as a diagnostic probe for pathologic conditions involving skeletal muscles. Ischaemia, inflammation, and injury to the muscle all provoke degenerative changes in the myofibril and are able to be detected via DTI metrics such as mean diffusivity and fractional anisotropy. Patients with defined CECS via T2-weighted imaging (>20% change in signal intensity in each compartment) had significantly increased diffusion rates that were anisotropic in nature after exercise with the most affected compartments being the anterior and superficial posterior compartment.

This was postulated to be from elevated temperatures increasing water diffusion rates, structural dilation of the myofibrils or interfibre oedema with exercise. Further development of this technique may lead to its use in the diagnosis and evaluation of response to treatment in CECS patients.<sup>16, 17</sup>

#### PRACTICE PEARL

Intracompartment pressure measurement is the gold standard in confirming the diagnosis of chronic exertional compartment syndrome in the athlete.

Pre-exertion and immediate post-exertion measurements are essential to confirm the diagnosis. Devices used to measure the pressure have ranged from a wall blood pressure monitor with intravenous tubing and a three-way stopcock (Whiteside's technique), the transducer and pump used for an arterial line, laboratory systems and hand-held devices. In each case, the fascia is punctured percutaneously with a hollow bore needle, a needle with a side-port or by placement of a slit catheter.

A summary of the recommended techniques with appropriate exercises to produce pain is shown in Table 38.4.

The anterior compartment is relatively easy to find just lateral to the anterior border of the tibia with the lateral compartment being just lateral to the anterior compartment and anterior to the fibula. The deep posterior compartment or, if present, the tibialis posterior compartment may be more difficult to locate but is usually accessed posterior to the posteromedial edge of the tibia. Some experts recommend the use of ultrasound guidance to ensure correct catheter placement.<sup>18</sup>

#### PRACTICE PEARL

In clinical practice, the most widely used diagnostic criteria has been a basal intracompartmental pressure (ICP) of >15 mmHg, 1 minute post-exertion >30 mmHg and a 5 minute post-exertion >20 mmHg.<sup>19</sup>

There is currently no universally accepted method or ICP threshold for the diagnosis of CECS. Pressures between 10–20 mmHg or those that decrease with exercise are considered to be inconclusive. A systematic review showed the strength of evidence supporting these criteria to be weak, owing to the fact that there is high variability and inconsistency in pressure measurements, operator experience, catheter type used, volume of

**Table 38.4** Compartment pressure testing

Compartment	Location of catheter	Exacerbating exercise	Compartment pressures (N=10 mmHg, post-exercise 5 min)
Deep posterior	Junction of lower and middle third of tibia Aim deep posteriorly just behind the posteromedial tibial border	Treadmill/running Stairs Run/jump Pulleys in PF/DF Repeated case raises Isokinetic PF with IV/EV Sports-specific challenges	>25 mmHg post exercise or an increase of >10 mmHg compared to resting baseline
Superficial posterior	Aim more posteriorly from deep posterior entry into medial gastrocnemius or soleus	Treadmill Stairs Repeated calf raises	Same as above
Anterior	Mid-belly of tibialis anterior Anterior to intermuscular septum (half-way between fibula and anterior border of tibia)	Repeated DF Treadmill/running Stairs Sports-specific challenges	Same as above
Lateral (Peroneal)	Mid-belly of peroneals Posterior to intermuscular septum	Repeated IV/EV Treadmill/running Stairs	Same as above

Ankle movements: PF = plantarflexion, DF = dorsiflexion, IV = inversion, EV = eversion

instilled fluid used and depth of catheter placement.<sup>20</sup> Admittedly, it is still the most common criteria used as there is no established technique that has been shown to be more effective.

Dynamic measurement of ICP has been introduced to address shortcomings associated with current static time driven methods of ICP measurement. This includes avoidance of multiple needle sticks and data collection that is reliable, extensive and not prone to artefact and technical issues associated with fluid-filled catheters/devices. Dynamic measurement allows changes in ICP to be matched to symptom development in real time during a standardised exercise challenge. This offers a more sensitive and specific method to diagnose CECS. Compared to the widely used Pedowitz criteria of ICP >30 mmHg 1 minute post exercise and ICP >20 mmHg 5 minutes post exercise, a threshold level of 105 mmHg achieved during active exercise was found to provide the greatest diagnostic validity in patients exhibiting symptoms of CECS. This indicates that continuous measurement of ICP throughout the duration of exercise improves its diagnostic utility in accurately diagnosing CECS.<sup>21</sup>

By increasing the diagnostic validity of methods used to diagnose CECS, we can potentially avoid poor outcomes after fasciotomy through better patient selection. By being able to differentiate between patients who exhibit symptoms of CECS but ultimately lack a pressure-related aetiology versus those that have a pressure-related condition, we can identify potential patients who stand to have a higher likelihood of a positive outcome after fasciotomy. Other authors have promoted the use of non-invasive methods such as near-infrared spectroscopy, and results are promising but require further validation.<sup>9</sup>

Additional work-up for more atypical causes of leg pain include:

- EMG/nerve conduction studies
  - peripheral nerve entrapments & metabolic neuropathy
- Ankle/brachial index
  - vascular claudication
- Venous Doppler
  - deep venous thrombosis
- Laboratory
  - CBC (complete blood count) with differential—infection or osteomyelitis
  - ESR (erythrocyte sedimentary rate)—inflammation, rheumatologic conditions
  - sickle cell preparation—sickle cell anemia
  - urine analysis with uromyoglobin—rhabdomyolysis
  - CPK (creatinine phosphokinase), myoglobin—rhabdomyolysis, myopathy
  - PT (prothrombin time), APTT (activated partial thromboplastin time)—deep venous thrombosis

- D-dimer—deep venous thrombosis
- metabolic panel—hypokalemia, hypocalcemia, hypomagnesium, etc
- T<sub>3</sub> (triiodothyronine), T<sub>4</sub> (thyroxine), TSH (thyroid stimulating hormone)—thyroid myopathy.

## MEDIAL STRESS FRACTURE OF THE TIBIA

Stress fractures are more commonly a cause of leg pain in athletes in impact, running and jumping sports. Overall limb and foot alignment as well as limb length discrepancy may also play a role. Runners with stress fractures have been shown to have a reduced cortical strength, a reduced cross-sectional area of cortical bone (thinner cortices) and reduced muscle cross-sectional area compared to athletes without a history of stress fractures.<sup>22</sup> The incidence of stress fractures increases on more rigid, unforgiving surfaces.

### PRACTICE PEARL

Approximately 90% of tibial stress fractures will affect the posteromedial aspect of the tibia. The most common site is near the junction of the middle and distal thirds.

Proximal metaphyseal stress fractures may lead to more time loss from sport, as they do not respond as well to the functional bracing that allows earlier return to play. We discuss the dreaded 'anterior cortical tibial stress fracture' in a separate section.

## Assessment

A typical posteromedial tibial stress fracture presents with the following clinical features:

- pain is gradual in its onset, aggravated by exercise, often with a recent history of an increase in training intensity
- pain may occur with walking, at rest or even at night.
- examination shows localised tenderness over the tibia.
- biomechanical examination may show a rigid, cavus foot incapable of absorbing load, an excessively pronating foot causing excessive muscle fatigue or a leg-length discrepancy
- tenderness to palpation along the medial border with obvious tenderness. Note that stress fractures of the posterior cortex occasionally produce symptoms of calf pain (Chapter 39) rather than leg pain
- bone scan and MRI appearances are of a stress fracture of the tibia, as shown in Figures 38.5a and 38.5b. MRI scans are particularly valuable, as the extent of oedema

and cortical involvement has been directly correlated with the expected return to sport<sup>7</sup>

- CT scan may also demonstrate a stress fracture (Fig. 38.6).

## Treatment

Prior to initiating treatment or during the treatment plan, it is important to identify which factors precipitated the stress fracture. The most common cause is an acute or chronic change in training habits, such as rapidly increasing distance over a short period,<sup>23</sup> beginning double-practice days after a period of reduced training or changing to a more rigid playing surface. Footwear, abnormal biomechanics, and repetitive impact sports such as running and gymnastics have also been implicated. Systematic reviews have shown that the use of custom semi-rigid orthotics led to lower incidence of stress fractures in athletes and military recruits.<sup>24</sup> Coaches can play a key role in modifying training patterns to reduce the risk of these injuries.

In women, reduced bone density may increase risk of stress fracture.<sup>25</sup> All female athletes with a first time stress fracture should be screened for Relative Energy Deficiency in Sport (RED-S) (Chapter 4). Research has focused on reducing the vertical loading rate and ground reactive force by modifying stride length, gait retraining and running speed.<sup>25-29</sup> These studies suggest that a softer running style can prevent the development of stress fractures. This can be attained through:

1. a shorter stride length
2. slower running speeds
3. reduced mileage (reduces the number of impacts).

**Figure 38.6** Axial CT at the region of the mid-calf showing the posteromedial aspect of the right tibia affected by a longitudinal stress fracture

The classic treatment plan is as follows:

- initial period of rest (sometimes requiring a period of non weight-bearing on crutches for pain relief) until the pain settles
- use of a pneumatic brace (Air-Stirrup® Leg Brace, Aircast®, New Jersey, USA), which has markedly reduced return to activity time compared with 'standard' recovery times in two of three studies<sup>30, 31</sup> and compared with a 'traditional treatment' group in the third.<sup>32</sup> In this latter study, the brace group returned to full, unrestricted activity in an average of 21 days compared with 77 days in the traditional group. The brace should extend to the knee as the mid-leg version may actually increase the stress across a midshaft stress fracture. Routine use of this treatment modality, implies rest and full-time use for 1-2 weeks. During that time, the athlete should notice excellent pain control while in the brace. If this positive response is achieved, then the athlete is allowed to gradually return to impact activities and play in the brace. If pain returns, the period of rest is extended. As long as the pain is well controlled, the athlete is allowed to return to full athletic participation in the brace. Most athletes will complete their competitive season using the brace as complete healing may not occur while the athlete is still loading the leg with or without the brace. Using this plan, there have been no reported cases of progression to complete catastrophic fracture of the tibia
- if pain persists, continue to rest from sporting activity until the bony tenderness disappears (4-8 weeks)
- once the patient is pain-free when walking and has no bony tenderness, gradually progress the quality and quantity of the exercise over the following month. Please note, the athlete is asked to continue to use a pneumatic brace to complete the current season until an appropriate period (4-8 weeks) of rest can occur
- cross-training with low-impact exercises including swimming, cycling, and water running maintains conditioning and reduces risk of recurrence
- pain associated with soft tissues distal to the fracture site can be treated using soft tissue techniques
- general principles of return to activity following overuse injury should be followed (Chapter 18).

## Prevention of recurrence

- Determine whether excessive training and abnormal biomechanics precipitated the stress fracture.
- Inadequate calorie balance is a risk factor for stress fractures (Chapter 4).
- Alternative treatments including electrical stimulation and low-intensity pulsed ultrasound (LIPUS)<sup>33, 34</sup> have

been tried as a way to accelerate healing or prevent recurrence but have not proven effective (Chapter 17).

- Bisphosphonates have no place in the treatment or prevention of these stress fractures.<sup>35</sup>

## STRESS FRACTURE OF THE ANTERIOR CORTEX OF THE TIBIA

### PRACTICE PEARL

Stress fractures of the anterior cortex of the mid-shaft of the tibia need to be considered separately because they are prone to delayed union, non-union and complete fracture.

Stress fracture of the anterior cortex of the medial third of the tibia presents with diffuse dull pain aggravated by physical activity. The bone is tender to palpation at the site of the fracture and periosteal thickening as evidenced by a palpable lump may be present if the symptoms have been present for some months. Isotopic bone scan (Fig. 38.7a) shows a discrete focal area of increased activity in the anterior cortex. The radiographic appearance at this stage shows a defect in the anterior cortex, which is termed the 'dreaded black line' (Fig. 38.7b). This appearance is due to bony resorption and is indicative of non-union.

The mid-anterior cortex of the tibia is vulnerable to non-union for two reasons: it has a relatively poor blood supply and it is an area under tension due to the morphologic bowing of the tibia. Excessive anterior tibial bowing is often noted in association with this fracture. In general, the prognosis for these resistant stress injuries is guarded, with an elevated risk of delayed or non-union. One study presented some success with the use of pneumatic air braces in this population, avoiding the need for surgery.<sup>36</sup> The average return to unrestricted activities was 12 months with this form of treatment. Other options for treatment include pulsed electromagnetic stimulation, surgical excision and bone grafting and transverse drilling at the fracture site. Chang and Harris described five cases treated with intramedullary tibial nailing.<sup>37</sup> They had two excellent and three good results.

### Treatment

Our current treatment protocol is as follows:

- immediate application of a pneumatic brace
- discontinuing anti-inflammatory medications and smoking
- thorough screening for associated nutritional, biomechanical and nutritional risk factors
- for all elite-level athletes, application of electrical or ultrasonic bone stimulation
- if no progress by 4-6 months, intramedullary rodding (+/-) bone grafting, debridement or drilling is recommended.

## MEDIAL TIBIAL STRESS SYNDROME

As noted previously, there has been a tendency in the past to categorise all shin pain, especially that which is not a stress fracture, under the term 'shin splints'.<sup>38</sup> Indeed, 'shin splints' is more of a vague symptom athletes describe for leg pain most commonly along the posterior medial border of their tibia. Imaging techniques such as CT and MRI allow us to make more precise anatomical and pathological diagnoses of patients with leg pain.

### PRACTICE PEARL

The most descriptive term that accounts for the inflammatory, traction phenomena on the medial aspect of the leg more common in runners is medial tibial stress syndrome or medial tibial traction stress syndrome.

However, recent studies have argued that the process may be more similar to stress injury of the bone and argue that no inflammatory process is present.

The patient with medial tibial stress syndrome complains of diffuse pain along the medial border of the tibia (the junction of the lower third and upper two-thirds of the tibia), which usually decreases with warming up. The incidence has been reported between 4% and 35% in military personnel and athletes.<sup>39, 40</sup> More focal pain should alert the examiner to the possibility of a true stress fracture. The athlete can often complete the training session but pain gradually recurs after exercise and is worse the following morning. Historically, the tibialis posterior was thought to be the source of the pain, but more recently the soleus and flexor digitorum longus have been implicated.<sup>39</sup>

### Risk factors

A number of factors may contribute to the increased stress and traction on the posterior medial aspect of the tibia. These include excessive pronation (Chapter 8), training errors, shoe design, surface type, muscle dysfunction, fatigue and decreased flexibility.<sup>41</sup> Other risk factors that have been reported include female sex, higher body mass index, greater internal and external rotation of the hip, increased calf girth, and a history of previous stress fractures or use of orthotics.<sup>40, 42</sup>

The biomechanics of medial tibial stress syndrome relates to the sequence of events that occurs with walking and running.<sup>43</sup> During midstance, foot pronation provides shock absorption and an accommodation to the varied

terrain. The medial soleus is the strongest plantar flexor and invertor of the foot. The soleus muscle eccentrically contracts to resist pronation. Excessive pronation due to pes planus or overuse combined with repetitive impact loading leads to chronic traction over its insertion onto the periosteum on posterior medial border of the tibia leading directly to medial tibial traction stress syndrome and medial tibial stress syndrome.

Metabolic bone health may also contribute. Magnusson et al. found athletes with medial tibial stress syndrome had lower bone mineral density at the affected region compared with control and athletic control subjects.<sup>44</sup> Bone mineral density was also decreased on the unaffected side in subjects with unilateral symptoms.<sup>44</sup> These athletes regained normal bone mineral density after recovery from their symptoms.<sup>45</sup> Reduced bone density or bone load tolerance may contribute to the increased risk of medial tibial stress syndrome seen in female military recruits. A study examining possible risk factors for the development of medial shin pain in military recruits showed that females were three times as likely to develop the syndrome.<sup>46</sup> Beyond sex, no other risk factors of statistical significance were noted; however, increased hip range of motion (both internal and external rotation) and lower lean calf girth were associated with medial shin pain in the male recruits.<sup>46</sup>

Radiographs are normally negative with medial tibial stress syndrome. However, it is sometimes possible to see periosteal reactions or localised swelling. Isotopic bone scan may show patchy, diffuse areas of increased uptake along the medial border of the tibia. This is in contrast to stress fractures, which should show focal uptake. In the early stages of medial tibial stress syndrome, however, the bone scan appearance may also be normal. MRI was found to have similar sensitivity and specificity to isotope bone scan.<sup>9</sup> Interestingly, there were a number of abnormal bone scan and MRI appearances in the asymptomatic control group in that study.

### Treatment

Most athletes will present with a long history of complaints, having tried a number of home remedies, stretches, medicines or cold treatment. Assessing previous treatments in terms of what provided relief and what exacerbated the problem is beneficial. While heat or whirlpool may improve flexibility and warm up muscles, it also increases the circulation to the region, which can increase symptoms.

The foundation of treatment is based on symptomatic relief, identification of risk factors and treating the underlying pathology. Symptomatic treatment begins

with rest, ice and analgesia as needed. Switching to pain-free cross-training activities such as swimming or cycling can keep the athlete active. Craig has suggested that no current method of treatment is better than rest alone; yet she still suggests the use of shock-absorptive insoles as promising.<sup>39, 47</sup>

In resistant cases, immobilisation and protected weight-bearing may be necessary to rest the chronic tension placed on the soleus insertion with repeated weight-bearing. Taping techniques are only effective if they control foot pronation.

A critical facet of treatment is based on a careful assessment of foot alignment and gait mechanics. Permanent relief can occasionally be achieved through appropriate footwear and the application of cushioned orthotics (for shock absorption assistance) with a semi-rigid medial arch support (to support the pronated foot). We have found positive results in our patients, at least in the initial phase, by treating them with the same knee-high pneumatic splint that we use for stress fractures (Air-Stirrup Leg Brace®, Aircast®, New Jersey, USA).

Alternative modalities can be effective in relieving pain and should be considered in patients with medial tibial stress syndrome. The entire calf muscle should be assessed for areas of tightness or focal thickening that can be treated with appropriate soft tissue techniques (Chapter 17). Digital ischaemic pressure may be applied to the thickened muscle fibres of the soleus, flexor digitorum longus and tibialis posterior adjacent to their bony attachment, avoiding the site of periosteal attachment, which may prove too painful (Fig. 38.8a). The effect may be enhanced by adding passive dorsiflexion and plantarflexion while digital ischaemic pressure is applied. Transverse frictions are commonly used in clinical practice to treat focal regions of muscle thickening in the soleus and flexor digitorum longus.

Abnormalities of the tibialis posterior may be treated through the relaxed overlying muscles. Sustained myofascial tension can be applied parallel to the tibial border, releasing the flexor digitorum longus and along the soleus aponeurosis in the direction of normal stress with combined active ankle dorsiflexion (Fig. 38.8b).

Physical therapy programs have focused on motor strengthening and flexibility, especially proprioceptive neuromuscular facilitation (PNF) stretching. In addition, electrical stimulation, iontophoresis and ultrasound have been attempted, with mixed results. Prolotherapy injection with agents intended to accelerate the healing process and platelet-rich plasma injections have also been performed, but very little quality research is available to validate their efficacy. In resistant cases, surgical release (with or without periosteal tissue resection or ablation)

(a)

(b)

**Figure 38.8** Soft tissue therapy in the treatment of shin pain (a) Digital ischaemic pressure to the medial soleus aponeurosis and flexor digitorum longus. of the superficial and posterior compartments from its conjoined insertion onto the posteromedial border of the tibia can be performed with a projected success rate of 70% improvement in high-performance elite athletes.<sup>38, 48</sup>

## CHRONIC EXERTIONAL COMPARTMENT SYNDROME

Compartment syndrome is defined as increased pressure within a closed fibro-osseous space causing reduced blood flow and reduced tissue perfusion subsequently leading to ischaemic pain and possible permanent damage to the tissues of the compartment.<sup>49</sup> This may be acute, chronic (exertional) or convert from chronic to acute. Together with stress fractures and medial tibial stress syndrome, CECS is a key differential diagnosis of leg pain in athletes, especially in distance runners and other endurance athletes. The syndrome is frequently bilateral. When the pain is in the calf, the clinician should also consider popliteal artery entrapment syndrome (Chapter 39).

### Pathogenesis

While classically, exertional compartment syndrome was believed to be an ischaemic phenomenon like acute compartment syndrome, the exact aetiology of CECS is still unclear. Repetitive overuse followed by associated inflammation may lead to fibrosis and therefore reduced elasticity of the fascia surrounding the muscle compartments. As a result, when the patient exercises, the muscles attempt to expand but are unable to do so.

Biopsies have revealed abnormally thickened, non-compliant fascia. A series of biopsies at the fascial-periosteal interface revealed varying degrees of fibrocytic activity, chronic inflammatory cells, vascular proliferation and a decrease in collagen irregularity, which suggests attempted remodelling was taking place.<sup>50</sup> As a result of this stiffened, abnormal fascial compartment, when the patient exercises, the muscle attempts to expand, but is resisted by a less compliant fascia. This results in increased pressure and subsequent pain. As noted previously, ischaemia likely plays some role; however, this has not been well documented.

Within a tight fascial compartment, it is possible that normal metabolic activity during exercise leads to a sufficient increase in pressure to compromise tissue perfusion. Birtles et al. induced similar symptoms to those of compartment syndrome by restricting venous flow during exercise.<sup>51</sup> Edmundsson et al. noted that when patients with CECS had muscle biopsies at the time of their fascial release, laboratory analysis revealed lower capillary density, lower number of capillaries around muscle fibres and lower density of capillaries per muscle fibre area.<sup>52-54</sup> Thus, the reduced

microcirculation likely contributed to the development or was secondary to the CECS.

Typical clinical features of CECS are the absence of pain at rest with increasing ache or pain and a sensation of tightness with exertion.

Symptoms usually resolve or significantly dissipate within several minutes of rest. Rarely, athletes will develop paraesthesia or motor weakness with exertion. At rest, physical examination is usually unremarkable. With exertion, the compartment may be tense on palpation, and it may be possible to see bulges or herniations in the leg.

The most common compartment involved is the anterior compartment, which presents as anterolateral pain with exertion. The other two common compartments are the lateral compartment, which may include paraesthesias in the distribution of the superficial peroneal nerve to the dorsum of the foot, and the deep posterior compartment, which is usually associated with posteromedial tibial pain. Symptoms arising from the superficial posterior compartment are rare.

### Clinical features

Work-up and screening should always include an assessment of limb and foot alignment, evaluation of the biomechanical demands of the specific sport including training surface and shoe-wear, a history of previous injuries or trauma, and a screen for overlapping pathology such as stress fractures and medial tibial stress syndrome, as well as metabolic and nutritional factors. In one study, diabetes mellitus was implicated as a risk factor for developing CECS.<sup>55</sup> Radiographs are frequently obtained as an inexpensive screening tool for associated bone pathology.

The definitive diagnosis is made on the basis of intracompartmental pressure measurements (Table 38.4). The use of near-infrared spectroscopy has shown promise as a non-invasive alternative, but is expensive and has not yet become commonly used.<sup>9</sup> A study comparing near-infrared spectroscopy to MRI and intracompartmental pressure measurements found that the sensitivity of near-infrared spectroscopy (85%) was superior to either MRI or intracompartmental pressure measurements (both 77%).<sup>9</sup>

More recently, Williams and associates have suggested that non-painful neurosensory testing can be performed using a pressure-specified sensory device pre- and post-exertion, which may guide the clinician both in diagnosing CECS and in assessing the efficacy of treatment.<sup>56</sup> Other investigators have looked more deeply into advanced imaging techniques to assist with a non-invasive diagnosis of CECS, including ultrasound, Tc-99-tetrofosmin single-photon emission CT, a novel dual birdcage coil, in-scanner MRI protocols and DTI.<sup>57, 58</sup> Nonetheless, intracompartmental pressure measurements remains the gold standard.

### Deep posterior compartment syndrome

Deep posterior compartment syndrome typically presents as an ache in the region of the medial border of the tibia or as chronic calf pain. Beware the multiple other causes of calf pain including popliteal artery entrapment syndrome (Chapter 39). The deep posterior compartment contains the flexor hallucis longus, flexor digitorum longus and tibialis posterior (Fig. 38.1). Occasionally, a separate fascial sheath surrounds the tibialis posterior muscle, forming an extra compartment that may provoke symptoms independent of the other compartments.

Active, passive or resisted motion of these muscles may exacerbate pain. The patient describes a feeling of tightness or a bursting sensation that increases with exercise. Distal symptoms such as weakness or pins and needles on the plantar aspect of the foot may indicate tibial nerve compression. Small muscle hernias occasionally occur along the medial or anterior borders of the tibia after exercise.

On examination, there may be tenderness along the medial aspect of the tibia, but this is often relatively mild. Due to the deep nature of the compartment, palpable fascial tightness is less obvious in comparison to anterior or lateral compartment syndromes. Nonetheless, the experienced clinician may be able to discern the difference between palpable tightness in the deep compartment and fascial thickening and induration found in association with medial tibial stress syndrome.

To measure deep posterior compartment pressures, the needle or catheter is inserted from the medial aspect through two layers of fascia aiming posterior to the tibia (Fig. 38.9). A range of exercises can be used to exacerbate complaints, such as running, jumping, stair climbing, repeated calf raises or resisted plantarflexion and dorsiflexion using elastics, pulleys or isokinetic resistance machines. Routinely, we ask patients to run 5 minutes into their pain to ensure a valid test. It is important to reproduce the patient's pain, otherwise the test is not considered valid.

Post-exertional measurements must be obtained immediately after ceasing exercise and may be repeated again after 10 minutes. Normal compartment pressures are regarded as being between 0 and 10 mmHg. Maximal pressure during exercise of > 25–30 mmHg, an elevation of pressures > 10 mmHg or a resting post-exercise pressure > 25 mmHg is necessary for the diagnosis of chronic compartment syndrome (Table 38.4). If the elevated pressure takes more than 5 minutes to return to normal, this may also be significant.

### Treatment

Treatment of isolated deep posterior exertional compartment syndrome usually begins with a conservative regimen of reduced exercise and deep massage therapy.

**Figure 38.9** Compartment pressure testing—deep posterior compartment. The Stryker catheter is inserted into the deep posterior compartment

All contributing factors and overlapping diagnoses must be carefully considered. Effective soft tissue techniques include longitudinal release with passive and active dorsiflexion (Fig. 38.10) and transverse frictions. Dry needling of the deep muscles may also be helpful. Assessment and correction of any biomechanical abnormalities, especially excessive pronation, must be included.

Isolated deep posterior exertional compartment syndrome is uncommon and may be confused with medial tibial stress syndrome, popliteal artery entrapment syndrome, vascular claudication and stress fractures. Indeed, it is not surprising that initial treatment is the same as that for medial tibial stress syndrome. Unfortunately, if associated diagnoses or contributing factors cannot be identified and if pressures are elevated, symptoms are usually refractory to treatment. In this case, surgical release is necessary.

The surgical approach is along the posterior medial edge of the tibia and may be performed through a single or two small incisions. The saphenous vein lies directly along the path to the fascial insertion onto the posteromedial border of the tibia. Extreme care must be used to control all bleeding at the time of surgery as injury to one of the branches is common and increases the risk of postoperative haematoma or cellulitis.<sup>59</sup>

Some authors have suggested a benefit of fasciectomy (removal of a portion of fascial tissue) over fasciotomy (simple incision) due to concerns that the fascial insertion and sheath reforms.<sup>18</sup> They argue that this periosteal stripping serves an added role of treating any associated medial tibial stress syndrome and it assures release of any anatomic variations of tibialis posterior compartments. Due to the extensive nature of the procedure, which requires longer incisions and has increased risk of

**Figure 38.10** Soft tissue therapy in the treatment of posterior compartment syndrome—longitudinal release with active or passive dorsiflexion

complications, we recommend this extensive approach only in revision cases. In addition, we believe it is prudent to limit treatment to the most affected compartment in patients who have positive anterior or lateral compartment pressures, but only borderline pressures in the deep compartment. This may reduce the risk of postsurgical complications, which is elevated when releasing the posterior compartments.<sup>59-61</sup>

### Anterior and lateral exertional compartment syndromes

The anterior compartment contains the tibialis anterior, extensor digitorum longus, extensor hallucis longus and peroneus tertius muscles, as well as the deep peroneal nerve. The lateral (peroneal) compartment contains the peroneus longus and brevis tendons as well as the superficial peroneal nerve. For anterior compartment pathology, exertional pain occurs just lateral to the anterior border of the shin. Paraesthesia may also occur in the first web space. For lateral

compartment pathology, pain is felt just anterior to the fibula and paraesthesia may occur over the dorsum of the foot. The intermuscular septum (raphe) between the two compartments can be seen in thin individuals by looking for the indentation of skin when you squeeze the soft tissues between the anterior border of the tibia and fibula.

Clinical examination at rest will usually be normal or there may be palpable generalised tightness of the anterior or lateral compartment with focal regions of excessive muscle thickening. It is also important to assess the plantarflexors, especially the soleus and gastrocnemius. If these antagonists are tight, they may predispose to anterior compartment syndrome. Muscle herniation may be palpable with exertion most commonly occurring 5-7 cm proximally to the distal tip of the fibula where the superficial peroneal nerve penetrates through the lateral compartment fascia. Diagnosis of anterior and lateral exertional compartment syndrome is confirmed with pre- and post-exertional compartment testing (Table 38.4).

### Treatment

Treatment is based on the same principles as for the deep posterior compartment. All contributing factors should be assessed and treated. Lowering the heel in the athlete's shoe or orthotics may reduce the load of the anterior muscles and alleviate pain. Soft tissue techniques, such as sustained myofascial tension combined with passive and active plantarflexion (Fig. 38.11), transverse frictions and dry needling may alleviate symptoms.

Dr Andrew Franklyn-Miller has argued for much more attention to the biomechanics of running to treat CECS.<sup>62, 63</sup> To reduce load on tibialis anterior, he promotes midfoot landing rather than heel-strike and an increased cadence of 5-10%. Other gait adjustments are made according to individual assessment, such as reducing the vertical tibial angle at foot strike, promoting a smooth gait pattern, a more anterior centre of mass and a shortened stride length.<sup>62</sup>

A study conducted among military personnel studied the effect of using a forefoot strike pattern among individuals with CECS symptoms for at least 10 months who had an initial hindfoot strike gait pattern.<sup>64</sup> Six weeks after the implementation of forefoot strike technique, subjects had reduced post-running ICP, reduced pain during running and increased running distance. Improvements were maintained at the 1-year follow-up, where subjects also had an improved 2-mile time trial performance. Most importantly, surgical intervention was not required in any of the individuals.<sup>64</sup>

Another non-operative CECS management strategy is the use of botulinum toxin. It reduces muscle hypertrophy and provide analgesic properties in treating myofascial conditions involving contractures and hypertrophy.<sup>65</sup> In one case series, intramuscular injection of botulinum

**Figure 38.11** Soft tissue therapy in the treatment of anterior compartment syndrome. Sustained myofascial tension with active or passive plantarflexion

toxin resulted in significant reduction of ICP at 1 minute and 5 minutes post exercise in both the anterior and lateral compartments. Subjective exertional pain scores also decreased, with 15 out of 16 study participants reporting no exertional pain at nine-month follow-up. However, the level of evidence to support this treatment is currently low, with several questions remaining regarding the exact mechanism and long-term outcome.<sup>66</sup>

When conservative treatment fails, surgical release is required, especially when there are no obvious precipitating factors to correct. Fasiectomy is rarely necessary for the anterior or lateral compartments, as they release with minimal incision. Indeed, percutaneous and endoscopically assisted releases are approaching 90% success rates. Newer equipment including balloon catheters or endoscopic vein harvesting retractors have been used to make endoscopic-assisted techniques even safer.<sup>67</sup> Special care is essential to visualise the superficial peroneal nerve at the time of surgery to avoid iatrogenic injury.

### Acute compartment syndromes

Acute compartment syndromes are usually associated with trauma. Intracompartmental pressures are significantly elevated and do not subside with rest. Immediate surgical release is essential to avoid ischaemic injury.

It is important to note a number of case reports which describe acute anterior compartment syndromes brought on by exercise rather than trauma.<sup>68, 69</sup> In many of these cases, the athlete continued to exercise through their initial pain, which was most likely an exertional compartment syndrome that would otherwise have gone away with rest. When pain does not subside within an appropriate time, conversion of an exertional compartment syndrome to an acute compartment syndrome should be considered.

### Outcomes of exertional compartment syndrome surgery

As noted previously, the majority of patients undergoing surgery for CECS (80-90%) have a satisfactory result, with many being able to return to their previous level of sport.<sup>70</sup> However, some patients either fail to improve after surgery or, after a period of improvement, have a recurrence of symptoms. Micheli noted a slightly decreased rate of successful outcomes among female patients,<sup>71</sup> but others have not found any difference in outcome between sexes.<sup>72</sup> Some studies suggest that failure and recurrences are more common in the deep posterior compartment,<sup>70, 73</sup> possibly due to failure to release the tibialis posterior compartment.<sup>70</sup> Indeed, there are few studies looking at outcomes of isolated CECS of the deep posterior compartment.

Patient satisfaction rates for surgical fasciotomy of the deep compartment have been reported to be as low as 52%.<sup>74-76</sup> This has been attributed to surgical technique, anatomic variation, over-extensive release (e.g. all four compartments) and inaccurate diagnosis. Confounding factors which may lead to inaccurate diagnosis of posterior CECS include venous insufficiency, popliteal and peroneal entrapment, and tibial stress fracture/periostitis. Thus, accurate diagnosis and conservative management may play a key role in avoiding poor outcomes associated with fasciotomy of the deep posterior compartment.

Several other factors are also associated with surgical outcomes for isolated CECS of the deep compartment. Preoperative ICP measured at four different time intervals (pre, immediately, 1 minute post, 5 minutes post exercise) predict outcomes: a higher area under the 4-point curve is an indicator of likely surgical success.<sup>72</sup> In addition, a delayed diagnosis is associated with poorer outcomes.<sup>72</sup>

In a study of 18 patients who underwent revision surgery, increased pressure was found only in a localised area at the site of the scar, whereas 40% had high pressures throughout the compartment.<sup>75</sup> The exuberant scar tissue was thicker, denser and more constricting than was the original fascia. Eight of the 18 patients had entrapment of the superficial peroneal nerve with numbness and paraesthesia over the dorsum of the foot with exertion, positive Tinel's sign, and localised tenderness over the nerve, exacerbated by active dorsiflexion and eversion, as well as passive inversion and plantar flexion. All those with peroneal nerve entrapment had a good result from the revision surgery, whereas only 50% of those without nerve entrapment had a satisfactory outcome.

### Lessons from surgery with unsatisfactory outcomes

The foundation of a successful surgical result begins with a proper anatomic diagnosis. The diagnosis should be confirmed preoperatively with intracompartmental pressure measurement, and all associated or contributing factors should be addressed.

- Surgery should target the specific anatomic pathology and the release of all four compartments should be avoided to reduce the risk of surgical complications.
- Meticulous control of intraoperative bleeding will reduce the risk of postoperative haematoma and cellulitis.
- Perioperative antibiotics and postoperative cryotherapy can reduce the risk of postoperative cellulitis or infection. If identified in the postoperative period, the surgeon should have a relatively low threshold to return to the operating room and perform early irrigation.
- A common complication is postoperative stiffness, which can be avoided by early and aggressive postoperative mobilisation.
- The absolute indication for fasciectomy in contrast to fasciotomy is not clear, as the former may increase the risk of bleeding and postoperative stiffness.

### Rehabilitation following compartment syndrome surgery

The following protocol is recommended:<sup>4</sup>

- perioperative antibiotics and cryotherapy to reduce complications of infection, haematoma and cellulitis
- range of motion exercises of the knee and ankle in the immediate postoperative period. Full plantar and dorsiflexion is encouraged
- three to five days of limited weight-bearing on crutches, then full weight-bearing as tolerated

- once wounds have healed, a strengthening program including cycling and swimming to commence
- gradual return to light jogging at about 4-6 weeks after surgery
- full sports participation anticipated at 6-8 weeks (if one compartment released) and 8-12 weeks (if both legs and multiple compartments released)
- athlete should be pain-free with 90% strength regained prior to full sports participation.

## LESS COMMON CAUSES

### Stress fracture of the fibula

Stress fractures of the fibula are not as common as stress fractures of the tibia. As the fibula plays a minimal role in weight-bearing, this stress fracture is usually due to muscle traction or torsional forces placed through the bone. In the athlete with excessive subtalar pronation, the peroneal muscles are forced to contract harder and longer during toe-off. Examination may reveal local tenderness and pain in springing the fibula proximal to the site of the stress fracture.

This injury is usually not as painful on weight-bearing as is a stress fracture of the tibia. It is treated symptomatically with rest from activity until bony tenderness settles. Due to poorer rotational control, knee-high pneumatic braces may not be as effective as on the tibia. There should then be a gradual increase in the amount of activity. Soft tissue symptoms should be treated. This injury is often associated with a biomechanical abnormality such as excessive pronation or excessive supination.

### Referred pain

Referred pain is not a common cause of leg pain in athletes, but should be considered in cases with persistent and atypical pain. Pain may be referred from the lumbar spine, proximal nerve entrapment, the knee joint (Baker's cyst, meniscal cysts), the superior tibiofibular joint (instability or ganglion cyst), and, occasionally, the ankle joint (instability, Maisonneuve fracture).

### Nerve entrapments

Within the leg itself, nerve entrapment of either the superficial peroneal nerve in the lateral compartment or the deep peroneal nerve in the anterior compartment can occur due to trauma or a tight brace or cast. Fascial entrapment at the level of the fibular head may also occasionally occur.

The tibial nerve in the deep posterior compartment is less commonly involved with entrapment, but can be injured with trauma. Pain and sensory changes may occur. This diagnosis may be suspected in the presence of motor or sensory changes, and it is confirmed with nerve

conduction studies performed pre- and post-exercise. Surgery may be required to alleviate these conditions.

### Vascular entrapments

Popliteal artery entrapment syndrome usually presents with calf pain and is therefore more fully described in Chapter 39, but may rarely present as pain in the anterior compartment.<sup>77</sup> It can be misdiagnosed as anterior compartment syndrome as they both present with claudication-type pain. However, the pain from popliteal artery entrapment disappears immediately on cessation of exercise, whereas compartment syndrome pain often persists for approximately 30 minutes as an aching sensation. While DVT is most commonly posterior, chronic venous stasis changes can occur anteriorly and may be evidence of systemic disease.

### Developmental issues

Juvenile tibia vara (Blount disease) usually presents due to deformity rather than pain. Osgood-Schlatter disease is a traction apophysitis at the insertion of the patellar tendon onto the tibial tuberosity seen commonly among adolescent athletes. Patients usually present with pain and tenderness at the tibial tuberosity (Chapter 44). 'Growing pains' may affect the leg and are usually a diagnosis of exclusion. Intermittent achy pain exacerbated by periods of active growth with completely negative imaging and work-up are characteristic. The youngest reported patient treated with surgical release for pressure positive CECS was 12 years old and it is unclear whether this patient would have grown out of the problem at maturity.

### Periosteal contusion

Periosteal contusion occurs as a result of a direct blow from a hard object such as a football boot. It can be extremely painful at the time of injury but the pain usually settles relatively quickly. Persistent pain may occur because of a haematoma having formed under the periosteum. There will be local tenderness and bony swelling. Treatment consists of rest and protection.

### Fractured tibia and fibula

Combined fractures of the tibia and fibula are often due to indirect violence in landing from a jump on a twisted foot. The tibia or fibula may be injured individually by a direct blow. Weight-bearing will be impossible in cases of displaced fracture of the tibia. Fracture of the tibia is often compound and visible through damaged skin. An isolated fracture of the fibula may exhibit only local tenderness. An isolated fractured fibula (except where it involves the ankle joint) requires analgesia only. However, the ankle and knee joint must be carefully examined for associated injuries (see Maisonneuve fracture, Chapter 41). The management of a combined fracture is that for fracture of the tibia. Patients with compound (open) fractures should be admitted to hospital.

Many closed tibial fractures can be treated conservatively as long as angulation is minimal. This involves an above-knee plaster with the knee slightly flexed and the ankle in 90° of dorsiflexion. The limb is elevated for 3–7 days until swelling subsides. A check radiograph should be taken after casting. Patients should be reviewed at 6–8 weeks, at which time they may be able to be placed in a hinged knee cast.

Bony union requires 8–12 weeks; however, 16–20 weeks are required for consolidation. Physiotherapy after removal of the plaster is aimed at regaining full range of knee flexion and quadriceps muscle strength. Activities such as swimming can be resumed immediately after removal of the plaster but multidirectional running sports must wait until range of movement and muscle strength have returned to normal.

#### PRACTICE PEARL

There is a strong trend toward early surgical fixation of unstable tibial fractures with intramedullary nailing, which allows athletes earlier weight-bearing, conditioning activities and return to sport, and obviates the risk of potential mal-union.

# Calf pain

with TAMIM KHANBHAI, MATT HISLOP and JEFF BOYLE

*Kompany remains sidelined with a calf injury, sustained after just seven minutes of City's goalless draw with Dynamo Kiev one month ago. Remarkably, it is the 14th time he has suffered a problem with his calf since joining the club in 2008—with five of them occurring this season—and his 32nd injury overall during the past eight years.*

PhysioRoom, 12 April 2016

Calf pain is common and if not managed appropriately it can persist for months and cause frustration for both athlete and clinician. Both acute and chronic calf pain can stem from injury to the calf muscle.

### ANATOMY

The anatomy of the posterior compartment of the leg (Fig. 39.1) will be covered here. The anterior and lateral aspects have been covered in Chapter 38.

The muscles in the posterior compartment of the leg comprise a superficial and deep group. The superficial group is composed of the triceps surae (gastrocnemius and soleus) and plantaris muscle. These form the bulk of the calf muscle. The deep group is composed of the tibialis posterior, flexor digitorum longus, flexor hallucis longus and popliteus muscles.

Gastrocnemius has two heads; the medial and larger head is attached to the posterior aspect of the medial epicondyle of the femur and the lateral head to the lateral femoral condyle (Fig. 39.1b) The muscle extends down to the mid-calf, following which it inserts into a broad aponeurosis which receives the tendon of the soleus to form the tendon of Achilles (TA). The two heads are overlaid by the tendon of biceps femoris and the common peroneal nerve laterally and the semimembranosus muscle medially. This latter area between the medial head and semimembranosus is the location of the 'Baker's cyst' (Chapter 37).

Soleus is a large flat broad muscle, deep to the gastrocnemius (Fig. 39.1c). It arises from a number of locations; the posterior aspect of the head and proximal shaft of the fibula, the soleal line (prominent ridge posterior tibia), medial aspect of the tibia and a fibrous band between the tibia and fibula. The muscle joins with

the tendon of gastrocnemius and together they form the TA, inserting into the calcaneal tuberosity.

Both the gastrocnemius and soleus muscles in the calf have been noted to have intramuscular tendons. In the

(a)

**Figure 39.1** Anatomy of the calf (a) Surface anatomy

**Figure 39.1 (cont.)** (b) Superficial calf muscles (c) Removal of the gastrocnemius showing the underlying soleus and plantaris muscles (d) The intramuscular tendinous structures within the soleus muscle

gastrocnemius muscle, separate proximal medial and lateral tendons arise from the posterior aspects of the medial and lateral femoral condyles respectively.

There are three tendinous structures within the soleus muscle—medial and lateral ‘aponeuroses’ proximally, and a distal central tendon.<sup>1</sup> The medial and lateral aponeuroses (Fig. 39.1d) arise from the medial (tibial) and lateral (fibular) origins of the soleal epimysium and descend inferiorly, penetrating deep into the medial and lateral aspects of the soleal muscle belly, whilst simultaneously curving towards the midline of the muscle belly and distal central tendon. As they progress distally, the aponeuroses decrease in size until they can no longer be visualised. This most distal point is from where the lowest muscle

fibres arise. As these aponeuroses are a continuation of the epimysium covering the soleus and act as rigid fibrous 'struts' from which the proximal soleus muscle fibres gain origin, they can indeed be considered as true intramuscular tendons from an anatomical, functional and pathologic perspective, albeit demonstrating a flattened and 'aponeurotic' morphology.

The central tendon (Fig. 39.1d) arises from the anterior aponeurosis and consequently represents the inferior muscular attachment; that is to say, the insertion of the soleal muscle fibres. This eventually forms the soleal contribution of the Achilles tendon, typically fusing along the most central aspect of the tendon, although it occasionally does so along the medial or lateral aspect.

## CLINICAL APPROACH

Calf injuries are common, particularly in ball sports. For example, a large study of injuries in professional football found that 13% of all injuries were located in the calf.<sup>2</sup> Of these, 61% resulted in more than a week of time loss and 13% took more than 28 days to recover. The re-injury rate was also high at 13%.

The medial head of the gastrocnemius is the most common site of calf injury. In an MRI study of calf injuries by Koulouris and colleagues,<sup>3</sup> a total of 79 separate sites of strain injury were identified (39 solitary, 20 dual) in 59 patients. Of the 39 isolated strains, injury to the gastrocnemius was most common (49%), preferentially involving the medial head in 18 cases and the lateral head in one case. The soleus was also commonly involved (46%), with two cases (5%) of distal avulsions of the plantaris. Of the 20 dual injuries, a combination of gastrocnemius injury with soleus injury was the most frequent finding (60%). Dual injuries of both heads of the gastrocnemius muscles were demonstrated in four cases (20%), with the soleus and tibialis posterior injured in three cases (15%). A combination of soleus and flexor hallucis longus injury was seen in one case (5%).

Most calf muscle strains occur at the musculotendinous junction (MTJ)—either at the intramuscular tendon or the distal MTJ. Balios and colleagues found that musculotendinous junction strains involved all three of the soleus intramuscular tendons.<sup>1</sup> Of 31 strains considered musculotendinous, 14 (45%) were located at the medial aponeurosis, 10 (32%) at the central tendon and seven (23%) involved the lateral aponeurosis.

A sudden burst of acceleration, such as stretching to play a ball in squash or tennis, may precipitate injury. The classic mechanism is seen in middle-aged tennis players, normally over 40 years of age, with a sudden onset of acceleration, where the calf muscle is stretched eccentrically when the knee is extended and the foot in a dorsiflexed position, such as when overstretching for a ball. This results in immediate pain, tenderness (medial belly of

gastrocnemius above the musculotendinous junction), a palpable defect and swelling. This is sometimes referred to as 'tennis leg'.

The calf region is also a common site of contusion caused through contact with playing equipment or another player. Muscle strains and contusions are acute injuries that present with typical histories that are usually easily distinguishable.

### PRACTICE PEARL

The possibility of referred pain from the lumbar spine, neural or myofascial structures should always be considered. This is sometimes the underlying basis of calf strains, especially in the older athlete.<sup>4</sup>

The calf is the most common site in the body for muscle cramps (Chapter 3). Cramps may occur at rest, during or after exercise. Cramps are not specific to environmental conditions such as exercise in the cold or heat. They can occur in acclimatised and conditioned athletes. Cramps probably result from alterations in spinal neural reflex activity activated by fatigue in susceptible individuals.

The calf is also a common site of the phenomenon known as delayed onset muscle soreness (Chapter 4). This may occur after the first training session following a lay-off or a period of relative rest, or when excessive eccentric muscle contractions are performed, for example, during plyometric training. Lateral calf pain may be due to a direct blow, referred pain from the superior tibiofibular joint, peroneal muscle strain or fibular stress fracture. The causes of calf pain are listed in Table 39.1.

A variety of contributing factors can predispose an athlete to calf injury. These include:

- foot biomechanics (excessive pronation/supination)
- pelvic biomechanics (e.g. internal rotation femur)
- muscle imbalances (quadriceps, hamstrings, ankle everters and inverters)
- stiff ankle joint (decreased dorsiflexion)
- poor jumping and landing technique
- change in sporting environment (terrain, weather)
- poor nutrition and hydration
- change in sporting activity (cycling and swimming compared with running)
- change in footwear
- reduced muscle power, endurance and muscle fatigue
- lack of conditioning.

## History

The most important aspect of the history is the description of the onset of pain. A sudden onset of a tearing or

**Table 39.1 Causes of calf pain**

popping sensation in the calf is diagnostic of calf muscle strains. The patient is usually able to localise the site of the tear. The degree of disability, both immediately after the injury and subsequently, is a guide to the severity of the tear.

In athletes with chronic mild calf pain, a history of a previous acute injury may be significant and is a risk factor for calf injury in marathon runners and soccer referees.<sup>5,6</sup> The practitioner should ask about the treatment and rehabilitation of the previous injury because inadequate rehabilitation will have an impact on recurrence rates.

Information about the training load, and especially running load, can be very helpful. Many runners now use GPS devices or mobile applications that provide extensive information about running distances, speed and total volume per week. This information can be very valuable.

A history of low back pain may be a clue to referred pain. The practitioner should also be alert to the possibility of referred pain if the calf pain is variable rather than constant. If there is no obvious precipitating cause of calf pain, the possibility of deep venous thrombosis after long car journeys, long flights or recent surgery needs to be explored.

Claudicant pain that comes on with exertion and then disappears may indicate proximal vascular occlusion by atheroma or entrapment (e.g. femoral or iliac artery stenosis) or exertional compartment syndrome. A ruptured Baker's cyst can also cause acute calf pain and swelling and should be considered as a differential diagnosis (refer to Chapter 37).

## Physical examination

The aims of examination in the patient with acute calf strain are to determine the site and the severity of the injury as well as to detect any predisposing factors such as chronic calf tightness. Examination of a patient with chronic or intermittent calf pain requires not only palpation of muscles, but also assessment of possible neural contributors, ankle reflexes and examination of the lumbar spine. It is important to palpate the entire length and width of the muscle bellies and their associated aponeuroses for areas of muscle and fascial tightness and thickenings that may predispose to injury. Due to its deep position, the soleus can be difficult to palpate.

Clinical assessment should include both static and dynamic tests and should be performed in both knee flexion and extension. Comparing calf girth between left and right is also important. Foot alignment and biomechanics should also be considered.

1. Observation
  - a. standing (foot posture, calf girth, swelling)
  - b. walking (on toes, on heels)
  - c. prone
2. Active ankle movements
  - a. plantarflexion/dorsiflexion (standing) (Fig. 39.2a)
  - b. plantarflexion/dorsiflexion (prone)
3. Passive ankle movements
  - a. dorsiflexion (knee flexion) (Fig. 39.2b)
  - b. dorsiflexion (knee extension) (Fig. 39.2c)

  - f. biomechanical examination (Chapter 8)
  - g. ankle jerk reflex
  - h. popliteal artery auscultation after provocative manoeuvres.

### Key outcome measures

There are no specific PROMs for calf strains. Generic measures such as a patient-specific functional scale or a numeric pain rating scale can be used to monitor progress (see Chapter 16).

### Investigations

Ultrasound or MRI may be useful for evaluating a calf injury. These imaging modalities can localise pathology, identify presence of haematoma and scar tissue, and differentiate between a muscle strain and a contusion if not clinically evident. MRI is preferred because of its ability to identify intramuscular tendon injuries. If deep venous thrombosis is suspected, a Doppler scan may be required.

## GASTROCNEMIUS MUSCLE STRAINS

### Acute strain

Acute strain of the gastrocnemius muscle occurs typically when the athlete attempts to accelerate by extending the knee from a stationary position with the ankle in dorsiflexion, or when lunging forward, such as while playing tennis or squash. Sudden eccentric overstretch, such as when an athlete runs onto a kerb and the ankle drops suddenly into dorsiflexion, is another common mechanism.

The medial head of the gastrocnemius has a greater proximal attachment and a longer distal insertion into the Achilles tendon than the lateral head.<sup>3</sup> Therefore the medial head may have a greater capacity for force generation and may be more susceptible to injury compared to the lateral head.

### History

The exact moment of injury was caught on video in the case of a famous Australian batsman whose gastrocnemius strain occurred when his entire body weight was over his foot on the injured side with the centre of mass well in front of the leg.<sup>8</sup> The gastrocnemius muscle-tendon complex was at close to maximal length, and the muscle-tendon length was also constant at the time. Therefore, the injury probably occurred just as the muscle-tendon complex was moving from an eccentric to an isometric phase.

The athlete often complains of an acute, stabbing or tearing sensation, usually either in the medial belly of the gastrocnemius or at the musculotendinous junction.

### Physical examination

Examination reveals tenderness at the site of a muscle strain and, in complete muscle tears, there may be a palpable defect. The athlete will walk with an antalgic gait. There may be skin changes such as bruising or discoloration and swelling. Assessing range of motion reveals pain on passive and active dorsiflexion (Fig. 39.2d), and on resisted plantarflexion with the knee extended. Assessment of the Achilles tendon and other structures in the calf and ankle are important.

If required, the functional competence of the injured muscle is assessed by asking the patient to perform a bilateral heel raise. If necessary, a unilateral heel raise, heel drop or hop may be used to reproduce the pain and to assess for weakness. Measuring the calf girth, comparing one side to the other in centimetres and a lunge test, when appropriate (not if examining the athlete acutely), can be useful objective markers during rehabilitation, and especially if there are baseline measurements for comparison.

Chronic gastrocnemius muscle strain may occur as an overuse injury or following inadequate rehabilitation of an acute injury. This results in disorganised, weak scar tissue that can predispose to further injury and compensatory movement patterns leading to muscle imbalances. Careful palpation of the muscle can reveal these tissue thickenings.

### Treatment

Rehabilitation consists of a progressive program starting from the acute phase through to the athlete returning to sport. It is tailored to the individual, rather than a fixed time frame. Some athletes will recover faster than others, depending on the risk factors of the injury, presence of scar tissue, haematoma, previous injuries and the sport they need to return to. The aim is to return the athlete, at a minimum, to their pre-injury level, but ideally to use

this opportunity to correct other issues so they are in a better position than their pre-injury level. There are five stages to rehabilitation of gastrocnemius strains:

- Stage 1: Acute phase
- Stage 2: Improve ROM
- Stage 3: Power and endurance
- Stage 4: Coordination, agility, sport skills
- Stage 5: Return to sport.

### Stage 1: Acute phase

Initial treatment of gastrocnemius strains aims to reduce pain, swelling and further injury. The initial approach is POLICE (protect, optimal loading, ice, compression, elevation)<sup>9</sup> and analgesics may be used if required, avoiding nonsteroidal anti-inflammatory drugs for the first 72 hours.<sup>10, 11</sup> Ice compression units may assist with this process, for 15-20 minutes every hour. Crutches may be necessary if the athlete is unable to bear weight, but should only be used for short periods as early mobilisation allows muscle fibres to regenerate and organise more effectively.<sup>12</sup>

A 6 mm heel raise may be used (on both the injured and uninjured side) to initially reduce calf length and off-load calf structures. There is no good quality evidence for electrotherapeutic modalities such as ultrasound therapy, but this can be used if the treating team is keen to incorporate this.

This stage can be achieved within a couple of days but can be longer depending on the severity of the injury. If the symptoms have failed to settle within 3-5 days, reassess and investigate further if required.

### Stage 2: Improve ROM +/- flexibility

Once the pain and swelling has settled, ankle and knee active range of motion exercises should commence and exercises in a swimming pool can aid recovery.

Gentle stretching of the gastrocnemius to the level of a feeling of tightness (Fig. 39.3) can begin soon after the injury. Stretching is important to lengthen the muscle, which improves its elasticity and distends scar tissue appropriately.<sup>12</sup> Following this, unloaded isometric calf exercise should be incorporated.

### Stage 3: Power and endurance

There are multiple facets to this stage. Within 10 days the scar tissue will have the same tensile strength as normal muscle and can be subjected to increased loading.<sup>13</sup> Progression from active ROM to strengthening of the plantarflexors can commence. This involves a progression of exercises starting with resistance band strengthening to concentric bilateral calf raises, unilateral calf raises and, finally, eccentric calf lowering. Weights can be

**Figure 39.3** Stretching exercise for the right gastrocnemius muscle with the knee in full extension. This can be performed over a step or with the foot placed against a wall to increase the stretch

added gradually at each stage (Fig. 39.4). Strengthening routines should begin with open chain then closed chain exercises.

Prior to rehabilitation, ensure the muscle has been warmed up appropriately. Rehabilitation should concentrate on both gastrocnemius and soleus by varying knee extension and flexion. Stretching exercises will restore normal muscle length and should be held for at least 15 seconds. A systematic review of calf stretching on ankle dorsiflexion range of motion found an improvement of up to 2-3°,<sup>14</sup> but it is unknown whether this is clinically relevant. Measuring the lunge test is a useful indicator of posterior calf flexibility as a score <13 cm has been associated with lower limb injuries.<sup>15</sup>

Treatment may also include transverse friction and longitudinal gliding soft tissue therapy at the site of any excessive scar tissue and along the entire musculotendinous unit. When appropriate, sustained myofascial tension (Fig. 39.5) or digital ischaemic pressure can be applied to areas of increased tone.

(a)

(c)

**Figure 39.4** Strengthening exercises for the gastrocnemius muscle (a) Bilateral calf raise (b) Unilateral calf raise (c) Eccentric lowering

(b)

**Figure 39.5** Soft tissue therapy—sustained myofascial tension to the muscle belly of the gastrocnemius

For favourable long-term results, treatment should address predisposing factors such as biomechanical factors, or risk factors that preceded the injury, such as calf muscle tightness, lumbopelvic dysfunction and knee or ankle-related abnormalities.

Normal, full weight-bearing gait should be achieved, following which proprioceptive exercises can be started. This begins with balancing on the injured leg, progressing through to a wobble board or BOSU® ball and incorporating functional movements like jumping onto or landing off the board once the strength in the calf is appropriate.

Increased amounts of cardiovascular exercise should be undertaken to maintain fitness levels. Low-impact cross training such as stationary cycling or swimming can be commenced as soon as pain allows. When active weight-bearing muscle contraction is pain-free, a cross trainer can also be used prior to running.

#### Stage 4: Coordination, agility, sport skills

By this stage, the strength on the injured side should be comparable to the non-injured leg. The aim now is to get the player ready for return to play. This involves continuing the gains made in the previous stage, such as strength work and proprioception. Now there needs to be a supervised, graduated running program, which should include sprint work, change of direction and change of pace. If the sport is football, for example, then during this stage ball work should be introduced, starting with short kicks and progressing to longer kicking drills. Athletes should undergo a supervised, graduated return-to-sport program.

#### Stage 5: Return to sport

This stage is often overlooked but is integral in a rehabilitation program (Chapter 19). Return to sport (RTP) needs a multidisciplinary approach, working with the coaching staff, informing and educating them about the injury. Often, coaches will feel that once a medical team hands a player back to them, they are ready to play. In fact, nothing in rehabilitation can replace or replicate the training and matches of team sport.

The aim should be to have a period of training with the team, the length of which is decided by the medical team and depends on factors such as the time out with that injury. Clearly if a player has been out for 1 week, they need less training time than if they are out for a period of 4–8 weeks. By this stage, strength, flexibility and proprioception should be equal to the uninjured site.

There is little evidence that a repeat MRI scan needs to be done to RTP as MRIs still show abnormalities 6 weeks after players had returned to play in Australian rules football.<sup>16</sup> The number of minutes the player participates in the sport should be lower than usual when the player first returns. This stage needs to be tailored to the individual,

the injury and the sport. Re-injuries often occur because the importance of this stage is ignored.

#### PRACTICE PEARL

When a 'tennis leg' occurs in an older athlete it can take a few months before the individual is ready to return to sport. In such cases there is often fibrotic tissue between the gastrocnemius and soleus muscles, seen on follow-up ultrasound. This fibrotic tissue may increase the risk of recurrence. One of the aims with any treatment is to achieve optimal rehabilitation and to prevent the formation of fibrotic tissue or scarring.

#### Operative intervention

Surgery is rarely required for gastrocnemius tears. However, if there is a complete rupture of the medial gastrocnemius head or a large disruption of muscle or intramuscular tendon fibres then a surgical opinion should be sought. Likewise, a failure of conservative treatment or prolonged pain (4–6 months) with a contracture warrants a surgical opinion.<sup>13</sup> Surgical intervention is only indicated when the presentation is associated with acute compartment syndrome.<sup>17</sup> Reconstruction of the medial head of gastrocnemius has limited evidence, with few case reports, a small case series and no long-term follow up data.<sup>18</sup> It is thus reserved for the rarer cases of this type of injury.

#### SOLEUS MUSCLE STRAINS

The soleus muscle contains a high proportion of type I, slow-twitch muscle fibres, unlike the gastrocnemius, which contains a higher proportion of type II, fast-twitch muscle fibres. This allows the soleus muscle to have a significant role in posture control, especially in standing.

Soleus muscle strains occurring at the perimeter of the muscle, and not centred at the tendons, can be classified as myofascial (epimysial) strains. These may be at the myofascial junction of the soleus with the gastrocnemius (posterior myofascial), or at the junction between soleus with the deep posterior compartment of the leg (anterior myofascial). Musculotendinous junction strains can involve the distal intramuscular tendon, or the proximal medial and lateral aponeuroses (Fig. 39.1d).

#### Epidemiology

Strains of the soleus muscle were not thought to be common in the elite athlete,<sup>17</sup> but Koulouris who reviewed MRI findings rather than purely ultrasound found large numbers of soleus strains, and combination strains with gastrocnemius and other deep crural muscles to be common.<sup>3</sup> Of the 18 isolated soleus strains reported by Koulouris, 11 were described as myofascial, with the other seven as musculotendinous junction injuries, all medial.

**Table 39.2** Distribution of soleus muscle strains

Myofascial vs musculotendinous strains			
	Myofascial		Musculotendinous
Koulouris et al <sup>3</sup>	11		7
Balius et al <sup>1</sup>	24		31
Distribution of musculotendinous strains			
	Medial	Lateral	Central
Koulouris et al <sup>3</sup>	7	0	0
Balius et al <sup>1</sup>	14	7	10

Balius reported a series of 55 cases of soleus muscle strains, of which 31 strains were considered musculotendinous and 24 were myofascial.<sup>1</sup> The distribution of the soleus strains in the two studies is shown in Table 39.2.

MRI demonstrates the differences between the myofascial (epimysial) strains (Fig. 39.6) and the more serious musculotendinous tear involving damage to the aponeurosis (Fig. 39.7).

### Clinical assessment

Patients with acute soleus strains may present with sudden onset pain, or alternatively with a history of increasing calf tightness over a period of days or weeks. Often walking and jogging are more painful than sprinting. The medial third of the fibres of the soleus and its aponeurosis are prone to becoming hard and inflexible, particularly in athletes with excessive subtalar pronation. This focal tissue can be more susceptible to strain, especially at its junction with adjacent 'normal' tissue. Therefore, careful assessment by palpation as well as assessment of foot biomechanics is essential.

Examination often reveals tenderness deep to the gastrocnemius, usually in the medial aspect of the soleus muscle. Often, both the soleus stretch (Fig. 39.2e) and resisted soleus contraction reproduce the athlete's pain. This can be differentiated from the stretch and contraction that provoke pain in gastrocnemius strains (Fig. 39.2d).

### Management

Treatment of soleus muscle strains is similar to gastrocnemius strains above and rehabilitation should target both muscles. It is important to note that activation of the soleus requires the knee to be partially flexed (lunge position). Soft tissue therapy is often directed at the site of the lesion as well as tissue proximally and distally (Fig. 39.8). Strengthening exercises are performed with the knee flexed, initially in a seated position (Fig. 39.9). If foot biomechanics are assessed to be a predisposing factor to injury, orthoses may be required.

(a)

(b)

**Figure 39.6** MRI of a 24-year-old running athlete presenting with sudden onset of calf symptoms (a) Axial fat-suppressed image shows epimysial tear of the superficial covering of medial soleus with tearing of the myofibrils from the connective tissue surface. The medial gastrocnemius epimysial surface is intact. Blood fluid products separate the two discrete layers (b) Sagittal fat-suppressed image

**Figure 39.7** Muscletendinous strain involving the lateral aponeurosis with damage to the aponeurosis itself (a) Sagittal MR image shows disruption of the intramuscular aponeurosis (arrow) of the right lateral soleus muscle with retraction of the aponeurosis to create a wavy appearance. Oedema and blood fluid products track into the torn muscle fibres (b) Axial fat-suppressed image shows a discrete gap at the site where the aponeurosis has torn (arrow). The aponeurosis of the medial soleus muscle is intact

**Figure 39.8** Soft tissue therapy—sustained myofascial tension to the soleus muscle

#### PRACTICE PEARL

When the soleus strain involves a lesion to the soleal aponeuroses (Fig. 39.7), rehabilitation time frames will be extended and management should be based on tendon treatment principles (see Chapter 4).

### Accessory soleus

The soleus accessory muscle is a relatively rare anatomical variant (0.7–5.5%) and is bilateral in 10% of cases. It appears as a soft tissue mass bulging medially between the distal part of the tibia and the Achilles tendon, and may be mistaken for a tumour or an inflammatory lesion.<sup>19</sup> Athletes may have a fullness on inspection of their Achilles region from behind.

It may be asymptomatic (25%), or associated with chronic exertional compartment syndrome or posterior tibial nerve compression (tarsal tunnel syndrome). Athletes can present with ankle pain and soft tissue swelling.<sup>20, 21</sup>

Presentation is usually in adolescence during periods of rapid muscle hypertrophy. Rapid muscle hypertrophy can lead to compartment-type syndrome, posterior tibial nerve compression, tendinopathy and/or partial accessory muscle strain.<sup>20, 21</sup>

Plain radiography generally shows soft tissue swelling between the deep compartment and the Achilles tendon, which obscures or obliterates Kager's triangle on the

**Figure 39.9** Strengthening exercises for the soleus muscle—calf raise with bent knee. This can be made more difficult by adding weights or having the patient drop down over the end of a step

lateral radiograph of the ankle. The appearance of normal muscle on MRI allows the clinician to distinguish it from both abnormal muscle and soft tissue tumours.<sup>20, 22</sup> Additionally, intrafascial fluid collection and perimucular oedema have been associated with symptomatic accessory soleus muscle presentation on MRI.<sup>21</sup>

Asymptomatic cases require no treatment. If pain or discomfort is present, conservative treatment is trialled first. Conservative treatment can include soft tissue therapy, stretching and strengthening of the calf muscles

and improvement of ankle range when limited.<sup>20</sup> Surgery (involving either fasciotomy alone or with excision of the accessory muscle) is recommended when conservative measures fail.<sup>19, 20</sup>

### CLAUDICANT-TYPE CALF PAIN

Another common presentation is the patient who complains of a claudicant-type calf pain with exercise. The differential diagnosis in this patient is a vascular cause (popliteal artery entrapment, atherosclerotic disease, endofibrosis), neuromyofascial causes (referred pain or nerve entrapment) or compartment syndrome (deep posterior or superficial).

### Vascular causes

Vascular causes of exercise-induced lower limb pain were originally thought to be uncommon but the incidence may be greater than previously recognised, and it is possible that these conditions are under reported.<sup>23</sup>

The pain of vascular entrapment is brought on by exertion, like chronic exertional compartment syndrome, but has subtle differences in that it can be present at rest (positional), will typically develop more quickly and (usually) dissipate more quickly.<sup>24</sup>

Post-exercise examination of the peripheral pulses and arterial bruits is vital and the diagnosis can be confirmed by Doppler ultrasound, ankle-brachial ratios and angiography. It may also be important to perform compartment pressure tests and nerve conduction studies to rule out coexisting conditions.

### Popliteal artery entrapment

Popliteal artery entrapment syndrome (PAES) is often not recognised, and misdiagnosed as a compartment syndrome.<sup>25, 26</sup> The syndrome was first described as a cause of exercise-induced leg pain in 1879. There are two types of popliteal artery entrapment syndrome: anatomical and functional (acquired).

The classically described anatomical (congenital) abnormality is a variation in the anatomical relationship between the popliteal artery as it exits the popliteal

**Table 39.3** Popliteal Vascular Entrapment Forum classification for popliteal entrapment syndrome (adapted from di Marzo and Cavallaro<sup>29</sup>)

Type I	Popliteal artery running medial to the medial head of gastrocnemius
Type II	Medial head of gastrocnemius laterally attached
Type III	Accessory slip of gastrocnemius/fibrous bands arising from medial head of gastrocnemius
Type IV	Popliteal artery passing below popliteus muscle/fibrous bands arising from popliteus
Type V	Primarily venous entrapment
Type VI	Other variants
Type VII	Functional entrapment

**Figure 39.10** Popliteal Vascular Entrapment Forum classification system for PAES.

REDRAWN FROM PILLAI<sup>30</sup>

fossa and the medial head of the gastrocnemius muscle. It is quite rare, with an estimated prevalence of between 0.6% and 3.5%. Popliteal artery entrapment syndrome can be classified into seven categories according to the anatomical relationship between the popliteal artery and the adjacent muscular or fibrous bands in the popliteal fossa (Table 39.3 and Fig. 39.10).<sup>26-28</sup>

The most common abnormality describes an abnormal medial head of the gastrocnemius muscle, the accessory part of which passes behind the popliteal artery. Other observed abnormalities include a tendinous slip arising from the medial head of the muscle, an abnormal plantaris muscle and multiple muscle abnormalities involving the lateral and medial heads of the gastrocnemius and the plantaris. Rarer anatomical variations of popliteal artery entrapment

syndrome include entrapment of the artery at the level of the adductor hiatus and an isolated entrapment of the anterior tibial artery as it passes through the interosseous membrane.

The term 'functional' or 'acquired' PAES was first described by Rignault et al. in 1985,<sup>31</sup> and describes a situation where no anatomical abnormality is visible at surgical exploration. Studies have shown that the medial head of gastrocnemius typically 'rests' in a lateral or intercondylar position, leading to crowding of the popliteal vessels and occlusion during muscle contraction (Fig. 39.11).<sup>30</sup> This syndrome is commonly seen in healthy young athletes and military recruits with hypertrophied gastrocnemius muscles.<sup>25, 27</sup>

Clinically, athletes present with claudication-type calf or anterior aspect of leg pain, which can be bilateral. The

### Differentiating artery entrapment from chronic compartment syndrome

With artery entrapment, cessation of exercise brings about rapid relief from the pain. This compares with the classic pain pattern of compartment syndrome, which is related to the volume of exercise and tends to settle over a period of around half an hour after exercise. If exercise is attempted on consecutive days, the

pain from compartment syndrome is often more severe on the second day. The pain from PAES is unaffected by exercise on the previous day. The pain can be paradoxically more severe on walking than on running. This is believed to be due to the more prolonged contraction of the gastrocnemius muscle while walking.

B

pain is brought on by exercise, and the severity of the symptoms is related to the intensity of exercise. Signs of ischaemia in the lower limb are uncommon.<sup>32</sup>

Examination of the distal pulses (dorsal pedis and posterior tibial) may be unremarkable at rest. Assessing the pulses while the athlete actively plantarflexes or passively dorsiflexes the ankle may reveal a popliteal artery bruit, but this may be unreliable.<sup>27</sup> Examining the athlete immediately post-exercise is important in making the diagnosis. Immediately post-exercise, a popliteal artery bruit may be heard and the peripheral pulses will be either weak, decreased or absent.

Ankle-brachial indices are useful for the more rare underlying vascular abnormalities, but not for functional PAES.<sup>33</sup> Doppler ultrasound is the initial investigation of choice, as it allows real-time assessment and can be performed during provocative manoeuvres. Angiography can rule out differential diagnoses such as aneurysms and emboli, and can be performed while the athlete actively plantarflexes, and actively and passively dorsiflexes the ankle.<sup>27, 28</sup>

MRI and MR angiography may be more useful with multiplanar views, non-ionising radiation and high soft

tissue contrast, and also allow much greater visualisation of the surrounding anatomy.<sup>27</sup>

There is some suggestion that the presence of chronic entrapment of the popliteal artery can lead to endothelial damage, which may lead to accelerated atherosclerotic disease in later life, especially in cases of anatomical PAES, where early surgical treatment is recommended.<sup>34</sup> In cases of functional PAES, the treatment is less clear. A pilot study on the use of ultrasound guided Botox<sup>®</sup> at the site of entrapment is showing promising initial results but requires further research.

### Atherosclerotic vessel disease

Atherosclerotic vessel disease classically affects middle-aged sedentary patients. However, some athletes, particularly in the veteran or masters class, fall into the category of middle-aged or elderly and possess risk factors that predispose them to atherosclerosis.

Pain may be felt in the thigh or the calf and is typically claudicant. With progression of the disease, the intensity of exercise needed to produce symptoms decreases. At rest, the peripheral pulses may be difficult to palpate or

**Figure 39.11** Axial MRI images of the popliteal region of both knees. The medial head of gastrocnemius muscle (MHGM) is seen to arise from a more lateral position off the posterior aspect of the medial femoral condyle (MFC) leading to ‘crowding’ of the popliteal vessels

absent. An arterial bruit may also be heard at rest. The presence of such bruits may be enhanced by examining the patient post-exercise.

The gold standard diagnostic test is Doppler ultrasound, although pre- and post-exercise ankle-brachial ratios can be used as a non-invasive screening test. Angiography can confirm the diagnosis.

Surgical treatments include angiographic balloon catheter dilatation or stenting, open endarterectomy or bypass surgery. Bypass surgery is the most commonly used surgical technique for atherosclerotic vessel disease and its success depends on the extent of the disease and on the viability of the smaller distal vessels.

### Endofibrosis

Endofibrotic disease can cause exercise-related calf pain, although more commonly the pain is felt in the thigh. Typically the lesion occurs in the proximal external iliac artery, but may extend distally towards the origin of the femoral artery beneath the inguinal ligament. It is bilateral in 15% of cases.

External iliac artery endofibrosis has been described in endurance athletes and professional cyclists, and causes exercise-related thigh or calf pain that is related to the intensity of cycling.<sup>35, 36</sup> The pain is therefore most commonly felt while racing, climbing a hill or riding into a strong wind. The pain is typically relieved rapidly by a drop in the intensity of exercise.

In cyclists, it is postulated that the cycling position may cause repetitive stress and folding of the artery during high flow rates associated with extreme exercise. As a result, micro-traumatic lesions lead to thickening of arterial walls.<sup>36</sup> Psoas hypertrophy may also have a direct effect on the stresses around the external iliac artery.

Examination at rest may reveal a positional bruit heard over the femoral artery with the hip held in flexion. The diagnosis is made clinically by examining the patient immediately post-exercise, detecting a bruit over the femoral artery, and weak or absent distal pulses. Pre- and post-exercise ankle-brachial ratios screen for the diagnosis, which is anatomically confirmed with angiography. Arterial ultrasound or echography can also be useful in visualising the endofibrotic lesion.

Non-surgical techniques for the treatment of external iliac artery endofibrosis include angioplastic balloon catheter dilatation and stenting, which can be planned for and performed at the time of angiography. Surgical techniques include bypass surgery and open endarterectomy. In the short term, use of these techniques has made a return to top-level cycling and triathlon possible in patients.<sup>37</sup> However, long-term follow-up of such patients has not been carried out.

The natural history of this pathology is not certain. However, Abraham et al. suggest that it is non-progressive once high-level sport is ceased.<sup>38</sup> They advise that an athlete who is reducing his or her sporting level, and who is asymptomatic with activities of daily living and submaximal, be managed conservatively but followed up regularly.

## LESS COMMON CAUSES

### Neuromyofascial causes

The neural component of calf pain can be assessed with the use of the slump test (Fig. 39.2h). This may reproduce the patient's calf pain. If pain is relieved by cervical extension, neural structures may be contributing to the patient's pain.

The joints of the lumbar spine may occasionally refer pain to the calf. This should be suspected clinically if the pain is somewhat variable in location or if there is a history of recurrent 'calf strains'.

Another source of referred pain is myofascial trigger points in the gluteal muscles. Myofascial pain may present as an episode of sudden sharp pain and mimic a calf strain, as pain of more gradual onset accompanied by tightness, or as muscle cramps. Treatment consists of ischaemic pressure or dry needling to the trigger points followed by muscle and neural stretching.

The knee joint may also refer pain to the calf (Chapter 35). This may be due to a Baker's cyst, or a posterior cruciate ligament injury. Bleeding may track down into the calf from a strain of the posterior capsule of the knee joint or a popliteus muscle injury.

### Nerve entrapments

Nerve entrapments around the calf include:

- tibial nerve entrapment secondary to a Baker's cyst (rare)
- popliteal artery aneurysm or ganglion resulting in ankle inverter and toe flexor weakness and paraesthesia to the sole of the foot
- sural nerve entrapment, which may result from compression (ski boots, casts), mass lesions, trauma or thrombophlebitis causing pain and paraesthesia in the lateral heel and foot.

The sural nerve may be compressed in a fibrous arch that thickens the superficial sural aponeurosis around the opening through which the nerve passes. Intense physical training may lead to an increase in the sural muscle mass, which in turn compromises the sural nerve in its trajectory through the unyielding and inextensible superficial sural aponeurosis. The nerve may also become trapped in scar tissue.<sup>39</sup>

Investigations can include nerve conduction studies +/- MRI to detect a space-occupying lesion. Management includes conservative measures such as neural stretches, fascial massage or corticosteroid injections, and failing this, consideration of surgical exploration and/or neurolysis.

### Superficial compartment syndrome

Patients with superficial posterior compartment syndrome, the least common of the lower leg compartment syndromes, present with calf pain. The superficial compartment contains the gastrocnemius and soleus muscles, which are enclosed in a fascial sheath. Symptoms are similar to those of the other compartment syndromes with pain aggravated by activity and relieved by rest. An elevated compartment pressure confirms the diagnosis during and after exercise. Treatment consists of soft tissue therapy or, if this is unsuccessful, surgery.

Patients with either deep posterior compartment syndrome or stress fracture involving the posterior cortex

of the tibia may present with calf pain instead of, or as well as, shin pain (Chapter 38).

### CONDITIONS NOT TO BE MISSED

Deep venous thrombosis occurs occasionally in association with calf injuries. The post-injury combination of lack of movement, disuse of the muscle pump and the compressive effect of swelling may all lead to venous dilatation, pooling and a decrease in the velocity of blood flow. Certainly athletes who sustain a calf muscle injury should avoid travelling on long flights in the days after injury.

Deep venous thrombosis is a rare, but potentially fatal, risk after arthroscopy.<sup>40</sup> The diagnosis should be suspected when the patient has constant calf pain, tenderness, increased temperature and swelling. Homan's sign (passive dorsiflexion) (Fig. 39.2c) may be positive. Homan's test is taught to all medical students but has poor diagnostic utility. The best test for deep vein thrombosis is Wells' clinical prediction rule.<sup>41</sup> The presence of deep venous thrombosis may be confirmed by Doppler scan and venography.

# Pain in the Achilles region

with JILL COOK, KARIN SILBERNAGEL, STEFFAN GRIFFIN, HÅKAN ALFREDSON and JON KARLSSON

*The anger is rage. Why the hell did this happen!!? . . . Now I'm supposed to come back from this and be the same player or better . . . How in the world am I supposed to do that?? . . . Maybe this is how my book ends. Maybe Father Time has defeated me . . . Then again maybe not!*

Kobe Bryant, LA Lakers shooting guard and five-time NBA champion, after rupturing his Achilles tendon in a game against the Golden State Warriors in 2013. He returned to play until his retirement in 2016

The Achilles tendon is prone to injury when subjected to unaccustomed repetitive high loads.<sup>1,2</sup> Runners, for example, have a 15 times greater risk of Achilles tendon rupture and 30 times greater risk of tendinopathy as they age than do sedentary controls.<sup>3</sup> In this chapter, we review the approach to assessment (history, examination, investigation). We then outline the specific treatment approaches.

### PRACTICE PEARL

Patients most commonly present with gradual (overuse) pain in the Achilles region due to pathology in the midportion of the Achilles tendon (Fig. 40.1a).

Other important conditions in order of prevalence at a sports clinic with a broad-based clientele are:

- pain at the insertion of the Achilles tendon and associated retrocalcaneal bursa ('enthesis organ')
- posterior impingement (an important differential diagnosis)
- Achilles pain related to the plantaris tendon
- pain related to friction between the Achilles tendon and surrounding tissues (peri-tendinopathy).

Achilles tendon pathology can also manifest in a very different, dramatic manner: via acute rupture of the Achilles tendon. This immediately disabling condition is captured in the chapter opening quote. The management of cases like that of Kobe Bryant is discussed in the last section of this chapter.

### CLINICAL PERSPECTIVE

The key areas of pain in the Achilles region (posterior heel and proximal toward the calf) are illustrated in Figure 40.1.

(a)

**Figure 40.1** The Achilles region (a) The midportion of the tendon is clearly distinct from the insertion—an important clinical feature

(b)

(c)

**Figure 40.1 (cont.)** (b) The anatomy of the Achilles midportion, Achilles insertion and posterior process of talus (c) Stylised illustration to show the blood supply of the normal Achilles tendon (top) and in tendinopathy (middle and below)

The Achilles tendon is the combined tendon of the gastrocnemius and soleus muscles, and is the thickest and strongest tendon in the human body.<sup>4</sup> Anteriorly, the deep surface of the tendon is supported by a fat pad (Fig 40.1b) through which most of the vessels and nerves enter the tendon (Fig. 40.1c). The tendon has no synovial sheath, but has a peritendon which is continuous with the perimysium of the muscle and the periosteum of the calcaneus, and which enfolds the anterior fat pad of the tendon. The tendon attaches to the inferior half of the calcaneus. The plantaris tendon is located medial to the Achilles and has variable anatomy, which is discussed later. The posterosuperior process of the calcaneus approximates the Achilles, usually with a bursa between.

The vast majority of patients who present with gradual onset of Achilles region pain can be treated successfully non-operatively. Experienced clinicians can quickly home in towards a diagnosis by following the clinical reasoning outlined in Figure 40.2. The first step is to rule out recent acute rupture by listening to the patient's history and performing one simple clinical test (see Physical examination, below). In many cases of acute Achilles tendon rupture, the patient or a friend has diagnosed the condition before reaching the clinician's office.

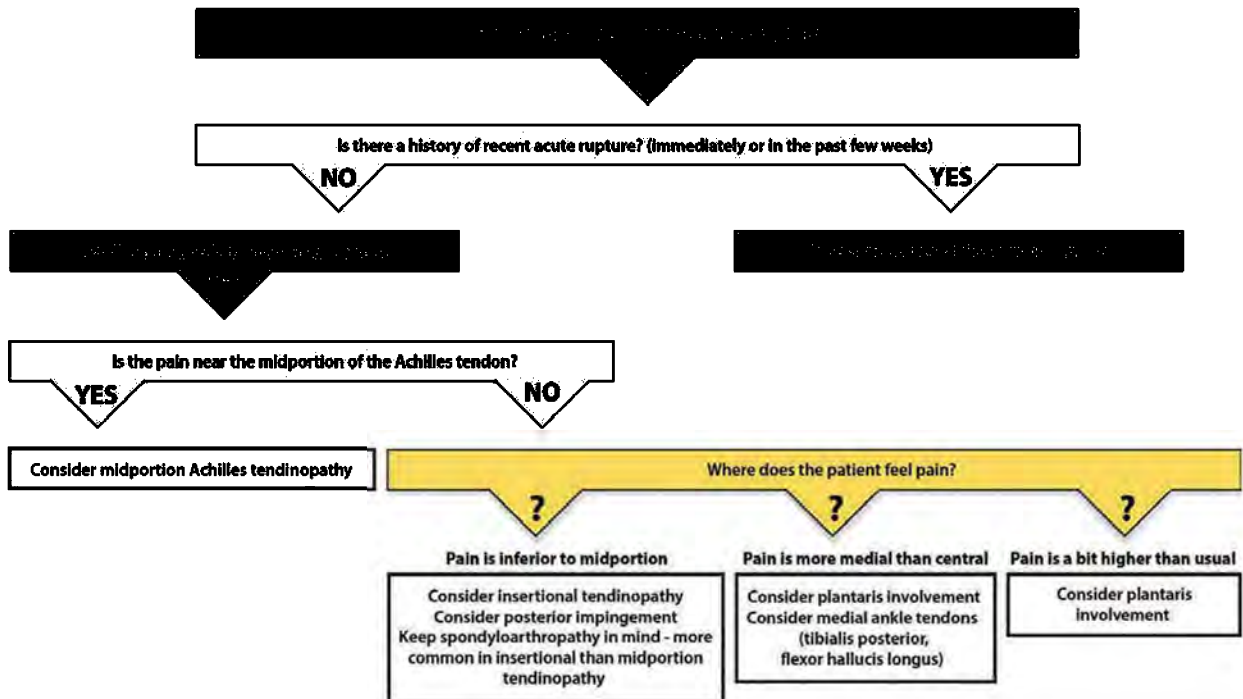

Among the conditions that manifest with more gradual onset of Achilles region pain, the most common is midportion tendinopathy. Have the patient point to the location of pain during the history—that part of the leg is easily accessible during the office consult with most types of clothing. If the history and location of pain do not fit the typical pattern for midportion tendinopathy, use the location of pain to consider other diagnoses. Broadly speaking, the second most prevalent condition is insertional tendinopathy and its associated bursitis, but in settings like a ballet school, posterior impingement will be more common than insertional tendinopathy (and more common than midportion tendinopathy too!).

## History

The standard presentation is with the patient reporting a gradual onset of pain around the midportion of the Achilles, often first noticed on waking and generally associated with a recent increase in load volume or intensity.<sup>1</sup> Patients complain of pain at the start of activity and pain and stiffness the following morning.

### PRACTICE PEARL

The combination of morning stiffness and pain confined to the tendon is a hallmark of Achilles tendinopathy. If these are not present, the clinician should consider alternative diagnoses.

**Figure 40.2** Flow diagram showing how to rapidly subgroup patients with various presentations of pain in the Achilles region

If the patient gives a history of typical midportion Achilles pain, the clinician can follow up with questions aiming to identify the cause. Was the main inciting factor a sudden increase in loading—for example, due to an increased volume, intensity or type of exercise, or a change in surface or footwear? Commonly, return to loading after a layoff for another injury is the catalyst; this also reflects a relative increase in load. Or is there a systemic condition underpinning tendinopathy (e.g. consider the possibility of Type 2 diabetes mellitus, especially in older and overweight people)?

Careful history taking is important in case the gradual-onset Achilles region pain arises from neighbouring anatomy. For example, pain medial to the Achilles tendon or deep to the Achilles tendon with a pain pattern that is not typical of Achilles tendon suggests an alternative diagnosis.

As highlighted in Figure 40.2, the location of pain provides important diagnostic information. Pain closer to the musculotendinous junction than the standard midportion Achilles pain (Fig. 40.1a) can arise from the plantaris tendon being pathological itself or causing local Achilles tendon pathology.

**Table 40.1** Causes of pain in the Achilles region

Common	Less common	Not to be missed
Midportion Achilles tendinopathy (including tendinosis—with or without partial tears—and peritendinopathy)	Plantaris tendon involvement	Achilles rupture—partial/total accessory soleus muscle
Insertional Achilles tendinopathy (at the superior lateral calcaneum, pathology includes retrocalcaneal bursitis)	Flexor hallucis longus and tibialis posterior tendinopathy (Chapter 42)	Referred pain <ul style="list-style-type: none"> <li>• Peripheral neural structures</li> <li>• Lumbar spine</li> </ul>
	Subcutaneous bursitis	Sever's disease (in adolescents)
	Posterior ankle joint impingement	Metabolic condition (potentially undiagnosed) <ul style="list-style-type: none"> <li>• Hypercholesterolaemia</li> <li>• Type 2 diabetes mellitus</li> </ul>
	Tightness of the posterior Achilles retinaculum, compressing the tendon (rare)	Spondyloarthropathy (Chapter 7)

## PRACTICE PEARL

If the patient offers a history of repeated soleus strains (low calf pain that comes and goes), has proximal, *medial* Achilles pain and is intolerant of dorsiflexion loading, be alert to the possibility of plantaris tendon involvement.

If the patient engages in activities that involve repeated end-range plantarflexion, posterior impingement is the key differential diagnosis for pain approximately at the midportion. The textbook activity with high prevalence of this condition is ballet (pointe/demi-pointe), but it is a common presentation to the clinic in football players (kicking), sprinters and cricket fast bowlers.

### A key alternate diagnosis

Anatomically, the impingement (of the os trigonum or the posterior process of the talus, Fig 40.10 below) takes place anterior and inferior to the Achilles midportion. Some patients appreciate that the pain feels 'deeper' than at the Achilles tendon, but many do not offer that distinction, so the clinician must bracket the midportion Achilles diagnosis with the possibility of posterior impingement. It is not uncommon for a patient to have wasted time and 'failed' prolonged Achilles rehabilitation when the true diagnosis was posterior impingement. Having considered these two conditions together, the clinician can easily distinguish them during physical examination (see passive plantarflexion).

The patient may report pain medially at about the level of the Achilles tendon; this can be due to tibialis posterior peritendinopathy (proximal to the flexor retinaculum of course) or flexor hallucis tendinopathy (a common ballet pathology). These two conditions generally present more inferiorly and more medially than typical midportion Achilles tendinopathy. These two conditions are discussed in Chapter 42.

If the patient gives a history of relatively unloaded plantarflexion and dorsiflexion, such as an inexperienced cyclist spiking his or her load, consider peritendinopathy.

### A sudden explosive event

A sudden, disabling sensation or pain and inability to function is often due to complete tendon rupture. The greatest prevalence is among men aged between 30 and 50.<sup>5,6</sup> It occurs in sports with explosive movements like basketball, tennis and Ultimate (Frisbee®), but it can arise in people with underlying degenerative (but asymptomatic) tendon pathology as simply as a result of stepping off a curb awkwardly. The patient often reports hearing a noise like a gunshot or feeling like he or she was kicked on the tendon.

## PRACTICE PEARL

Many textbooks suggest that complete Achilles rupture prevents active plantarflexion. This is wrong! Patients can often plantarflex weakly in non weightbearing positions using intact accessory plantar flexors such as tibialis posterior, plantaris, flexor digitorum longus and flexor hallucis longus. It is a naive error to rule out Achilles tendon rupture from patient reports of plantarflexion. The key diagnostic test is the 'calf squeeze test' (also called Simmond's or Thompson's test)<sup>7,8</sup> (see Fig. 40.3h).

When the patient reports an acute episode, other possibilities include (i) partial rupture of the Achilles tendon and (ii) plantaris tendon rupture. The latter presents with acute onset of pain on the medial side of the upper Achilles midportion. In athletes, this typically occurs during sprinting. If the presentation to the clinic is not acute, the patient may report having had a short period (3–5 days) with disabling pain and then being able to run again.

### Physical examination

If there is no suspicion of tendon rupture, the examination should begin with the patient standing. The clinician should first assess the muscles for signs of wasting, then examine how the patient copes with loading tasks likely to provoke pain. In most patients, simple double or single-leg heel raises will cause pain. In more active individuals whose tendon can tolerate higher loads, ask the patient to hop on the spot or hop forward to reproduce pain.

In some athletes, repeated loading tests (multiple hops, jumps) or examination after a training session will be valuable to fully evaluate the tendon. Record not only the function of the calf and Achilles tendon, but also note how the lower limb kinetic chain is performing. Longstanding symptoms can cause substantial unloading (favouring the unaffected side) and impair the function of the entire kinetic chain (see Chapter 8).

After assessing function, assess strength and strength endurance, and seek possible predisposing factors such as unilateral calf tightness, reduced dorsiflexion and abnormal lower limb biomechanics. This may require analysis of treadmill running or video analysis of jump and other sporting movements that are provocative (Chapter 8).

Finally, compare the resting muscle tone between sides and palpate around the tendon for specific areas of tenderness (e.g. ventral, superficial, medial tendon), crepitus (a 'crackling' feeling that arises because of the fibrinous exudate in the peritendon) and tendon thickening.

**PRACTICE PEARL**

Palpation tenderness in the Achilles is not a diagnostic or prognostic sign. Achilles tendons are always sore to touch. (Tenderness—pain on palpation—has a very poor positive likelihood ratio (LR+). See Chapter 14.)

**B**

A focused examination relevant to the patient who presents with Achilles pain includes:

## 1. Observation

- standing and walking: Observe soleus and gastrocnemius muscle bulk on both sides. Look for wasting of quadriceps femoris and gluteal muscles
- ask the patient to identify the location of pain (midportion, distal, specific to Achilles tendon or more medial/lateral) (Fig. 40.1a). You may see thickening at site of pain or you may be able to feel crepitus
- if Achilles tendon rupture is a possibility, inspect for obvious swelling (Fig. 40.3a). If the patient is seen acutely, the tendon defect is evident beneath the skin at the site of rupture. This defect fills rapidly with blood but if the patient is lying supine, the unsupported foot rests in excessive dorsiflexion due to loss of resting calf muscle (plantarflexion) tone (see also special tests, below).

## 2. Functional tests

- plantarflexion—double- and single-leg calf raises for pain
- hopping/forward hopping (if clinically indicated—in higher-functioning patients while testing their capacity) (Fig. 40.3b)
- strength/endurance—examine the patient's capacity to repeat single-leg heel raises with full height. Record the number as a baseline
- biomechanics (see also Chapter 8 for general biomechanical assessment)
  - Active dorsiflexion (lunge)
  - Gastrocnemius stretch (Fig. 40.3c)
  - Soleus stretch (Fig. 40.3d)

## 3. Supine/prone

- active movements (only useful if rupture suspected)
  - plantarflexion and dorsiflexion
  - first-toe flexion and extension in full ankle plantarflexion for flexor hallucis longus tendinopathy (Fig. 40.3e)

(a)

(b)

**Figure 40.3** Examination of the patient with pain in the Achilles region (a) Inspect for Achilles tendon rupture if this is a possibility. In this case the right side has a ruptured Achilles tendon (b) Functional tests. These can be used to reproduce pain, if necessary, or to test strength. Tests include double-leg and single-leg calf raises, hops (illustrated), hops forward, eccentric drops and lunge

(c)

(d)

**Figure 40.3 (cont.)** (c) Passive movement—muscle stretch (gastrocnemius). The patient stands so that body weight causes overpressure. The knee must remain extended and the heel (back foot) keeps contact with the floor. The foot remains in neutral if the patient keeps the patella in line with the second metatarsal. Compare the stretch on both sides (d) Passive movement—muscle stretch (soleus). The patient stands upright and keeps the knee flexed. The foot should remain in a neutral position

b. Passive movements

- i. plantarflexion with and without overpressure (Fig. 40.3f) to assess posterior impingement)
- ii. inversion and eversion

c. Palpation

- i. firm palpation of the Achilles tendon is not recommended as normal tendons are tender—they are painful to touch
- ii. palpation may identify associated pathologies (such as the more proximal medial tenderness

if the plantaris is a cause of pain/contributing to Achilles tendinopathy)

- iii. Posterior talus may be tender in posterior impingement but the key test is the passive plantarflexion test
- iv. Palpate more inferiorly and medial to the midportion Achilles tendon for flexor hallucis longus tendinopathy
- v. Palpate the tibialis posterior tendon before it passes under the flexor retinaculum to ensure it is not contributing to symptoms
- vi. Assess the flexor hallucis longus, which is a differential for posterior impingement

(e-i)

(e-ii)

(g)

(f)

**Figure 40.3 (cont.)** (e) Active first-toe flexion and extension in full ankle plantarflexion for flexor hallucis longus tendinopathy (e-i) Active movement without resistance (e-ii) Movement against the examiner's resistance. Examiner is feeling for FHL swelling or crepitus with her left hand (f) Passive movement—plantarflexion. This will be painful if posterior impingement is present. Overpressure can be applied (g) Observation (prone)—for suspected Achilles tendon rupture. The Achilles tendon would normally bridge the space from the superior calcaneum through to the muscle tendon junction (normal anatomical skin/tendon position shown by dotted line). In cases of tendon rupture (arrow), the tendon is not connected to the calcaneum and rests on underlying soft tissue. (h) Special test—the calf squeeze test. (h-i) At rest. The ruptured Achilles (right leg, white arrow) hangs more vertically compared to the uninjured leg (red arrows). (h-ii) Squeeze. The ruptured Achilles (right leg) fails to plantar flex (red arrow), while the normal leg plantar flexes on squeeze (green arrow)

(h-i)

(h-ii)

- vii. Achilles tendon insertion and retrocalcaneal bursa (insertional tendinopathy)
- viii. Tightness in the posterior retinaculum
- ix. Crepitus associated with peritendinopathy

#### 4. Special tests

- a. Inspect for tendon defect and loss of resting tone for tendon rupture (Fig. 40.3a, g)
- b. Simmond's/Thompson's calf squeeze test<sup>7, 8</sup> (Fig. 40.3h).

### Key outcome measures (PROMs)

Functional tests mentioned and depicted above (number of calf raises, hops) provide a baseline against which to compare treatment response. In addition, the Victorian Institute of Sport Assessment–Achilles (VISA-A) has been widely used since 2001 to monitor the clinical progress of Achilles tendinopathy<sup>17</sup> (Table 40.2). It takes less than 5 minutes to complete and once patients are familiar with it they can complete it themselves. Scores range from 0–100, where 100 represents no pain, full function and no limitation of training or competition. Baseline values for Achilles tendinopathy patients can be expected to be between 24 and 60, and scores above 90 represent full recovery.<sup>18</sup> The minimum clinically important difference (MCID) of the VISA-A score is in the range of 12–20.<sup>19–21</sup> The VISA-A should be administered monthly rather than daily or weekly as 40% of the score comes from capacity to complete higher-load activities.

### Investigations

Plain radiographs are of limited value—they do not improve the positive likelihood ratio (Chapter 14) of making the diagnosis of a form of Achilles tendinopathy (either midportion or insertional).<sup>22</sup> Tendon calcification is not a predictor of current symptoms or prognosis (Fig. 40.4a). The patient should be managed according to symptoms. A radiographic finding of a prominent superior projection of the calcaneus (Haglund's morphology) is normal. See discussion of this condition below. Anatomical changes responsible for posterior impingement may also be evident on plain radiographs (see posterior impingement section later in this chapter); such anatomy does not predict current symptoms or prognosis.

In patients with Achilles tendon pain, ultrasound examination can help distinguish whether the Achilles or the peritendon or both have pathology. Greyscale ultrasound examination (Fig. 40.4b, c) can be combined with colour and power Doppler (Fig. 40.4d) that reflects blood flow inside and outside the tendon. MRI can demonstrate abnormal tendon morphology (Fig. 40.4e) but it did not prove a good predictor of current or future symptoms.<sup>15</sup>

#### PRACTICE PEARL

**Under careful diagnostic scrutiny, imaging such as colour and power Doppler examinations and MRI have been disappointing for clinicians who had hoped they could offer prognostic information or guide response to treatment<sup>15, 23–25</sup> (see also Table 40.4 and Chapter 15).**

Ultrasound tissue characterisation (UTC) (Fig. 40.4f) is not grouped with ultrasound modalities above as it is not in wide clinical use. It is an extension of traditional ultrasound<sup>19</sup> (Chapter 15) that allows intratendinous structure to be quantified. As with other imaging modalities, an abnormal UTC appearance does not guarantee that the tendon is the source of pain; experienced clinicians believe that the appearance of abnormal collagen may increase the positive likelihood ratio (Table 40.3). UTC can demonstrate changes in Achilles tendon structure with loading rehabilitation (i.e. the effect of mechanotherapy, Chapter 17),<sup>23</sup> in cases of tendinopathy and also after tendon rupture. UTC is not yet useful to guide treatment; rehabilitation should be guided by clinical assessment and functional testing.

### MIDPORTION ACHILLES TENDINOPATHY

This section outlines (i) pathology so that it can be explained to patients, (ii) relevant risk factors and (iii) treatment principles including a four-stage exercise program based on the concept of tendon capacity (Chapter 4, Fig. 4.14).

#### Pathology

The macroscopic changes seen at surgery for chronic midportion Achilles tendinopathy are characterised by a poorly demarcated dull-greyish discolouration of the intratendinous collagen with a focal loss of normal fibre structure.<sup>26, 27</sup> Partial ruptures may occur in regions of pre-existing pathology.<sup>28</sup> Peritendinous structures may be normal, oedematous or scarred. If scarred, the peritendon may adhere to the tendon.

Under the light microscope, pathological tendon reveals abnormal proliferation of tendon cells (fibroblasts), increases in ground substance, collagen fibre disarray and increased vascularity as outlined in Chapter 4 (see box and Figs. 4.10 and 4.11). These regions of tendon disarray correspond to areas of increased signal on MRI and hypoechoic regions on ultrasound<sup>29</sup> (Fig. 40.4c, d, e).

(c)

(e)

**Figure 40.4** Imaging findings in the Achilles region (a) Calcification is a common finding in pathological tendons. It should not influence management and a bone spicule (circle) is very difficult to find in surgery. The take-home message is to manage according to symptoms and function; do not manage the radiograph (b) Greyscale ultrasound of a normal Achilles tendon (arrows). The superior calcaneum (arrowhead) prevents sound waves from penetrating, hence the acoustic 'shadow' deep to the calcaneal margins (c) Greyscale ultrasound of an Achilles tendon with mild morphological abnormality (arrows)—thickening of the tendon and less echodensity (because of increased matrix ground substance and associated fluid) (d) Colour Doppler ultrasound showing abnormal vessels in symptomatic tendinopathy. Appearances do not mirror symptoms enough to provide definitive clinical support (e) MRI appearance of increased signal in the distal Achilles tendon extending into the insertion (blue oval)

(f)

**Figure 40.4 (cont.)** (f) Ultrasound tissue characterisation (UTC). This ultrasound modality has been most used in Achilles tendinopathy as the subcutaneous tendon anatomy is well suited to the linear probe. Whether the instrument will have widespread clinical utility remains to be seen

**Table 40.4 Imaging findings in overuse Achilles tendinopathy (i.e. not a complete rupture). Imaging appearances do not equate with symptoms nor do they predict time to return to sport (recovery). See also Figure 40.4**

Imaging appearance	Variations seen in clinical practice
Normal appearance on ultrasound/MRI	It is possible, but unusual, to have a normal imaging with symptoms of Achilles tendinopathy. Carefully evaluate alternative structures as a potential source of pain
Ultrasound and MRI tendon swelling	Tendon thickening varies, but there is often a fusiform swelling. Evaluate contribution of peritendon to swelling
Ultrasound discontinuity of tendon fascicles	Hypoechoic regions are often seen inside the thickened tendon. This corresponds to a fluid-rich region with irregular collagen fascicle arrangement
Doppler ultrasound evidence of high blood flow	May be extensive or absent and may vary in amount when imaged after rest or activity, and on different days
Increased MRI signal	Abnormal high signal, best seen on T2-weighted sequences (see also Chapter 15 for more advice for clinicians on interpreting MRI)

Inflammatory cells are few in midportion Achilles tendinopathy.<sup>26, 30</sup> Intratendinous microdialysis<sup>31, 32</sup> and analysis of appropriately prepared biopsy tissue using cDNA-arrays and real-time quantitative polymerase chain reaction (PCR)<sup>33</sup> all failed to show prostaglandin-mediated inflammation.<sup>34</sup> The debate around whether Achilles tendinopathy has an inflammatory component or not<sup>35</sup> is complicated because of the various definitions of inflammation.<sup>36</sup>

Biopsy specimens from midportion Achilles tendinopathy show increases in some cytokines and neuropeptides, such as substance P and calcitonin gene-related peptide (CGRP). Activated tendon cells can produce substances that can cause pain that may be detected by nerves in the peritendon.<sup>37</sup> Tendon pain is complex and the source is often unknown.<sup>38</sup> (See Chapters 5 and 6 for more on pain biology.)

## Predisposing factors for Achilles tendinopathy

Midportion Achilles tendinopathy is most common among active people, but it also occurs in inactive individuals. Irrespective of the baseline level of activity, relative tendon overload is the main trigger. This may occur in a single episode or, more often, over a period of time. Athletes, for example, may overload their tendon during an intensive period of competition or training, whereas for inactive people the commencement of a new exercise regimen may be sufficient. Although overload is considered to be the primary inciting event for tendinopathy, tendons' response to load is also influenced by a range of intrinsic and extrinsic risk factors.

### Intrinsic risk factors

Modifiable intrinsic risk factors include central adiposity in men and peripheral adiposity in women,<sup>39</sup> increased BMI,<sup>40, 41</sup> hypercholesterolaemia and diabetes mellitus (type 1 and 2).<sup>42, 43</sup> Non-modifiable factors include previous injury/tendinopathy,<sup>44, 45</sup> genetic predisposition (certain genes coding for collagen),<sup>46, 47</sup> exposure to fluoroquinolones<sup>48</sup> or steroids,<sup>49</sup> and (for insertional tendinopathy) inflammatory arthritis.<sup>50</sup> Older age may also be a risk factor; however, the current evidence is conflicting, suggesting that other specific factors such as cumulative load may influence this association.<sup>51</sup>

There are also a number of modifiable biomechanical factors associated with Achilles tendinopathy, shown in Table 40.5. These either increase strain on the tendon or reduce its ability to bear load. Contrary to popular belief, there is little evidence of an association between subtalar joint pronation and Achilles tendinopathy.<sup>52</sup> In fact, a *supinated and rigid foot* is associated with tendinopathy.<sup>53-55</sup>

### Extrinsic risk factors

In active individuals, the main extrinsic risk factor for Achilles tendinopathy is a recent change in tendon loading, such as increasing distance, speed or frequency of training/competition with insufficient recovery between loading periods.<sup>61-64</sup> In particular, a sudden increase in activities involving high energy storage, such as jumping and landing, is thought to be important. In sedentary individuals this stimulus may be significantly less but the principles still apply. Other extrinsic risk factors such as changes in footwear or training surface may be important, especially in elite athletes, but are secondary to load.

### Treatment of midportion Achilles tendinopathy

Experienced clinicians begin conservative treatment by identifying and correcting possible aetiological factors. Most importantly, this involves management of the patient's tendon load (first decrease load to control symptoms and then increase load to improve tendon capacity). Biomechanical limitations such as restricted ankle dorsiflexion and hallux rigidus should also be addressed if possible. Below, we outline common treatments for Achilles tendinopathy including targeted exercises (mechanotherapy,<sup>65</sup> see Chapter 17), injections and surgery.

### Focused rehabilitative exercise training: the hub of tendinopathy treatment

Exercise training is at the hub of effective treatment for midportion Achilles tendinopathy (Fig. 40.5). Such

treatments became the preferred non-surgical management for Achilles tendinopathy after Alfredson published his eccentric loading program in 1998.<sup>66</sup> Repeated and, initially, pain-provoking exercise led to patients being pain-free in about 12 weeks. This program was a landmark in moving treatment away from rest and passive approaches. In addition to the good clinical results, ultrasound and MRI follow-up demonstrated that patients' tendons improved in appearance and decreased in thickness, although they did not return to a normal appearance.<sup>67</sup>

#### PRACTICE PEARL

Various types of exercise programs are effective for tendinopathy—there does not appear to be anything 'magical' about eccentric exercise in this setting.<sup>68, 69</sup> The combination of eccentric and concentric movements may be as beneficial as eccentric movements alone.<sup>69-71</sup>

Doing both concentric and eccentric exercises may also promote muscle strength and endurance adaptation.<sup>69, 72</sup> In addition, the inclusion of more dynamic exercise may not adversely affect the outcome.<sup>73</sup>

The take-home message in 2017 appears to be that progressively loading the muscle tendon unit (kinetic chain) to promote recovery of full-capacity tendon is likely the effective stimulus; this argues against 'recipe

**Table 40.5 Biomechanical factors that are associated with Achilles tendinopathy and their possible mechanisms**

Factor	Possible mechanisms	Assess by
Relative weakness in plantarflexion strength <sup>53</sup>	Increased load on tendon by failing to attenuate load	Single-leg heel raise, single-leg hop, dynamometer or strength/endurance tests (heel raise to fatigue)
Increased dorsiflexion range of motion <sup>53</sup>	Increased tendon load (via longer loading period) and longer levers Possible collagen abnormalities (e.g. benign hyperlaxity syndrome/Ehlers–Danlos syndrome)	Weight-bearing (knee to wall) and non weight-bearing assessment of dorsiflexion ROM
Reduced dorsiflexion range of motion with or without supinated foot type <sup>54, 56</sup>	Increased tendon load (due to faster loading time)	Weight-bearing (knee to wall) and non weight-bearing assessment of dorsiflexion ROM
Reduced knee flexor strength <sup>57</sup>	Increased tendon load by increasing demand on plantarflexors	Dynamometry or clinical strength/endurance tests (bridging) <sup>58</sup>
Poor quality tendon structure <sup>59, 60</sup>	Reduced capacity to tolerate load Less effective load-bearing tissue	Ultrasound, Ultrasound Tissue Characterisation (UTC), MRI

physiotherapy' ('Do X of these exercises twice a day like a robot'). The 'capacity' concept<sup>74</sup> is illustrated and discussed in Chapter 4 (see Fig. 4.14). That key diagram can be photocopied and marked up to show patients their current capacity (triangle at bottom left of the figure) and their required capacity (triangle at top right of the figure). Different exercises are prescribed to improve the patient's capacity (Chapter 4, four-stage training program).

### Four-stage, progressive Achilles exercise program adapted to the clinical assessment

In this chapter, the broad 'capacity' concept is customised for Achilles tendinopathy in Figure 40.6. The four stages of treatment include three relating to developing tendon capacity and one that provides analgesia (isometric exercises). The four stages are outlined in the box.

### Prevention: Can exercises prevent tendinopathy?

Eccentric exercise appears to be ineffective as a prophylactic treatment to prevent Achilles tendinopathy. Soccer players who performed eccentric exercise and stretches during the playing season were no more likely to be free of Achilles tendon injury than those who did not.<sup>59</sup>

### Beware: Is the plantaris tendon a culprit?

The plantaris tendon is usually a tiny benign tendon medial to and removed from the Achilles (Fig. 40.8a) In some people, it enlarges and compresses the Achilles tendon, in others it can be ensheathed in the Achilles peritendon (Fig. 40.8 b, c, d) In both cases the variable properties of the plantaris and Achilles cause compression of the Achilles tendon and may provoke tendinopathy.<sup>77-79</sup> The plantaris was first identified as a potential contributor to midportion Achilles region pain around 2011.<sup>80</sup> The clinical clues to this culprit are pain and tenderness that are more medial and more proximal to the 'classic' midportion Achilles tendinopathy symptoms and pain aggravated by loading in dorsiflexion.

If this diagnosis is suspected, imaging (ultrasound or MRI) is indicated.

**Figure 40.5** Treatment of midportion Achilles tendinopathy. Warning! Warning! The numbers in this conceptual figure are not to be taken literally. There are many possible treatment options for Achilles tendinopathy. Systematic reviews indicate that various forms of exercise prescription provide superior pain relief over control treatments (level 1 evidence). The relative effect sizes suggested in this figure should be considered estimates and will vary from patient to patient. The estimates of relative importance reflect the chapter authors' expert clinical experience (level 5 evidence). It highlights that not all treatments are created equal

### Plantaris management

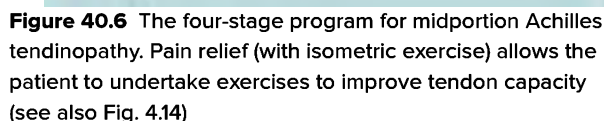

Conservative management of this condition follows the loading principles of the four-stage program (outlined in the box below, Figs. 40.6 and 40.7) while reducing compression of the plantaris against the Achilles tendon. This is achieved by ensuring the patient completes all exercises with a moderate degree of ankle plantarflexion, and avoids loads in dorsiflexion, especially in the early stages of rehabilitation. Using a high heel raise similar to those used for insertional Achilles tendinopathy (see below) will allow the patient to complete these exercises pain-free. At stages 3 and 4 of the rehabilitation program, it is appropriate to gradually reduce the heel height until the exercise can be completed through the full range.

### The four-stage program for midportion Achilles tendinopathy

This four-stage rehabilitation program incorporates the exercises from various published programs and is clinically effective for Achilles tendinopathy. The key elements are its (i) stages, (ii) progressive nature, and (iii) flexibility (to adapt it to clinical re-assessment).

#### Stage 1—Pain relief. Isometric exercises

Patients focus on isometric calf raise exercises that relieve pain. These can be done with simple body-weight holds (single- or double-leg depending on strength and pain), but athletes require weights in a standing heel raise machine.

The isometric holds should be long (up to 45 seconds) with the load that can be held without perturbation in the muscle. Four to five repetitions interspersed with 2 minutes rest have proven effective in our clinical experience. This exercise can be repeated several times a day to provide the patient with pain relief as needed.

In those who have substantial pain and pathology, the seated heel raise exercise offers the opportunity to use loads that are below body weight; it is possible to find an isometric load that is suitable for even the most compromised tendon.

Progress the patient to this stage when Achilles tendon pain has settled and the patient is competent at isometrics and slowly building both (i) hold time (45 s, as above) and (ii) weights (adjusted based on what the patient can do and hold steady). Isotonic exercise (slow concentric and eccentric heel raises) with body weight or additional weights with a weight-based machine strengthens muscle and provides beneficial load to tendon. Aim to go from full plantar flexion to plantar grade (i.e. neutral). Only lower into dorsiflexion for athletes who need strength in this range.

Remember: Isometrics can be done prior to isotonic loading as they may relieve cortical motor inhibition that will assist with strength gains.<sup>75,76</sup>

If necessary, a strength endurance exercise can be added, where one set to fatigue of repeated heel raises is completed each night. A functional alternative is stair climbing with the foot maintained in sustained plantarflexion; that is, the heels do not touch the steps while climbing.

Exercises in this stage place faster loads on the tendon and this causes the tendon to store energy and begin to act as a spring. In stages 3 and 4 (see below) the patient does not carry additional weight; body weight is sufficient and provides close to maximum load for the tendon. Any fast exercise, particularly if it includes eccentric loading, will induce energy storage, so exercises such as slow skipping-type activities and faster stair climbs are ideal. Stage 3 and 4 loads should be completed a maximum of three times a week. The remaining days can be used to continue strength work and cross-training.

These exercises are a progression of stage 3, where the speed increases and the release of energy from the tendon occurs. Faster skipping, running drills and change of direction drills begin to prepare the athlete for return to training.

This is an essential, and often neglected, element of successful tendon rehabilitation (see also Chapters 18 and 19). We distinguish this final element from the four-stage tendon rehabilitation so as not to dilute the tendon-specific elements of that program. Return-to-training or return-to-play exercises are constructed with the athlete's specific functional requirements in mind. Thus, there is no recipe because the demands of an elite track athlete and recreational runner are very different even within the one activity/sport (running). Transition to training is permitted when the person can complete stage 4 exercises repeatedly without an increase in symptoms the morning after the rehabilitation session.

### How does exercise promote tissue repair in tendinopathy?

Exercise therapy can affect any tissue at the cellular level through the process of mechanotherapy,<sup>65</sup> and this is detailed in Chapter 17.

**Figure 40.7** Loading exercises (left panel), cause sliding of collagen fibres (illustration of the microscopic view, top centre panel) leading to intercellular<sup>65</sup> communication via gap junctions (top right panel), and intracellular communication with the cell nucleus (lower right panel).

REPRODUCED WITH PERMISSION OF BRITISH JOURNAL OF SPORTS MEDICINE

Because the aberrant plantaris can be fixed to the Achilles tendon (Fig. 40.8), conservative management may not be successful. Sweden's Professor Håkan Alfredson was a pioneer in identifying this pathology in patients with painful Achilles tendons.<sup>80</sup> Surgery is performed under ultrasound and Doppler guidance. The symptomatic pathological region is approached using a medial incision and the adherent tendons are separated or the plantaris tendon is extirpated (divided and removed).<sup>81</sup>

### Other interventions used in conjunction with staged progressive exercise therapy

We summarise interventions that have been used in conjunction with an exercise program (Table 40.6) and note two things. First, exercise is excellent for tendons and, second, added interventions add minimally to exercise therapy. It is important to apply the 'exercise is medicine' message from public health to tendons.

**Figure 40.8** The anatomical relationship between the (a) Anatomy considered 'normal' for the Achilles and plantaris tendons (b) The plantaris commonly inserts in an aberrant manner—to the medial border of the Achilles tendon (green arrow). This can promote Achilles tendinopathy (black arrow) (c) Cross-sectional schematic showing commonly seen variations in the anatomical relations

It is unfortunate that among many patients and clinicians, exercise is incorrectly assumed to be less effective than traditional medical therapies such as medication or injection.

### Injections

There are a range of substances that have been used both in and around the Achilles tendon. The basis for injection is variable, but should only be used when there is failure

(d)

**Figure 40.8 (cont.)** (d) Plantaris tendon (P) adherent to the medial aspect of the Achilles tendon (arrow) with prominent richly vascularised fat tissue that (G) contains sympathetic and sensory nerves

to respond to a good quality exercise program for an extended time.

### Corticosteroid injections

Corticosteroid injections are falling out of favour for long-term management of tendinopathy.<sup>86</sup> Corticosteroid has an immediate and short-term pain-relieving effect (for up to 8 weeks). The mechanism for cortisone potentially healing a tendon has not been clearly articulated and clinical trials of the medication consistently point to poorer long-term outcomes than 'wait and see' in various tendons. There has been no high-quality study of corticosteroid injection versus placebo or 'wait and see' at the Achilles tendon as there has been at the elbow. Longer-term outcomes at various anatomical sites are poorer than both no intervention and exercise interventions.<sup>96</sup>

### Autologous blood and platelet-rich plasma (PRP)

With ROBERT-JAN DE VOS

Autologous blood and platelet-rich plasma (PRP) has become popular in recent years. They have been proposed to improve tendon healing because of the growth factors and cytokines present in blood.<sup>97, 98</sup> There are many protocols for the preparation and injection of the blood products and cells, making it harder to compare studies. A

number of clinical trials have been performed on patients with chronic midportion Achilles tendinopathy. One small randomised study did not show benefit of PRP compared to eccentric exercise therapy.<sup>99</sup> One placebo-controlled randomised trial on the effectiveness of PRP combined with eccentric exercises did not show differences in clinical recovery or improvement of tendon structure.<sup>19, 100</sup>

### Sclerosing

This treatment consists of injecting a vascular sclerosant (polidocanol, an aliphatic nonionised nitrogen-free substance with a sclerosing and anaesthetic effect) using ultrasound guidance in the area of neo-vascularisation anterior to the tendon. In a small double-blind, randomised controlled study comparing the effects of injections of a sclerosing and a non-sclerosing substance (lidocaine plus adrenaline), the sclerosing therapy had superior results to placebo.<sup>83</sup> In a 2-year clinical and ultrasound follow-up, good clinical results persisted and the tendon had decreased in thickness.<sup>84</sup> Whether the sclerosant decreases vascularity or pain is not known. Sympathetic and sensory nerves run alongside blood vessels.<sup>101</sup> Short-term follow-up of tendons that have had vessels sclerosed demonstrated an increase in both short- and medium-term vascularity.<sup>102</sup> This, in combination with

the anaesthetic properties of polidocanol, suggests that a change in vascularity is not necessary for a change in pain. Complications include a small risk of rupture and infection; they are very rare if small volumes of polidocanol are used.

#### High-volume imaging-guided (HVIG)

Despite the general lack of success of injection therapies for Achilles tendinopathy, optimists continue to trial various combinations of compounds in low-quality case series. One combination, called high-volume image-guided injection (HVIGI), includes normal saline, local anaesthetic and corticosteroid. Uncontrolled case series have reported decreases in patient pain over time and improvements in VISA-A scores.<sup>87</sup> A 2016 study acknowledged fatal (in the research sense of that word) confounding in study design; investigators were unable to draw conclusions from a retrospective series using high-volume injection.<sup>103</sup> As summarised in Table 40.6, current evidence does not support such treatments. One can always speculate as to possible mechanism of action for any physical agent

(volume) or compound (pharmaceutical or naturopathic). See Chapter 2 for discussion of 'evidence' in contemporary medical practice.

#### Cell-based therapies

Therapies that inject cells (stem, fibroblasts) into the tendon are nascent but currently only supported in humans by case series.<sup>104</sup> It is critical to remember that tendon pathology is largely a pathology of hyper-cellularity, so the underlying premise for the use of additional cells is not obvious. Most biological processes need a careful interplay of elements (cells, hormones, cytokines). Because the ideal tendon milieu for healing has not been identified, it appears that a lot more research will be needed before clinicians can customise cell therapy (biologics) to match the healing stage of the underlying tendon. Inventors and investors stand to make large profits in the biotechnology arena. It is also important to be explicit that some healthcare systems provide financial incentives (fee for service) for clinicians to offer permitted, but unproven, treatments.

## Medications

Nonsteroidal anti-inflammatory medications have failed to improve patient outcomes in tendinopathy. This is supported by individual randomised controlled trials (RCTs), one systematic review<sup>105</sup> and clinical impression. Leading SEM physicians do not prescribe NSAIDs for long-term treatment of tendinopathy in the routine clinical setting. They may consider these medication as an adjunct for short-term pain relief or if a player continues to compete with tendinopathy because of a short-term goal.

Professional sport is a different context and players often seek the analgesic effect of NSAIDs.<sup>106</sup> The ethical issues of using pain-relieving medication in sport are beyond the scope of this chapter.

## Electrophysical agents

There is evidence that extracorporeal shock wave therapy (ESWT) is effective in treating lower limb tendinopathies including Achilles tendinopathy (AT).<sup>89, 107-109</sup> This mechanical treatment is described in Chapter 17. Studies have shown small benefits over and above eccentric exercise in treating midportion tendinopathy.<sup>89</sup> The mechanism of action of ESWT is unknown, but it may affect the nerves or provide a physical stimulus to tendon cells. The modality caused disorganisation of tendon collagen in Shetland ponies.<sup>110</sup> It damages renal tissue when used in humans for lithotripsy. Because it is a physical agent, collateral damage is inevitable. Whether this damage is clinically relevant in human tendons has not been studied.

One RCT found that laser therapy was an effective adjunct to eccentric exercise compared to a placebo.<sup>91</sup> Placing laser therapy in a clinical context is difficult as how it has an effect on tendon pathology and pain is unknown.

## Surgical treatment

A systematic review of Achilles tendon surgery identified 23 studies with almost 1200 patients in total who underwent five different categories of types of surgery.<sup>111</sup> The main types of surgery, and those common in clinical practice, were open surgical debridement (11 studies) and minimally invasive procedures (7 studies). Patient satisfaction and complication rates were the main reported outcomes.

### PRACTICE PEARL

It is difficult to draw conclusions about Achilles tendinopathy surgery because no study has yet (as of November 2016) compared surgical intervention with non-surgical or placebo intervention.

The minimally invasive procedures yielded lower complication rates with similar patient satisfaction in comparison with open procedures.<sup>111</sup> In clinical practice, it is clear that Achilles tendon surgery is not a quick fix for patients.

If a patient is not making progress with an exercise program, it would be reasonable to refer the patient to a fellow clinician who is expert in treating tendinopathy (e.g. specialist physiotherapist, sport and exercise physician, or other non-surgical specialist) rather than opting to refer to a surgeon who is not expert in treating tendinopathy. There are of course, expert sports surgeons who provide excellent advice (Chapter 1). The key is to find tendon-specific expertise from among the disciplines in our community.

## INSERTIONAL ACHILLES TENDINOPATHY INCLUDING RETROCALCANEAL BURSTITIS—THE 'ENTHESIS ORGAN'

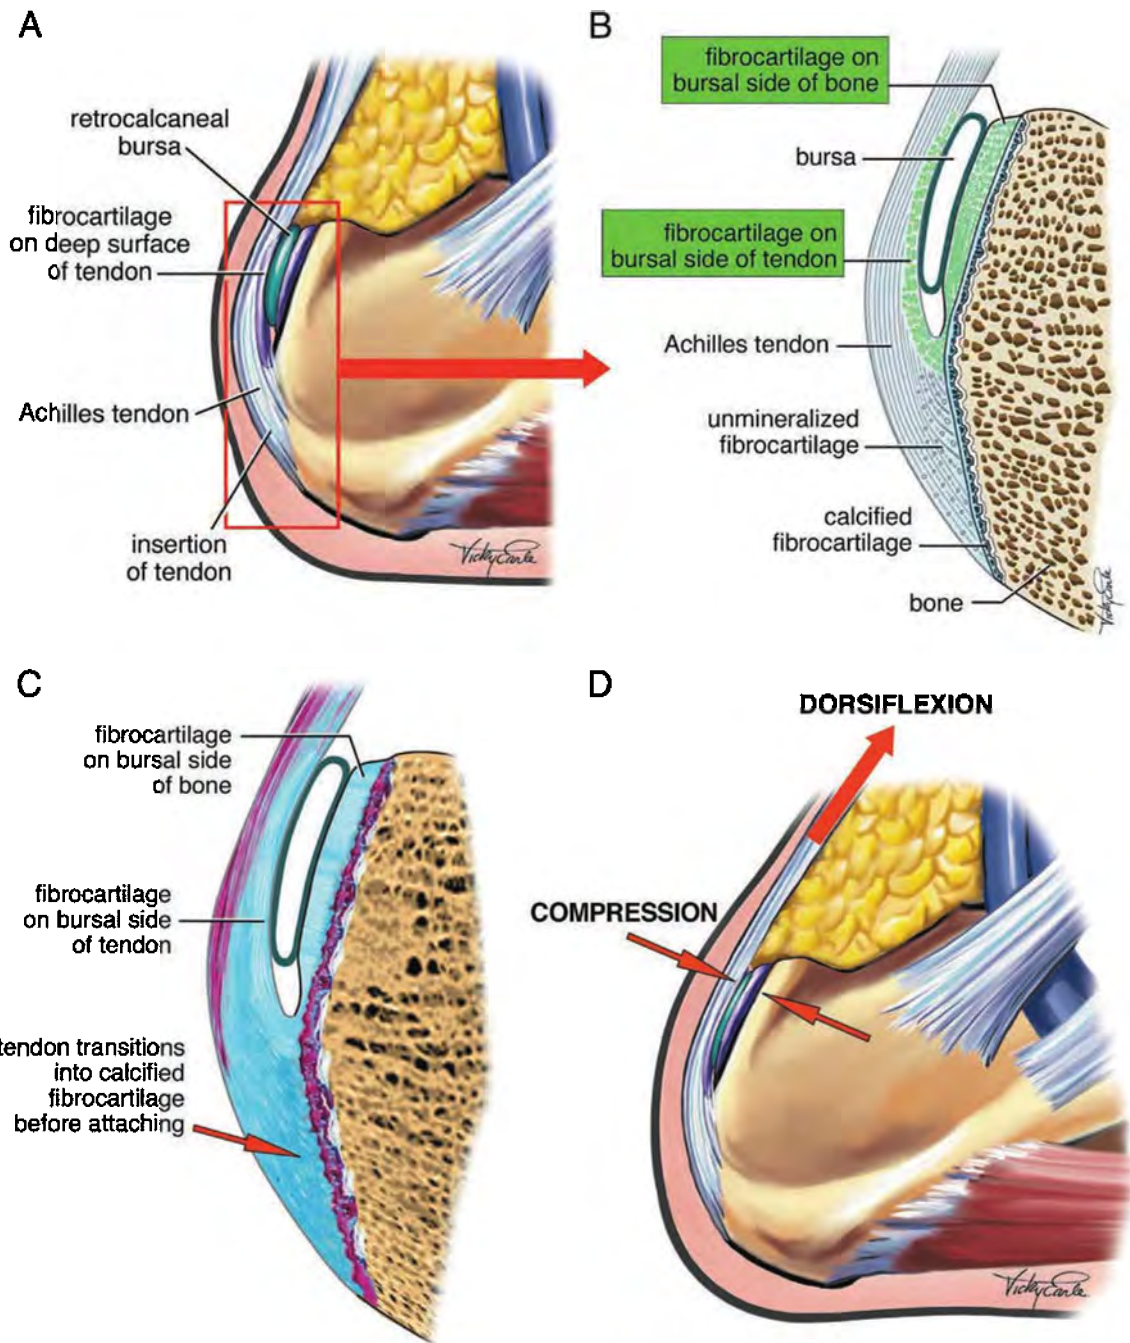

There has been confusion regarding the terminology in this region (see box). To aid new clinicians, we first consider three separate diagnoses: (i) insertional Achilles tendinopathy, (ii) retrocalcaneal bursitis and (iii) Achilles (superficial calcaneal) bursitis. In clinical practice the first two commonly occur together because they have a shared aetiology—excessive tendon load in compression against the calcaneum.

The key concept is that at the Achilles insertion, the tendon, bursa and bone are intimately related so that in dorsiflexion (compression) they operate in partnership to *reduce* strain on the insertion itself<sup>112</sup>—the 'enthesis organ'<sup>113</sup> (Fig. 40.9). Excessive dorsiflexion, especially with high tensile loads, will predispose to mechanical irritation of the bursa and the tendon just proximal to the insertion.<sup>114</sup> In response to such irritation, the tendon adapts with increased fibrocartilage and, if the loads are excessive, tendon pathology. If the compression is sufficient and over an extended time period, the tendon may develop foci of ossification. This is how the body responds to high compressive loads.

## Anatomy and the key role of compression

At the Achilles tendon insertion, the fibrocartilaginous walls of the retrocalcaneal bursa extend into the tendon (Fig. 40.9b) and the adjacent cartilage-covered calcaneum. Let us examine each element in turn. First, the calcaneum and the 'Haglund deformity'.

Historically, much has been made of the so-called Haglund deformity (see box below). However, this is normal anatomy, the way the greater trochanter serves as a cam for the gluteal tendons and the ischial tuberosity plays that role for hamstring tendons.<sup>117, 118</sup> Tendons insert at an angle into a hollow over a bony prominence to obtain mechanical advantage (i.e. a cam) and to protect the insertion from high loads. This is

**Figure 40.9** The critical role of compression in 'retrocalcaneal bursitis' (a) The anatomy represents an 'enthesis organ'. A prominent calcaneum greatly predisposes to mechanical irritation of the bursa and development of excess fibrocartilaginous tissue on both sides of the bursa (b). Note that fibrocartilage is normal at that site, but it can become thickened with excessive compression (c) Shows the microscopic appearance of the tendon insertion (red and blue, [from photomicrograph]) attaching to the artist's rendition of the calcaneum (d) This image highlights the effect of dorsiflexion—excessive compression. This underpins the treatment principle of limiting dorsiflexion (compression) with a substantial heel raise

### Haglund: time to take this eponym out of the books?

There has always been considerable confusion about the terminology associated with pain in this region. Originally, Haglund described pain in the hindfoot caused by a prominent posterosuperior corner of the calcaneus in combination with wearing a rigid low-back shoe.<sup>115</sup> Since then, various terms have been used incorporating Haglund's name.

'Haglund-type calcaneus' or 'Haglund deformity' or 'Haglund's exostosis' is a descriptive label for a protuberance of the posterolateral calcaneum, where a calcaneal prominence can often be palpated. This is also known as 'pump bump', with alternative names such as calcaneus altus, high prow heels, knobby heels, and cucumber heel. This deformity is frequently present in asymptomatic patients. There is a school of thought that considers it normal and thus better referred to as a Haglund *morphology*.

Haglund's syndrome involves a painful swelling of an inflamed retrocalcaneal bursa, sometimes combined with insertional tendinopathy of the Achilles tendon. It must be distinguished from Haglund's disease, which is the term for osteochondrosis of the accessory navicular bone.

It has been proposed<sup>116</sup> that terms such as Haglund's disease, Haglund's syndrome, Haglund's deformity, pump bump, calcaneus altus, high prow heels, knobby heels and cucumber heel no longer be used.

the point where the tendon is compressed against the calcaneus in dorsiflexion; this load can induce pathology at this site.

Much of the pathology is seen at the upper calcaneal/bursa/tendon interface (the cam), where the compression of the tendon against the upper calcaneus occurs.

### Clinical assessment

Good clinical practice includes evaluation of the tendon and tendon insertion by taking a careful history and performing functional tests in addition to inspecting and palpating the region for bony prominence and local swelling. Discriminating between pain with tensile, compressive and combined loads can help with diagnosis. For example, hopping on the toes (tensile loads) may give some pain, but a hop-lunge into dorsiflexion (compression and tensile loads) may be more painful at the insertion.

#### PRACTICE PEARL

A heel raise of 30–50 mm is a good practical way of reducing compressive loads.

Ultrasound and MRI can help to assess the extent of pathology in the tendon and the bursa. Ultrasound + Doppler (US + DP) examination can image the bursa and tendon insertion (thickening and localised high blood flow).

Symptoms of insertional Achilles tendinopathy, as with any enthesopathy, should raise suspicion about the possibility of rheumatoid arthritis or spondyloarthropathy, and this is particularly true if symptoms are bilateral.

### Treatment

Treatment must consider the enthesis organ as a unit. Isolated treatment of a bursitis is generally unsuccessful. Their key principle is to use a staged loading program

with particular attention to avoiding dorsiflexion (to avoid compression of the tendon).<sup>119</sup>

Repeated stretching is not recommended as it provides compression load to the insertion.

Alternative treatments for chronic insertional tendinopathy include sclerosing of regions with high blood flow and nerves with polidocanol.<sup>120, 121</sup>

Treatment of insertional tendinopathy with extracorporeal shock wave therapy (ESWT) showed more benefit than a low-quality exercise,<sup>122</sup> but the eccentric program used was designed for mid-Achilles tendinopathy, and better benefits from exercise are evident when using the specific insertional protocol.<sup>119</sup>

#### PRACTICE PEARL

Conservative management is usually successful, while surgery can require long-term rehabilitation. Our clinical experience includes elite middle-distance runners who were unable to return to their previous level of competition after surgery. Some case series report unflattering outcomes.<sup>123</sup>

Only a few case series have reported outcomes after surgery for insertional Achilles tendinopathy.<sup>124–126</sup>

### Retrocalcaneal bursitis

The reader coming to this subheading 'cold' from the index will also need to read the section above. Retrocalcaneal bursitis is not generally an isolated condition in the sports medicine setting. Inflammation of the retrocalcaneal bursa (Fig. 40.9a) results in a painful soft tissue swelling, medial and lateral to the Achilles tendon at the level of the posterosuperior calcaneus.

## PRACTICE PEARL

*Histopathologically, the fibrocartilaginous bursal walls show degeneration and/or calcification, with hypertrophy of the synovial infoldings and accumulation of damaged fibrocartilaginous cells and fluid in the bursa itself.<sup>127</sup>*

B

Rarely, but not to be missed, this condition may signal an underlying infectious bursitis due to an inflammatory arthropathy.<sup>116</sup>

To determine whether tendon or bursa is the primary pain generator, one of the clues suggesting retrocalcaneal bursitis is irritable pain and symptoms on low-load activities such as heel raises or end-range compression in dorsiflexion. A lot of fluid or thickening of the bursa on imaging (ultrasound or MRI) may be associated with the bursa being a pain generator. Conversely, a little fluid on imaging is normal in active populations.

For treatment of the combined 'enthesis organ'—the bursa and associated tendon—see the section above and note the need to avoid compression (see Fig. 40.9). Principles of quality tendon management apply (see the four-stage Achilles rehabilitation program above).

Injection of corticosteroid into the bursa, preferably under ultrasound guidance, can be effective in relieving symptoms<sup>128</sup> but is associated with an increased risk of Achilles tendon rupture.<sup>129</sup> This may be due to the presence of a connection between the retrocalcaneal bursa and the anterior fibres of the Achilles tendon.

If conservative treatment fails, then surgery to remove the bursa and any associated bony prominence is often advocated;<sup>123, 130</sup> Our reasons for making that an absolute last resort have been laid out.

### Achilles (superficial calcaneal) bursitis

The Achilles or superficial calcaneal bursa (Fig. 40.1b) is located between a calcaneal prominence or the Achilles tendon and the skin, resulting in a visible, painful, solid swelling and discolouration of the skin. It is most often located at the posterolateral aspect of the calcaneus. Histopathologically, the subcutaneous bursa is an adventitious bursa, which is acquired after birth, and develops in response to friction. Unlike the retrocalcaneal bursa, which is lined by fibrocartilaginous cells, this bursa consists of hypertrophic synovial tissue and fluid. A superficial calcaneal bursitis can be further specified by its location; that is, posterior, posterolateral or posteromedial.

It is generally caused by excessive friction, such as by heel tabs, or wearing shoes that are too tight or too large. Various types of stiff boots (skating, cricket bowling, etc.)

can cause such friction. Removing the source of the friction by using a punch to widen the heel of the boot, or providing 'donut' protection to the area of bursitis as it resolves is generally successful. As with many conditions, corticosteroid injection was considered a quick fix in the 1990s but is falling out of favour as a definitive treatment. The underlying cause of the pathology (the culprit) needs to be addressed.

### POSTERIOR IMPINGEMENT SYNDROME

with SUSAN MAYES

Posterior impingement syndrome of the ankle refers to impingement of soft tissue or bony structures between the posterior aspect of the tibia and the superior aspect of the calcaneus in extremes of plantarflexion. Gradual onset of posterior pain may arise from impingement of an enlarged posterior tubercle of the talus (Fig. 40.10a) or an os trigonum (Fig. 40.10b), but is usually the result of impingement of the synovium or capsuloligamentous structures. This condition is common among ballet dancers, gymnasts, cricket bowlers and football players, all of whom maximally plantarflex their ankles in a loaded position. It is also seen secondary to ankle plantarflexion or inversion injuries. It can also arise from an acute presentation—when a forceful hyperplantarflexion fractures the posterior process of the talus (Chapter 41).

The diagnosis of posterior impingement syndrome is suggested by pain at the posterior aspect of the ankle and confirmed by a positive posterior impingement test—pain reproduced on passive plantarflexion of the ankle (Fig. 40.3f). Flexor hallucis longus (FHL) tenosynovitis commonly coexists with posterior impingement in dancers (Chapter 42). Pain with active first-toe flexion and extension in full ankle plantarflexion indicates FHL tenosynovitis (Fig. 40.3e). Another differential in ballet dancers is Achilles tendinopathy. The posterior impingement test is pain-free (negative) in that condition.

In ballet dancers, forcing turnout or 'fishing' the foot (Fig. 40.11) can predispose to this condition. Forced turnout occurs when the feet are planted in greater external rotation than is available at the hips—this places excessive rotary forces at the posterior ankle (and knee). 'Fishing' is a ballet term referring to foot deviation away from the ideal leg/foot alignment as shown in Figure 40.11.

Technique assessment, and strength and endurance training of the hip external rotators, calf complex and foot intrinsic muscles are an essential part of treatment. Treatment of posterior impingement syndrome includes modified workload, manual mobilisation of the subtalar, talocrural and midfoot joints as well as NSAIDs or paracetamol (acetaminophen) for symptomatic relief. Ballet dancers can cross-train via Pilates and gradually

(a)

(b)

**Figure 40.10** Anatomy that underpins posterior impingement when symptoms are present. These anatomical changes can be asymptomatic (a) A prominent posterior process of the talus (arrow) (b) The os trigonum (arrow)

progress their training from working flat (no raising) to *en pointe* during the treatment phase.

If the condition persists, a corticosteroid injection around the area of maximal tenderness may reduce pain. This is best done from the lateral side, as the medial aspect of the ankle contains the neurovascular bundle.

If posterior impingement does not respond to conservative management, then arthroscopic or open removal of the enlarged posterior process or the os trigonum is indicated. For dancers, the modal time it takes to return to full performance is around 4 months.

## SEVER'S DISEASE

Sever's disease or calcaneal apophysitis is a common insertional enthesopathy among adolescents (Chapter 44). It can be considered the Achilles tendon equivalent of Osgood-Schlatter disease at the patellar tendon insertion. It should be treated by reducing load until pain is settled, (a heel raise is helpful) increasing strength and endurance, and then gradually reintroducing load.

## OTHER CAUSES OF PAIN IN THE ACHILLES REGION (GRADUAL ONSET)

### Accessory soleus

A rare cause of Achilles region pain in the sports medicine setting, an accessory soleus is present in about 5-10% of people.<sup>131, 132</sup> The condition is more common among men than women, and average age of presentation is 20 years. The true accessory soleus inserts into the calcaneum, but it may also insert into the distal part of the tendon. It generally occurs unilaterally, but it may occur bilaterally.<sup>133</sup>

The primary presenting patterns are pain in the Achilles region during exercise (a 'compartment' type pain) with swelling, or a painless swelling. There is an obvious muscle bulk very low, deep to the Achilles, on both the medial and lateral sides which is often tender on palpation. The main differential diagnosis is soft tissue tumour. Imaging findings are characteristic; plain radiographs have poor sensitivity for this condition but, when positive, show a soft tissue shadow posterior to the tibia obscuring the pre-Achilles fat pad. MRI is the investigation of choice<sup>132</sup> and confirms a mass with the same signal intensity as muscle; ultrasound can also confirm that there is a low-lying soleus (or accessory) soleus. In cases that are a symptomatic, observation is an appropriate treatment, but if symptoms warrant, surgical removal of the accessory soleus is probably the best treatment.<sup>134</sup> Botulinum toxin has been trialed in a case series.<sup>123</sup>

### Referred pain

Referred pain to this region from the lumbar spine or associated neural structures is unusual, but always warrants consideration in challenging cases.

(a)

(b)

**Figure 40.11** 'Fishing' at the ankle can predispose to posterior impingement in a ballet dancer (a) 'Fished' position. The midline (second metatarsal) of the foot deviates laterally to the midline of the ankle (b) Correct demi-pointe position. The midline of the foot is aligned with the midline of the ankle

## ACUTE ACHILLES TENDON RUPTURE (COMPLETE)

### Clinical approach

Complete rupture of the Achilles tendon (Fig. 40.12) classically occurs in athletes in their 30s or 40s, and the male:female ratio is 10:1. The typical patient is a 40-year-old sports-active male. The incidence is reported to be 5–36 in 100 000 and is increasing, especially over the last 10 years, with 60–90% of all Achilles tendon ruptures occurring during sports. The majority of the patients have not had any symptoms from the Achilles tendon region prior to injury. We address the debate around conservative versus surgical treatment of Achilles rupture below. Regardless of treatment, long-term deficits in strength and function are common and approximately only 30–40% of athletes return to their previous pre-injury level.<sup>135</sup>

### History

Usually the rupture occurs when the person performs a quick change of direction and the ankle is forced into dorsiflexion while the calf muscle contracts. The patient describes feeling 'as if I was hit or kicked in the back of the leg'; pain might not always be the strongest sensation. This is immediately followed by grossly diminished function. A snap or tear may be audible and the patient has difficulty walking. However, the ability to resume walking with short steps returns quickly, but without power in the push-off phase.

The patient will usually have an obvious limp, but may have surprisingly good function through the use of compensatory muscles such as plantaris and the long toe flexors. That is, the patient may be able to walk, but not on

**Figure 40.12** Achilles tendon rupture presents very differently from overuse Achilles tendinopathy. This intraoperative photograph highlights the severity of this injury. Not all cases need to be operated on (see below)

his or her toes. During the initial assessment, the clinician should take time to ask about risk factors for Achilles tendon rupture (including previous Achilles rupture, other major tendon rupture, recent local corticosteroid injection, or clues to other collagen diseases, diabetes mellitus type 2, etc.).<sup>136</sup>

### Physical examination

Four clinical tests greatly simplify examination for complete Achilles tendon rupture (Fig. 40.3):

1. The calf squeeze test (also known as Simmond's or Thompson's test) (see Fig. 40.3h) has a sensitivity of 0.96, a specificity of 0.93, a positive likelihood ratio of 13.7 and a negative likelihood ratio of 0.04.<sup>10</sup>
2. Matle's test has a sensitivity of 0.88, a specificity of 0.85, a positive likelihood ratio of 6.3 and a negative likelihood ratio of 0.14.<sup>10</sup>
3. Copeland's test has a sensitivity of 0.78 (specificity and likelihood ratios are unreported).<sup>10</sup>
4. Palpation for a gap in the tendon has a sensitivity of 0.73, a specificity of 0.89, a positive likelihood ratio of 6.6 and a negative likelihood ratio of 0.3.<sup>10</sup> The gap in the tendons becomes increasingly difficult to palpate as time between rupture and clinical assessment increases.

### Key outcome measures

The Achilles tendon total rupture score (ATRS) is a patient-reported outcome measure developed to evaluate outcome after an Achilles tendon rupture.<sup>137, 138</sup> ATRS evaluates aspects of symptoms and physical activity. The score consists of 10 questions, where the score for each item ranges from 0–10 on a Likert scale, with a maximum score of 100. It has been shown to have excellent reliability (ICC 0.98–0.99), an effect size of 0.87–2.21 and a minimal detectable change of 6.75 points. The score in patients varies from 17–100 depending on the stage of

recovery (approximately a mean of 40/100 at 3 months, 70/100 at 6 months and 80–100/100 at 12 months).

A heel raise test to measure both calf-muscle endurance and the maximal heel raise height is commonly used to measure outcome in this population. For this test the person is asked to perform as many high single-leg heel raises at a standardised frequency (usually 30 reps/min) as possible to evaluate the endurance of the calf muscles. The maximal heel raise height is measured by evaluating how high the patient can lift the heel off the floor. This test has good reliability (ICC 0.78–0.84) and has been used to evaluate recovery over time in patients with Achilles tendon rupture.<sup>137, 139–143</sup> The side-to-side differences in maximal heel raise height, when comparing the injured and healthy sides in patients with an Achilles tendon rupture, correlated<sup>141</sup> with the occurrence of tendon elongation on the injured side.

Outcome measures that evaluate higher-level function, such as single-leg jump tests for distance or height, are used later in rehabilitation, and the performance on the injured side can be compared to the healthy side.

### Investigations

Investigations such as ultrasonography and magnetic resonance imaging (MRI) are sometimes used as adjuncts to clinical investigation. However, such investigations are seldom necessary if the clinical history and clinical examination are thorough. Ultrasonography and MRI are needed only in doubtful cases, such as re-ruptures and when there is a long delay from the index injury. However, they are not needed in routine healthcare to establish the diagnosis of a torn Achilles tendon.

### Rehabilitation of Achilles tendon ruptures

Historically, there was a fear of loading the Achilles tendon during the initial 6–8 weeks because of a putative risk of re-rupture and other complications. Systematic

## Treatment of the acutely ruptured Achilles tendon: To operate or not to operate

### Surgical management

With a 2–3% re-rupture rate, open surgical treatment of Achilles tendon rupture has approximately 10% lower risk of re-rupture compared with non-surgical treatment, which stands at just under 13%.<sup>144</sup> Promising new surgical techniques may further reduce the rate of postoperative re-rupture (see below). However, open operative treatment is associated with an increased risk of complications, including superficial wound infection, adhesions and disturbed skin sensitivity.<sup>145</sup> Another approach to reduce these surgical

complications is to perform surgery percutaneously, but this does not entirely eliminate the risk of complications.

The postoperative treatment regimen has a significant effect on the outcome.<sup>146</sup> Comparisons of rigid cast immobilisation with a short period of rigid cast and then use of a functional brace after surgical intervention, indicates that early mobilisation decreases re-rupture rates without an increased risk of other complications. Furthermore, patient satisfaction is higher with the functional brace. Postoperative management is usually with an immobilising brace for the

first 6–8 weeks; however, the period of postoperative immobilisation may very well be shortened and recent studies have used short or even no immobilisation after surgery. Because range of movement and strength can be difficult to regain after rupture repair, the earliest possible mobilisation and rehabilitation is recommended.

Surgery using stable core sutures and local augmentation has good results with no re-ruptures.<sup>147</sup> This technique is based on the principle of using the strongest possible suture material to make the surgical construct as strong as possible and enable the patient to start early range-of-motion training, even without any immobilisation at all. Early weight-bearing is encouraged as well.

#### Non-surgical management

Historically, non-surgical management of an Achilles tendon rupture has been recommended in older patients or patients with low levels of activity.<sup>144</sup> Early mobilisation for non-surgically treated patients also decreases the re-rupture rate compared with rigid cast immobilisation.<sup>146</sup> When both surgically and non-surgically treated patients received identical mobilisation protocols (cast for 2 weeks and then a functional brace), there was no difference in patient-reported outcome. Non-surgical treatment leads to a high success rate, provided no re-rupture occurs, and may therefore be considered a valid option for all patients (Fig. 40.13).

**Figure 40.13** There is increasing evidence that non-surgical management with appropriate rehabilitation can be effective

B

reviews<sup>146</sup> report that simple and early mobilisation while in the functional brace improved outcomes. Thus, patients are often instructed to move the toes and perform light plantar flexion isometrics or active range of motion (if the brace allows for it). This advice applies whether the patient has undergone surgical repair of the tendon or is being managed non-surgically.

After the removal of the brace or cast, the goal for the patient is to regain calf-muscle strength and achieve normal gait while limiting the chance of re-rupture. It is usually at this stage that the formal rehabilitation starts. It is important to understand that the load on the Achilles tendon can be increased both by increasing the external load and by increasing the speed of movement. Therefore, during the initial 4 weeks of rehabilitation, slower and controlled movements are recommended. All the muscles around the ankle need to be strengthened and this can be progressed through the use of exercise tubing (Fig. 40.14a). Moreover, the calf muscle is strengthened by progressively increasing the load through sitting heel raises (Fig. 40.14b) and bilateral heel raises, and ultimately the patient should be able to perform a single-leg heel raise.

#### PRACTICE PEARL

Achieving full ankle range of motion (as compared with the healthy side) is important in all cases of Achilles rupture treatment. It should not be achieved by stretching the calf musculature in the first 3–4 weeks in the rehabilitation period. Such stretching can leave the Achilles tendon to heal in an elongated position.<sup>147, 148</sup> Instead, full ankle range of motion can be achieved through joint mobilisation and stretching into dorsiflexion with the knee in a flexed position.

#### Timing to return to jogging and sports

Whether or not treatment is surgical or non-surgical, the decision to return to jogging and sports is often time-based. Traditional recommendations are that jogging can be started after 12–16 weeks, return to non-contact sports after 16–20 weeks and contact sports after 20–24 weeks.

Time criteria may be inadequate, and it is essential that the key criteria for return to jogging and sports be functional, such as the recovery of the capacity of the tendon to store and release energy in sports-specific

(a)

(b)

**Figure 40.14** Calf muscle strengthening after Achilles tendon rupture (a) Early rehabilitation includes low-load ankle plantarflexion with knee extended (e.g. with Thera Band™) (b) Seated heel raise against resistance loads the soleus preferentially

loading, as well as the patient having excellent calf-muscle strength and ankle range of motion. Muscle bulk may lag many months behind these functional criteria and should not be used to delay return to sport. The patient should be able to hop similarly to the unaffected side, and repeatedly store and release energy (repeated hopping) in the tendon adequately for their sport. Strength, measured with single-leg heel raises, should be at least 20 reps but can range from 6–70 reps in healthy individuals.<sup>149</sup>

### Longer-term rehabilitation deficits

Regardless of whether initial treatment was surgical or non-surgical, complications such as calf-muscle weakness, tendon elongation and gait abnormalities can persist for at least a year after injury. Because of individual differences, rehabilitation should be tailored to each patient's deficits. Often the patient cannot raise the heel as high on the injured side as the uninjured side. The clinician should test whether this is due to tendon elongation, weakness or both. This does not appear to limit return to physical activity in the majority of patients, and whether it has any long-term implications is not known.

About 50% of patients can perform a single-leg heel raise 3 months after their injury. Between 3 and 6 months after injury, the majority of patients can achieve this milestone. However, it is common to have a strength deficit of 10–30% in the calf musculature on the injured side compared with the healthy side, and this commonly becomes permanent.

Thus, it is important to encourage the patient to persist with a comprehensive functional rehabilitation program and ideally return to full activity. The clinician needs to be alert to identifying any specific barriers to this successful return to activity. The early phase of rehabilitation in particular should be closely monitored. Studies have shown very limited improvement between 1 and 2-year follow-ups.

Additional studies are needed to garner better evidence about the appropriate and most beneficial type of exercises both in the initial immobilisation period (if any) and during rehabilitation. The issue of tendon lengthening after treatment, especially non-surgical treatment, leading to insufficient power in the calf muscles is still not well studied.

# Acute ankle injuries

with PIETER D'HOOOGHE, EVERT VERHAGEN and JON KARLSSON

*Total rupture of left ATFL (ankle ligament) and associated joint capsule damage in a soccer kickabout with friends. Continuing to assess extent of injury and treatment plan day by day. Rehab already started.*

World golf number 1 Rory McIlroy on Instagram, nine days before the British Open, 6 July 2015

Ankle injury is arguably the most common sporting injury. In 24 of the 70 sports for which there are quality data, ankle injury holds the number 1 spot.<sup>1</sup> In sports such as volleyball, ankle injuries account for nearly half of all injuries.<sup>2</sup>

Ankle injuries include, but are not limited to 'ankle sprains'. The first half of this chapter focuses on anatomy, clinical assessment and management of lateral ligament injuries after ankle sprain and their sequelae. We address less common immediate diagnoses for ankle sprains: medial ligament injury and significant ankle fractures.

Importantly for clinicians who work in sport, a 'sprained ankle' can mask damage to other structures, such as subtle fractures around the ankle joint, osteochondral fractures of the dome of the talus, and dislocation or longitudinal rupture of the peroneal tendons. Such injuries and their complaints persist longer than would be expected with a straightforward lateral ligament sprain. This is often referred to as 'the difficult ankle' and it is the focus of the second half of this chapter.

### FUNCTIONAL ANATOMY

The ankle contains three joints (Fig. 41.1):

1. talocrural (ankle) joint
2. inferior tibiofibular joint (syndesmosis)
3. subtalar joint.

The talocrural or ankle joint (Fig. 41.1a) is a hinge joint formed between the inferior surface of the tibia and the superior surface of the talus.

The medial and lateral malleoli provide additional articulations and stability to the ankle joint. The ankle joint can plantarflex and dorsiflex. As the ankle is least stable in plantarflexion, where most stability is provided

by the ligaments, injuries are more common when the foot is in this position.

The distal parts of the fibula and tibia articulate at the inferior tibiofibular joint where they are supported by the inferior tibiofibular ligaments or syndesmosis. The small amount of movement present at this joint is extremely important for normal walking and running. Injuries to this joint are more common than previously recognised.

The subtalar joint (Fig. 41.1b), between the talus and calcaneus, is divided into an anterior and posterior articulation separated by the sinus tarsi.

(a)

**Figure 41.1** Anatomy of the ankle. (a) Talocrural (ankle) joint

**Figure 41.1 (cont.)** (b) Subtalar joint (c) Ligaments of the ankle-lateral view (d) Ligaments of the ankle-medial view

Inversion and eversion occur at the subtalar joint. It provides shock absorption and permits the foot to adjust to uneven ground. The subtalar joint allows the foot to remain flat on the ground when the leg is at an angle to the surface.

The ligaments of the ankle joint are shown in Figures 41.1c and d.

The lateral ligament consists of three parts:

- anterior talofibular ligament (ATFL), which passes as a flat and rather thin band from the anterior aspect of the fibula anteriorly to the lateral talar neck
- calcaneofibular ligament (CFL), a cord-like structure directed inferiorly and posteriorly
- posterior talofibular ligament (PTFL), a short structure running posteriorly from the fibula to the talus.

The medial or deltoid ligament of the ankle is a fan-shaped ligament extending from the medial malleolus anteriorly to the navicular and talus, inferiorly to the calcaneus and posteriorly to the talus.

It can be differentiated into the anterior tibiotalar ligament (most commonly affected), tibiocalcaneal ligament, posterior tibiotalar ligament and the tibionavicular ligament. This strong ligament is composed of two layers, one deep and the other more superficial.

The syndesmosis consists of the anterior and posterior inferior tibiofibular ligament (AITFL/PITFL) and the interosseous tibiofibular ligament (IOTFL). In almost 75% of cases, there are contact facets with articular cartilage between the distal tibia and fibula, forming a true synovial joint. The PITFL provides approximately 40% of the resistance to lateral displacement, the AITFL 35% and the IOTFL 22%. The remaining stability is provided by the interosseous membrane.

Relevant nerves for the ankle originate from the lower lumbar and higher sacral spinal roots (L4-S2). Efferent fibres of the deep peroneal nerve innervate the anterior muscles of the leg, the superficial peroneal nerve innervates the peroneal muscles on the lateral side, and the tibial nerve innervates the muscles on the posterior side of the leg. The afferent path consists of all nerves that send proprioceptive information from mechanoreceptors around the ankle to the central nervous system.

## CLINICAL PERSPECTIVE

It is estimated that 10 ankle sprains occur per 1000 exposures.<sup>1</sup> Inversion injuries are at least four times more common than eversion injuries due to the relative instability of the lateral joint and weakness of the lateral ligaments compared with the medial ligament.<sup>3</sup> Around 80% of ankle sprains are ligamentous caused by sudden inversion or supination.<sup>1</sup> The injury motion often happens at the subtalar joint and tears the ATFL which is the weakest of the lateral ankle ligaments.

Table 41.1 Acute ankle injuries

Common	Less common	Not to be missed
Lateral ligament sprain <ul style="list-style-type: none"> <li>• ATFL</li> <li>• CFL</li> <li>• PTFL</li> </ul>	Osteochondral lesion of the talus Ligament sprain/rupture <ul style="list-style-type: none"> <li>• Medial ligament injury</li> <li>• AITFL injury</li> </ul> Fractures <ul style="list-style-type: none"> <li>• Lateral/medial/posterior malleolus (Pott's—bimalleolar)</li> <li>• Tibial plafond</li> <li>• Base of the fifth metatarsal</li> <li>• Anterior process of the calcaneus</li> <li>• Lateral process of the talus</li> <li>• Posterior process of the talus</li> <li>• Os trigonum</li> </ul> Dislocated ankle (fracture/dislocation) Tendon rupture/dislocation <ul style="list-style-type: none"> <li>• Tibialis posterior tendon</li> <li>• Peroneal tendons (longitudinal rupture)</li> </ul>	Complex regional pain syndrome type 1 (post-injury) Greenstick fractures (children) Syndesmosis injury Tarsal coalition (may come to light as a result of an ankle sprain)

ATFL = anterior talofibular ligament; AITFL = anteroinferior tibiofibular ligament; CFL = calcaneofibular ligament; PTFL = posterior tibiofibular ligament

As the stronger medial ligament requires a greater force to be injured, these sprains almost always take longer to rehabilitate. The differential diagnoses that must be considered after an ankle injury are listed in Table 41.1. The aim of the initial clinical assessment is to rule out ankle fractures (see Ottawa ankle rules, below), and if possible, to diagnose the site of abnormality as accurately as possible.

## History

### PRACTICE PEARL

The mechanism of the ankle sprain is an important clue to diagnosis. An inversion injury suggests lateral ligament and medial compression damage. Eversion injury suggests medial ligament damage. If the injury involved ankle compression, the clinician should consider osteochondral injury.

The onset of pain is very important. A history of initial ability to weight-bear after an injury followed by a subsequent increase in pain and swelling with continued activity suggests a ligament injury rather than a fracture. The location of pain and swelling generally indicates which ligaments were injured. The most common site is over the anterolateral aspect of the ankle involving the ATFL, in approximately two-thirds of all injuries.

In inversion injuries the ATFL is the first ligament to tear, and is torn in 97% of cases. The CFL can then subsequently

tear after the ATFL. Isolated rupture of the CFL occurs in only 3% of inversion injuries. The last ligament to tear is the PTFL, which is usually uninjured unless there is a frank dislocation of the ankle. In severe injuries, both medial and lateral ligaments may be damaged; however, this is infrequent. The degree of swelling and bruising is usually, but not always, an indication of the severity of injury.

The degree of disability, both immediately following the injury and subsequently, indicates the severity of the injury (Fig. 41.2). The practitioner should ask about initial management, the use of the POLICE regimen (Chapter 17) and the duration of restricted weight-bearing after the injury, as a poorly managed injury will appear 'more significant' in terms of swelling and long-term disability than a similar injury that has been managed appropriately. An example of severe swelling and bruising in an ankle managed without POLICE is shown in Figure 41.2.

The practitioner should ask about a previous history of ankle injury and assess whether the post-injury rehabilitation was adequate. Did the athlete use protective tape or braces for the first 3–6 months after the previous injury, or until the end of the season?

## Examination

The aims of ankle examination are to:

- assess the degree of instability present (grade the ligamentous injury)
- detect functional deficits (i.e. loss of range of motion, reduced strength and reduced proprioception)

**Figure 41.2** Severe swelling and bruising in an ankle

- detect any associated injuries (e.g. avulsion fracture of the base of the fifth metatarsal is commonly overlooked but is easily detected by palpation. Also, injury to the peroneal tendons may lead to longstanding disability and is easily missed during the acute phase.).

Examination involves:

1. Observation
  - a. standing
  - b. supine
2. Active movements
  - a. plantarflexion/dorsiflexion (Fig. 41.3a)
  - b. inversion/eversion

**(a)**

**Figure 41.3** (a) Active movement—plantarflexion/dorsiflexion. Assessment of dorsiflexion is important as restriction results in a functional deficit. Range of motion can be compared with the uninjured side. Tight calf muscles may restrict dorsiflexion. This can be eliminated by placing the knee in 70–90° flexion

3. Passive movements
  - a. plantarflexion/dorsiflexion
  - b. inversion/eversion (Fig. 41.3b)
4. Resisted movements
  - a. eversion (Fig. 41.3c)
5. Functional tests
  - a. lunge test (Fig. 41.3d)
  - b. hopping
6. Palpation
  - a. distal—and proximal—fibula
  - b. lateral malleolus
  - c. lateral ligaments (Fig. 41.3e)

**(b)**

**(c)**

(b) Passive movement—inversion/eversion. Inversion is frequently painful and restricted in lateral ligament injury, while eversion is painful following injuries to the medial ligament. Increased pain on combined plantar flexion and inversion suggests ATFL injury (c) Resisted eversion—this can be difficult in the acute setting. In cases of persistent pain, weakness of the evertors (peroneal muscles) should be assessed

(d)

(e)

**Figure 41.3 (cont.)** (d) Functional test—lunge test. Assess ankle dorsiflexion compared with the uninjured side. Note any pain. Other functional tests may be performed to reproduce the patient's pain if appropriate (e.g. single-leg standing, hopping) (e) Palpation—lateral ligament

- d. talus
- e. peroneal tendon(s)
- f. base of fifth metatarsal
- g. anterior joint line

- h. medial ligament
- i. sustentaculum tali
- j. sinus tarsi
- k. anteroinferior tibiofibular ligament

7. Special tests (comparison with other side necessary; however, it should be borne in mind that there is no obvious correlation between increased anterior drawer and/or lateral talar tilt and symptoms of ankle insufficiency)
  - a. anterior drawer (Fig. 41.3f)
  - b. lateral talar tilt (increased inversion) (Fig.41.3g)
  - c. proprioception (Fig. 41.3h).

### Investigations

Should the clinician order a radiograph? Clinicians can use Ottawa ankle rules to assist them in making this decision (Fig. 41.4).<sup>4, 5</sup>

Radiographs of the ankle joint should include the base of the fifth metatarsal to exclude avulsion fractures. If damage to the lower tibiofibular syndesmosis (AITFL) is suspected, special ankle mortise or syndesmosis views are required.

An osteochondral lesion of the talus—especially the medial side—may not be apparent on initial radiograph. If significant pain and disability persist despite appropriate

(f)

(f) Ligament testing—anterior drawer test. The ankle is placed in slight plantarflexion and grasped as shown. Pressure is exerted upwards and the degree of excursion (anterior drawer) is noted and compared with the uninjured side. This test assesses the integrity of the ATFL and CFL. Pain on testing should also be noted; if painful it may indeed mask injury to the ligament. Then the test should be repeated after five days. The optimal time to test the integrity of the lateral ligaments is on the fifth post-injury day

(g)

**Figure 41.3 (cont.)** (g) Ligament testing—talar tilt. This tests integrity of the anterior talofibular and calcaneofibular ligaments laterally and the deltoid ligament medially. The ankle is grasped as shown and the medial and lateral movement of the talus and calcaneus are assessed in relation to the tibia and fibula. Pain on this test must also be noted (h) Special test—proprioception. Single-leg standing with eyes closed may demonstrate impaired proprioception compared with the uninjured side

(h)

**Figure 41.4** Ottawa ankle rules X-ray recommendation<sup>4</sup>—Ankle X-rays are only required if there is any pain in the malleolar zone, and any one of these findings: bone tenderness at A; bone tenderness at B; inability to bear weight both immediately and at the clinical assessment (four steps). Foot X-ray recommendation—foot X-rays are only required if there is any pain in the midfoot zone, and any one of these findings: bone tenderness at C; bone tenderness at D; inability to bear weight both immediately and at the clinical assessment (four steps)

treatment 4–6 weeks after an apparent 'routine' ankle sprain, MRI is the investigation of choice to exclude an osteochondral lesion, especially when dealing with

the 'difficult ankle', that is, longstanding pain/disability without obvious cause or pathology. If MRI is not available a radioisotopic bone scan or CT can be used.

## LATERAL LIGAMENT INJURIES

Lateral ligament injuries often occur during activities requiring rapid changes in direction, especially if these take place on uneven surfaces (e.g. grass fields). They also occur when a player, having jumped, lands on another competitor's foot. They are very common in basketball, volleyball, netball and most football codes.

The usual mechanism of lateral ligament injury is inversion and plantarflexion, and this damages the ATFL before the CFL.<sup>6</sup> This occurs because the ATFL is taut in plantarflexion and the CFL is relatively loose (Fig. 41.5).

Also, the ATFL can only tolerate half the strain of the CFL before tearing. A complete tear of the ATFL, CFL and PTFL is rare and results in a dislocation of the ankle joint (Fig. 41.6). Isolated ligament ruptures of the CFL and especially the PTFL are also rare.

**Figure 41.5** A plantarflexion injury generally leads to injury of the anterior talofibular ligament before the calcaneofibular ligament

**Figure 41.6** A posteromedial ankle dislocation

Ankle sprain may be accompanied by an audible snap, crack or tear, which, although often of great concern to the athlete and onlookers, has no particular diagnostic significance. This is unlike the case in knee ligament injuries where a 'pop' has profound implications (see Chapter 35). Depending on the severity of the injury, the athlete may continue to play or may have to stop immediately. Swelling usually appears rapidly, although occasionally it may be delayed some hours.

To assess lateral ligament injuries, examine all three components of the ligament and determine the degree of ankle laxity:

- A grade I tear has normal ligament laxity. It is important to compare both sides (assuming the other side has not been previously injured) as there is a large inter-individual variation in normal ankle laxity.
- A grade II tear reveals some degree of laxity but with a firm end point.
- A grade III tear shows gross laxity without a discernible end point.

All three grades are associated with pain and tenderness, although grade III tears may be least painful after the initial episode has settled. Grading of these injuries guides prognosis and helps determine the rate of rehabilitation. Grading also affects selection of the acute treatment. Note that in the acute phase, the reliability and validity of manual stress tests (e.g. anterior drawer or talar-tilt test) are very low. Manual stress tests are more reliable and valid when performed 5-7 days post injury. But keep in mind the limitations of 'special tests' in general (Chapter 14).<sup>7</sup>

## TREATMENT AND REHABILITATION OF LATERAL LIGAMENT INJURIES

The management of lateral ligament injuries regardless of the grade follows the same principles. After minimising initial haemorrhage and reducing pain, the aims are to restore range of motion, muscle strength and proprioception, and then prescribe a progressive, sport-specific exercise program.

### Initial management

Lateral ligament injuries require POLICE treatment where the letters ICE represent ice, compression and elevation (Chapter 17). This limits the haemorrhage and subsequent oedema that can cause an irritating synovial reaction and restrict joint range of motion for a long period of time. The injured athlete should avoid things that promote blood flow and swelling, such as hot showers, heat rubs or excessive weight-bearing. Gradually increased weight-bearing will, however, help

reduce the swelling and increase the ankle motion, and enhances recovery.

### Reduction of pain and swelling

Analgesics and/or NSAIDs may be required. After 48 hours, gentle soft tissue therapy and mobilisation may reduce pain. By reducing pain and swelling, muscle inhibition around the joint is minimised, permitting the patient to begin range of motion exercises.

The indications for the use of NSAIDs in ankle injuries are unclear. Many clinicians prescribe these drugs after lateral ligament sprains although their efficacy has not been proven (Chapter 17). The rationale for commencing NSAIDs 2-3 days after injury is to reduce the risk of joint synovitis with early return to weight-bearing.

### Restoration of full range of motion

If necessary, the patient may be non weight-bearing on crutches for the first 24 hours, but then should commence partial weight-bearing in normal heel-toe gait. This can be achieved while still using crutches or, in less severe cases, by protecting the damaged joint with strapping or bracing.<sup>8</sup> Thus, partial and, ultimately, full weight-bearing can take place without aggravating the injury. Lunge stretches, and accessory and physiological mobilisation of the ankle (Fig. 41.7a), subtalar (Fig. 41.7b) and midtarsal joints should begin early in rehabilitation.

As soon as pain allows, the clinician should prescribe active range of motion exercises (e.g. stationary cycling).

### Muscle conditioning

Active strengthening exercises, including plantarflexion, dorsiflexion, inversion and eversion (Fig. 41.8), should begin as soon as pain allows.

The exercises should be progressed by increasing resistance (a common method is to use rubber tubing). Strengthening eversion with the ankle fully plantarflexed is particularly important in the prevention of future lateral ligament injuries. Weight-bearing exercises (e.g. shuttle [Fig. 41.9] and wobble-board exercises [Fig. 41.10a]) are encouraged as soon as pain permits, preferably the first or second day after injury.

### Proprioception

Proprioception is invariably impaired after ankle ligament injuries. The assessment of proprioception is shown in Figure 41.3h. The patient should begin proprioceptive retraining (Chapter 18) early in rehabilitation and these exercises should gradually progress in difficulty. An example of a common progression is balancing on one leg, then using the wobble board (Fig. 41.10a) or mini-trampoline, and ultimately performing functional activities while balancing (Fig. 41.10b).

(a)

(b)

**Figure 41.7** Mobilisation of the ankle joint (a) ankle dorsiflexion. The calcaneus and foot are grasped to passively dorsiflex the ankle (b) eversion mobilisation techniques to restore subtalar joint movement after ankle sprain

### Functional exercises

Functional exercises (e.g. jumping, hopping, twisting, figure-of-eight running) can be commenced once an athlete is pain-free, has full range of motion, and adequate muscle strength and proprioception. Specific technical training can accelerate a player's return to sport and substantially reduce the risk of re-injury.<sup>9, 10, 11</sup> Remember that approximately 75% of those who sustain an ankle ligament injury have had a previous injury. In many cases this old injury was not fully rehabilitated.

#### PRACTICE PEARL

The high risk of recurrent injury means that all ankle ligament injuries should be fully rehabilitated.

**Figure 41.8** Strengthening exercises—eversion using a rubber tube as resistance

**Figure 41.9** Strengthening exercises—weight-bearing shuttle exercises

(a)

(b)

**Figure 41.10** (a) Proprioceptive retraining following acute ankle injury using wobble board (b) Proprioceptive retraining following acute ankle injury using functional activity while balancing

### Return to sport

Return to sport is advised when functional exercises can be performed without pain during or after activity. However, any athlete who has had a significant lateral ligament injury has an increased risk of injury recurrence post injury for a minimum of 6–12 months post-injury.<sup>2, 12, 13</sup> There are a number of methods to protect against these subsequent inversion injuries. Both external prophylactic measures (i.e. tape or brace), as well as neuromuscular training, seem equally effective in reducing the increased risk of ankle sprain recurrences after an index ankle sprain.<sup>14, 15</sup> They have seemingly different pathways through which they achieve this secondary preventive effect.

The relative advantages of taping and bracing have been discussed in Chapter 12. As both seem equally effective, the choice of taping or bracing depends on patient preference, cost, availability and expertise in applying tape.<sup>16</sup>

The three main methods of tape application are stirrups (Fig. 41.11a), heel lock (Fig. 41.11b) and the figure of six (Fig. 41.11c). Usually at least two of these methods are used together.

Braces have the advantage of ease of fitting and adjustment, lack of skin irritation and reduced cost compared with taping for a lengthy period. There are a number of different ankle braces available. Lace up and/or Velcro braces are the most common (Fig. 41.12).

External measures (e.g. braces/tape) act primarily by temporarily enhancing proprioception after an ankle sprain, rather than by restricting ankle range of motion.<sup>17–20</sup> This support is immediately available. Nonetheless, external measures only support the impaired ankle and do not rehabilitate the underlying impaired neuromuscular function. As such, their preventive effects are limited to the period when the athlete is wearing the external measure. This means that an athlete should brace or tape for the entire 6–12 month healing period during which risk is increased to fully benefit from any preventive effects.<sup>21</sup>

In contrast neuromuscular training targets the underlying impairment by re-establishing and strengthening the ligament, muscles and protective reflexes of the ankle.<sup>22, 23</sup> After completion of the training the athlete's increased recurrence risk is reduced and, in theory, no

(a)

(b)

**Figure 41.11** Application of ankle tape (a) stirrups. After preparation of the skin, anchors are applied circumferentially. The ankle should be in the neutral position. Stirrups are applied from medial to lateral, and repeated several times until functional stability is achieved (b) heel lock. To limit inversion, taping is commenced at the front of the ankle and then angled inferiorly across the medial longitudinal arch, then diagonally and posteriorly across the lateral aspect of the heel, and then continued medially over the back of the Achilles tendon to loop back anteriorly. Tape direction is thereafter reversed to restrict eversion

further preventive means are necessary. However, these exercises do not reduce injury risk immediately with the first training session.

#### PRACTICE PEARL

It takes 8–10 weeks for more intensive neuromuscular training programs to achieve an effect.<sup>9, 24</sup>

When external measures are employed during a period of intensive neuromuscular training after return to sport, the patient benefits from an immediate risk-reducing effect while targeting the underlying causes of an increased recurrence risk. This results in full reduction of the risk of a recurrent sprain within 10 weeks after return to sport.

#### Treatment of grade III injuries

Systematic reviews support non-surgical treatment of grade III ankle sprains.<sup>25, 26</sup> Functional recovery (as measured by return to work) was quicker in those treated with rehabilitation, subsequent rate of ankle sprains was no different between groups, and there was more ankle stiffness in those treated surgically.<sup>26</sup>

Finnish researchers compared surgical treatment (primary repair plus early controlled mobilisation) with early controlled mobilisation alone in a prospective study of 60 patients with grade III lateral ankle ligament injuries.<sup>27</sup> Of the patients treated with rehabilitation alone, 87% had excellent or good outcomes compared with 60% of patients treated surgically. Thus, early mobilisation alone provided a better outcome than surgery plus mobilisation in patients with complete tears of the lateral

(c)

**Figure 41.11 cont.** Application of ankle tape (c) figure of six. This is applied over stirrups. Tape runs longitudinally along the medial ankle, under the heel and is pulled up to loop back around the medial ankle as shown

ankle ligaments. Dutch investigators have reported better long-term outcomes after surgery for lateral ligament rupture compared with rehabilitation, but this conclusion was controversial.<sup>28</sup> Differences in rehabilitation protocols may explain such contradictory study results.

#### PRACTICE PEARL

Thus, grade III ankle injuries warrant a trial of initial conservative management over at least a 6–12 week period, irrespective of the level of the athlete.

If, despite appropriate rehabilitation and protection, there is recurrent instability or persistent pain, then surgical reconstruction of the lateral ligament is indicated.

The preferred surgical method is anatomical reconstruction using the damaged ligaments; this method produces good functional results in several studies, with

**Figure 41.12** Ankle braces—a variety of braces are available

low risk of complications. The ligaments are shortened and reinserted to bone. If the ligament tissue is extremely damaged or even absent, other methods can be considered. Postoperatively, early range of motion training, such as using an air-cast stirrup, is recommended.

Following surgery, it is important for the patient to undertake a comprehensive rehabilitation program to restore full joint range of motion, strength and proprioception. The principles of rehabilitation outlined earlier are appropriate.

Anatomical reconstruction produces good clinical results in more than 90% of patients. There is, however, increased risk of inferior results in cases of very longstanding ligament insufficiency and generalised joint laxity.

## LESS COMMON CAUSES

### Medial (deltoid) ligament injuries

As the medial ligament is stronger than the lateral ligament, and probably because eversion is a less common mechanism of ankle sprain, medial ankle ligament injuries are less common than lateral ligament injuries.

The classical injury mechanism of a medial ligament lesion is forced eversion of the foot, such as a direct

trauma to the lateral aspect of the foot and ankle. It is relatively uncommon that an inversion trauma causes combined lateral and deltoid ligament injuries.

Physical examination reveals swelling and pain on palpation of the medial ligament with signs of talar subluxation in complete lesions. Standard radiographs are frequently normal. The sensitivity of MRI to detect medial ligament lesions is high. However, there is a risk of over-diagnosing medial ligament lesions—which can be seen after a classical inversion trauma (with lateral ligaments injuries) in 60% of the cases, but this frequently does not match the clinical findings.

Medial ligament injuries may occur together with fractures (e.g. medial malleolus, talar dome, articular surfaces) and the treatment will depend on these associated injuries. Isolated medial ligament sprains should be treated in the same manner as lateral ligament sprains. In cases of gross laxity, elite athletes can be advised to consider a surgical option.

#### PRACTICE PEARL

After a medial ligament injury, return to activity takes about twice as long (or more) as would be predicted were the injury on the lateral side.

### Significant ankle fractures

A fracture affecting one or more of the malleoli (lateral, medial, posterior) can be difficult to distinguish from a moderate-to-severe ligament sprain because both conditions result from similar mechanisms of injury and cause severe pain and inability to weight-bear. Careful and gentle palpation can generally localise the greatest site of tenderness to either the malleoli (fracture) or just distal to the ligament attachment (sprain). Radiographs should be ordered; the Ottawa ankle rules (Fig. 41.4) are useful to avoid missing fractures or performing unnecessary investigations in these cases.

Treatment of ankle fractures (sometimes called Pott's fractures) requires restoration of the anatomy of the superior surface of the talus and the ankle mortise (inferior margins of the tibia and fibula). If the anatomy has been disrupted with dislocation of the joint surface, internal fixation is almost always required. When using stable internal fixation, early range of motion training can be started early.

Isolated undisplaced spiral fractures of the lateral malleolus (without medial ligament instability) and posterior malleolar fractures involving less than 25% of the articular surface are usually stable. These fractures can be treated symptomatically with early mobilisation using crutches in the early stages for pain relief.

Lateral malleolar fractures associated with medial instability, undisplaced medial malleolar fractures or larger undisplaced posterior malleolar fractures are potentially unstable, but may be treated conservatively with six weeks of immobilisation using a walking boot (Fig. 41.13) that extends to include the metatarsal heads. In cases of undisplaced or minimally displaced fractures, the immobilisation time may be shortened considerably, using an ankle brace and early range of motion training.

Displaced medial malleolar, large posterior malleolar, bimalleolar or trimalleolar fractures, or any displaced fracture that involves the ankle mortise, require orthopaedic referral for open reduction and internal fixation. A comprehensive rehabilitation program should be undertaken following surgical fixation. The aims of the rehabilitation program are to restore full range of motion, strengthen the surrounding muscles and improve proprioception. Refer to guidelines provided earlier.

### Lateral malleolar fracture with syndesmotic injury (Maisonneuve fracture)

This injury is more common in patients presenting to emergency departments than in the sports setting, but occasionally high-impact sports injuries can cause this variant of the syndesmosis sprain.

#### PRACTICE PEARL

The injury involves complete rupture of the medial ligament, the AITFL (see below) and interosseous membrane, along with a proximal fibular fracture.

Surprisingly, non weight-bearing X-rays may not demonstrate the fracture, and the unstable ankle can reduce spontaneously. Urgent referral to an orthopaedic surgeon is necessary.<sup>29</sup>

### PERSISTENT PAIN AFTER ANKLE SPRAIN—‘THE DIFFICULT ANKLE’

Most cases of ankle ligament sprain resolve satisfactorily with treatment—pain and swelling settle and function improves. However, as ankle sprain is such a common condition, a substantial number of patients do not progress well and complain of pain, recurrent instability, swelling and impaired function 3–6 weeks after injury, or even longer. This is a common presentation in sports medicine practice and the key to successful management is accurate diagnosis. The ankle may continue to cause problems because of an undiagnosed fracture or other bony abnormality (Table 41.2). Alternatively, there may be ligament, tendon, synovial or neurological dysfunction (Table 41.3). Here we discuss a clinical approach to managing patients with the difficult ankle before detailing management of specific conditions.

**Table 41.2 Fractures and impingements that may cause the ‘difficult ankle’—persistent ankle pain after ankle injury**

Fractures	Bony impingements <sup>(a)</sup>
Anterior process calcaneus	Anterior impingement
Lateral process talus	Posterior impingement
Posterior process talus (also os trigonum fracture)	Anterolateral impingement
Osteochondral lesion	
Tibial plafond chondral lesion	
Fracture of base of fifth metatarsal	

(a) Although impingements are included here in the bony causes, pain commonly arises from soft tissue impingement between bony prominences.

### Clinical approach to the difficult ankle

The clinician should take a detailed history: clarify whether pain or impairment started following an ankle sprain (the true ‘difficult ankle’) or if it is longstanding and arose without a history of injury (see Chapter 42). The patient who has had inadequate rehabilitation will usually complain of persistent pain, reduced range of motion and limitation of function with increasing activity. The clinician should determine whether the rehabilitation was adequate by asking the patient to demonstrate the exercises he or she performed in rehabilitation. Did therapy include range of motion exercises (particularly dorsiflexion), strengthening exercises (with the foot fully plantarflexed to engage the peroneal tendons/muscles) and proprioceptive retraining?<sup>30</sup>

Examination of the inadequately rehabilitated ankle reveals decreased range of motion in the ankle joint (especially dorsiflexion), weak peroneal muscles and impaired proprioception. These findings can be reversed with mobilisation of the ankle joint (Fig. 41.7a), muscle strengthening (Fig. 41.8) and training of proprioception (Fig. 41.10). Other abnormalities can also cause this constellation of examination findings—remember that the ankle may be inadequately rehabilitated because of the pain of an osteochondral lesion of the talus.

If rehabilitation has been appropriate and symptoms persist, it is necessary to consider the presence of other abnormalities. Was it a high-energy injury that may have caused a fracture? Symptoms of intra-articular abnormalities include clicking, locking and joint swelling. The clinician should palpate all the sites of potential fracture very carefully to exclude that condition. See also the section on Ottawa ankle rules (Fig. 41.4).

Soft tissue injuries that can cause persistent ankle pain after sprain include chronic ligament instability, complex regional pain syndrome type 1 and, rarely, tendon dislocation or subluxation, or even tendon rupture (partial or total). Inflammation of the sinus tarsi (sinus tarsi syndrome) can also cause persistent ankle pain, but this can also occur secondary to associated fractures. Thus, even if there are features of the sinus tarsi syndrome, the clinician should still seek other injuries too.

Appropriate investigation is a key part of management of patients with the difficult ankle. MRI is preferred to bone scan as it can detect bony and soft tissue abnormalities. Clinicians must remember that a subluxing tendon can appear normal on MRI.

#### PRACTICE PEARL

Isotope activity in the bone phase is normal in soft tissue problems and increased if bony damage is present.

### Osteochondral lesions of the talar dome

An osteochondral lesion of the talus is an important cause of residual pain after an ankle sprain. It is defined as the separation of a fragment of articular cartilage, with or without subchondral bone. Its incidence after an ankle sprain has been reported to be around 6.5%, and is probably underestimated because these lesions often remain undetected. The grading of osteochondral fractures of the talar dome is shown in Figure 41.15.

### History

Osteochondral fractures of the talar dome usually occur in association with ankle sprains when there is a compressive

**Table 41.3 Ligamentous, tendon and neurological causes of the ‘difficult ankle’—persistent ankle pain after ankle injury**

Atypical sprains	Tendon injuries	Other soft tissue and neural abnormalities
Chronic ligamentous instability	Chronic peroneal tendon weakness	Inadequate rehabilitation
Medial ligament sprain	Peroneal tendon subluxation/rupture	Chronic synovitis
Syndesmosis sprain (AITFL sprain)	Tibialis posterior tendon subluxation/rupture	Sinus tarsi syndrome
Subtalar joint sprain		Complex regional pain syndrome type 1

**Figure 41.13** A CAM (Controlled Ankle Movement) walker boot is a useful adjunct to rehabilitation for several different ankle injuries

component to the inversion injury, such as when landing from a jump. The talar dome is compressed by the tibial plafond, causing damage to the osteochondral surface. The lesions are usually in the superomedial corner of the talar dome, and are less common superolaterally.

Large fractures may be recognised at the time of injury. The fracture site will be tender and may be evident on plain radiography (Fig. 41.14a).

Often an osteochondral lesion of the talus is not detected initially and the patient presents later with unremitting ankle aching and locking or catching, despite appropriate treatment for an ankle sprain. The patient often gives a history of initially progressing well following a sprain, but then developing symptoms of increasing pain and swelling, stiffness and perhaps catching or locking as activity is increased. Reduced range of motion is often a prominent symptom. The reason why an osteochondral lesion of the talus produces these symptoms is poorly understood. It has been hypothesised that a focal loss of structural support of the talar dome or cyclical change in intra-osseous pressure with gait, triggers pain receptors in the richly innervated subchondral bone.

### Examination

Examination with the patient's foot plantarflexed at 35° to rotate the talus out of the ankle mortise may reveal

tenderness of the dome of the talus. This may, however, be difficult due to pain. The diagnosis of osteochondral lesion of the talus requires a high index of suspicion. Focal chondral and osteochondral defects may eventually progress to ankle joint osteoarthritis.<sup>31</sup>

### Investigations

Plain radiographs often appear normal or show only minor changes resulting in a delayed diagnosis. If osteochondral lesion of the talus is suspected, an MRI (Fig. 41.14b) should be requested.

A CT scan (Fig. 41.14c) can be used to determine the exact degree of skeletal injury.

MRI provides anatomical and pathological data, and is the investigation of choice. MRI has a benefit of being positive in grade I lesions. The grading of osteochondral fractures of the talar dome is shown in Figure 41.15.

### Treatment

The treatment of an osteochondral lesion of the talus is complex and numerous non-surgical and surgical options including marrow stimulation techniques and tissue transplantation have been reported. All options have some limitations, mainly due to the poor regenerative capacity of the articular cartilage and the limited access to the ankle joint.

(a)

(b)

(c)

**Figure 41.14** Osteochondral lesion of the talar dome  
(a) radiograph (arrow) (b) MRI (circle) (c) CT scan (grade IV)

Chronic grade I and II lesions should be treated conservatively. Patients should avoid activities that cause pain and ride an exercise bike with low resistance. Cast immobilisation has now been replaced with early joint motion without significant loading to promote articular cartilage. If there is pain, symptoms of clicking, locking or giving way persisting after 2–3 months of conservative

management, ankle arthroscopy is indicated in order to remove or fix loose bodies. A grade IIa, III or IV lesion also requires arthroscopic removal of the separated fragment or cyst, and curetting and drilling of the fracture bed down to bleeding bone. After surgical treatment of osteochondral lesions, a comprehensive rehabilitation program is required. Tibial plafond chondral lesions (see below) are managed identically.

Clinical outcome studies have identified some prognostic parameters, such as the size of the lesion. However, there is only limited information available to predict the individual patient outcomes when treating osteochondral lesions of the talus.

### Avulsion fracture of the base of the fifth metatarsal

Inversion injury may result in an avulsion fracture of the base of the fifth metatarsal. This benign fracture can occur in isolation or, more commonly, in association with a lateral ligament sprain. The fracture results from traction of the peroneus brevis tendon attachment at the base of the fifth metatarsal.

Plain radiographs should be examined closely. Avulsion fracture is characterised by its involvement of the joint surface of the base of the fifth metatarsal (Fig. 41.16).

A potentially confusing fracture is the fracture of the proximal diaphysis of the fifth metatarsal that does not involve any joint surfaces. This fracture is known as the Jones fracture and may require internal fixation (Chapter 43).

**Grade I** Subchondral fracture Investigation: MRI

**Grade II** Chondral fracture Investigation: CT/MRI

**Grade IIa** Subchondral cyst Investigation: CT/MRI

**Grade III** Chondral fracture with separated but not displaced fragments Investigation: CT/MRI

**Grade IV** Chondral fracture with separated and displaced fragment(s) Investigation: X-ray/CT/MRI

**Figure 41.15** Grading of osteochondral fracture of the talar dome

**Figure 41.16** Avulsion fracture of the base of the fifth metatarsal

#### PRACTICE PEARL

It is important to distinguish between the benign fracture of the base of the fifth metatarsal and a Jones fracture. Refer to Chapter 43 for more information.

Although the mechanism can appear to be one of 'acute' injury, in most cases the Jones fracture is a result of repetitive overuse (i.e. a stress fracture) of the proximal diaphysis of the fifth metatarsal.

### Other fractures

A number of other fractures can occur as a result of acute ankle injuries (Fig. 41.17), alone or in association with ligamentous injury. They may be undetectable or subtle on plain radiograph.

### Fractured lateral talar process

The lateral talar process is a prominence of the lateral talar body with an articular surface dorsolaterally for the fibula and inferomedially for the anterior portion of the posterior calcaneal facet (Fig. 41.17). Patients with a fracture of this process may present with ankle pain, swelling and inability to weight-bear for long periods. Examination

**Figure 41.17** Fractures around the talus and calcaneus

reveals swelling and bruising over the lateral aspect of the ankle and tenderness over the lateral process, immediately anterior and inferior to the tip of the lateral malleolus. The fracture is best seen on the mortise view radiograph of the ankle. Undisplaced fractures may be treated in a short leg cast. Fractures displaced more than 2 mm require either primary excision or reduction and internal fixation. Comminuted fractures may require primary excision, which is a safe treatment, followed by short immobilisation only.

### Fractured anterior calcaneal process

Fractures of the anterior calcaneal process may cause persistent pain after an ankle sprain. Palpation of the anterior calcaneal process, just anterior to the opening of the sinus tarsi (Fig. 41.17), is painless in patients with a tear of the ATFL, but will cause considerable pain in those with a fracture of the anterior process. If plain radiographs (including oblique foot views) fail to show a fracture that is suspected clinically, MRI or CT is indicated (Fig. 41.18).

If the fracture is small, symptomatic treatment may suffice. If large, it requires four weeks of non weight-bearing cast immobilisation or surgical excision of the fragment.

### Tibial plafond chondral lesions

Tibial plafond (the inferior tibial articular surface) injuries may occur with vertical compression forces, such as a fall from a height. However, they can also result from straightforward ankle sprains. The patient complains of difficulty weight-bearing, and examination reveals swelling and restricted dorsiflexion. As with talar dome lesions, plain radiograph can be normal, so MRI or CT are necessary to demonstrate the lesion (Fig. 41.19).

If imaging and clinical features are consistent with bony damage, arthroscopic debridement, including microfracturing is indicated but ankle pain can persist for months to a year, even after treatment.

**Figure 41.18** Sagittal CT image showing an anterior process calcaneal fracture

### Fractured posterior process of the talus

Posterior process fractures occur usually as a result of forced plantar flexion injuries and are even less common than lateral process fractures (Fig. 41.17). This mechanism is often seen during kicking and has been reported in fencing.

Routine AP and lateral radiographs may not show the acute fracture and can be wrongly interpreted. CT scanning remains the mainstay of diagnosis, but a high index of suspicion is required.

Most of these injuries will be treated initially with conservative treatment. Acute fractures of the posterior process of the talus may require surgical excision.

### Medial tubercle fractures

Fractures of the medial tubercle of the posterior process talus are rare in sports. They can occur due to a dorsiflexion avulsion by the posterior talotibial ligament (posterior aspect of the deltoid ligament) and eversion (Cedell fracture), or by direct traumatic compression.

In contrast to lateral tubercle injuries, pain and swelling is usually present between the Achilles tendon and the medial malleolus, but there may be limited pain on walking or moving the ankle. It is difficult to visualise fractures of the medial tubercle on plain AP and lateral radiographs, and it has been suggested that the addition of two oblique views at 45° and 70° of external rotation may

**Figure 41.19** Sagittal T2 MRI image of an anterior tibial plafond cartilage lesion with a loose fragment of cartilage in the joint

significantly aid detection prior to resorting to a CT or MR imaging. The fracture can be treated arthroscopically with a posterior approach.

### Impingement syndromes

Ankle impingement syndromes are usually the result of overuse, but can occur following acute ankle injuries. For example, ballet dancers often suffer posterior impingement following lateral ankle sprain, due to the presence of an os trigonum, processus posterior of the talus and/or posterior osteophytes. In the acute ankle a blocked kicking action can cause posterior impingement. Posterior impingement syndrome is discussed in detail in Chapter 40. Anterior and anterolateral impingement syndromes and their treatment are discussed in Chapter 42.

### Tendon dislocation or rupture

Dislocation or longitudinal rupture of the peroneal tendons (in most cases peroneus brevis tendon) can cause persistent lateral ankle symptoms. Tibialis posterior injury can cause similar symptoms on the medial side but is very uncommon in sport.

### Dislocation of the peroneal tendons

The peroneal tendons are situated behind the lateral malleolus and held there by the superior peroneal

retinaculum. They are occasionally dislocated as a result of forceful passive dorsiflexion with rupture of the retinaculum from the posterior edge of the lateral malleolus. This may occur when a skier catches a tip and falls forward over the ski. Rupture of the peroneal retinaculum allows one or both of the tendons to move out of their groove. The dislocated tendon(s) may remain in a dislocated position or spontaneously relocate and subsequently become prone to recurrent subluxation. Examination reveals tender peroneal tendons that can be dislocated by the examiner, especially with ankle plantarflexion.

Treatment of dislocation of peroneal tendons is surgical replacement of the tendons in the peroneal groove and repair of the retinaculum, using bone anchors or drill holes. If the peroneal groove is shallow, then retinacular repair should be accompanied by deepening of the groove or rotation of the malleolus (not often recommended). Soft tissue repair, however, produces a good result in most cases.

### Dislocation of the tibialis posterior tendon

Dislocation of the tibialis posterior tendon is extremely rare in sport. It occurs with ankle dorsiflexion and inversion, where forceful contraction of the tibialis posterior muscle pulls the tendon out of its retinaculum using the malleolus as a fulcrum. The patient may complain of moderate medial ankle pain and inability to weight-bear. Examination reveals swelling and bruising around the medial malleolus with tenderness along the course of the tibialis posterior tendon. The tendon can be subluxed anteriorly and subsequently relocated posteriorly with the foot in the fully plantarflexed position. The diagnosis is clinical, but ultrasonography or MRI (Fig. 41.20) may reveal fluid around the tendon.

Immediate surgical treatment is indicated to minimise the time that the tendon is dislocated while permitting primary repair of the flexor retinaculum and reattachment of the tibialis posterior sheath.<sup>32</sup> Postoperatively the ankle is immobilised in a CAM walker for a total of six weeks' non weight-bearing. Once the walking boot is no longer required an ankle brace can be used to support the ankle with active ankle motion permitted three times daily while taking care to avoid resisted inversion. Weight-bearing can recommence at six weeks under physiotherapy supervision followed by strengthening and functional rehabilitation.

### Rupture of the tibialis posterior tendon

An athlete with a ruptured tibialis posterior tendon presents with pain in the region of the tubercle of the navicular extending to the posterosuperior border of the medial malleolus and along the posteromedial tibial border. Examination reveals thickening or absence (less

**Figure 41.20** MRI appearance (T2-weighted) shortly after tibialis posterior tendon dislocation shows the tibialis posterior tendon (dark) in cross-section surrounded by abnormal fluid (high signal intensity). The tendon is in its normal position during this examination. If imaging had been delayed sufficiently, fluid would have been absent and the MRI appearance may have been normal

frequent) of the tibialis posterior tendon and inability to raise the heel. A flattened medial arch is a classic sign. MRI is the investigation of choice in this condition, although ultrasound may also be helpful. However, there is low correlation between MRI findings and symptoms. Surgical repair, often including major reconstruction of the midfoot anatomy is indicated as the tibialis posterior tendon is essential to maintain the normal medial arch of the foot.

### Other causes of the difficult ankle

#### Anteroinferior tibiofibular ligament injury/syndesmotic injury

The distal tibiofibular joint is a fibrous syndesmotic articulation consisting of the concave surface of the distal tibia and convex shape of the distal fibula.<sup>33</sup> The syndesmosis is a complex ligamentous structure including three different portions. The anterior syndesmosis consists of the anterior inferior tibiofibular ligament (AITFL); the middle part consists of the interosseous ligament (IOL); and the posterior syndesmosis includes the posterior inferior tibiofibular and the transverse ligaments (PITFL and TL). Each structure plays a critical role to provide

stability of the ankle mortise. The resistance to diastasis comes from the PITFL and TL for 40–45%, the AITFL for 35% and the IOL for 20–25%.<sup>34</sup>

Injuries to the distal tibiofibular syndesmosis (Fig. 41.21) account for 11–17% of the ankle sprains in athletic populations.<sup>35</sup> Acute syndesmotomic injuries have been reported especially in football and skiing. They can range from stable minor sprains to significant fractures (e.g. Maisonneuve fracture) of the distal fibula with combined syndesmotomic disruption. Syndesmotomic injuries usually present with more pain and disability than a typical lateral ankle sprain.

The mechanism of syndesmotomic injury can be an isolated hyperdorsiflexion force, but is most commonly due to an external rotation injury, in combination with axial loading of the ankle. In patients with a combined deltoid injury or medial malleolar fracture, an abduction force is the main cause of the associated syndesmotomic lesion.

Syndesmotomic injuries can be isolated or associated with bony or ligamentous ankle injuries. The term 'isolated' is commonly used for syndesmotomic injuries without ankle fractures, although concomitant ligamentous or soft tissue injuries and tibiofibular avulsion fractures may be present.<sup>36</sup>

If there is pain on palpation over the anterior and posterior tibiofibular ligaments, the more proximal the pain, the greater the extent of the lesion. It is also important to check the entire fibula up to the knee if there is any suspicion of syndesmotomic/Maisonneuve

**Figure 41.21** Anatomy of a syndesmosis sprain. This injury may be associated with medial malleolar fracture (not illustrated)

fracture. Swelling is less marked in syndesmotomic injury compared with a normal ankle sprain and bruising is usually more proximal to the ankle joint.

#### PRACTICE PEARL

There is no pathognomonic clinical test to evaluate a syndesmotomic injury but the external rotation test is the most helpful test. The test is performed by stabilising the leg with the knee flexed at 90° and then rotating the foot externally.

A positive test will elicit pain at the syndesmosis. During physical examination, it is important to palpate the medial ankle in addition to determine the integrity of the deltoid ligament, since it can highlight a more significant unstable syndesmotomic injury.

Radiographic imaging must include an AP view and a mortise view of the syndesmosis to rule out the tibiofibular clear space, medial clear space overlap, tibial width and fibular width. In acute syndesmotomic lesions, MRIs have a sensitivity and specificity that are about 100%.<sup>37</sup> Furthermore, injury to the distal tibiofibular syndesmosis has a significant association with a number of secondary findings on MRI, including bone bruises, osteochondral lesions, tibiofibular joint congruity and height of the tibiofibular recess.

Acute ankle injuries with an isolated lesion of the syndesmosis should be classified as stable or unstable.

- The stable ankle sprain is characterised by a lesion of the AITFL with or without interosseous ligament (IOL) with a continent deltoid ligament.
- The unstable ankle sprain should be classified as latent or frank diastasis. The latent diastasis is characterised by a rupture of the AITFL with or without IOL and deltoid ligament. It can be detected on MRI and/or arthroscopic assessment. The frank diastasis is characterised by a rupture of all the syndesmotomic and deltoid ligaments, and it is visible on standard radiographs.<sup>33</sup>

Syndesmotomic sprains without instability should be treated non-operatively with a CAM walker (Fig. 41.13) or brace. Syndesmosis injuries frequently require almost twice as much time rehabilitating compared with patients who have lateral ankle sprains. An acute syndesmotomic ligament rupture with instability of the ankle should be managed operatively.<sup>33</sup>

#### Post-traumatic synovitis

Some degree of synovitis will occur with any ankle injury due to the presence of blood within the joint. This

**Figure 41.22** Corticosteroid injection into the ankle joint in the treatment of post-traumatic synovitis. The needle is inserted medial to the tibialis anterior tendon and directed posterolaterally

usually resolves in a few days, but may persist if there is excessive early weight-bearing, typically in athletes eager to return to training soon after their ankle sprain, or due to insufficient rehabilitation. These athletes will often develop persistent ankle pain aggravated by activity and associated with swelling. Synovitis of the ankle joint is also seen in athletes who have chronic mild instability because of excessive accessory movement of the ankle joint during activity.

Treatment of synovitis includes NSAIDs, rest from aggravating activity and local electrotherapy. A corticosteroid injection into the ankle joint (Fig. 41.22) may be required. An injection should be followed by 48 hours of limited weight-bearing and gradual resumption of activity. Sometimes arthroscopy with synovectomy may be indicated.

When synovitis is associated with a degree of chronic instability, treatment involves taping or bracing. Such patients can have significant relief when wearing a brace for

**Figure 41.23** Injection into the sinus tarsi. The lateral opening of the sinus is maintained when the foot is inverted. The needle is directed towards the tip of the medial malleolus

activities of daily living as well as sport. These patients may also benefit from ankle ligament reconstructive surgery.

### Sinus tarsi syndrome

Sinus tarsi syndrome may occur as an overuse injury secondary to excessive subtalar pronation (Chapter 42) or following an ankle sprain. Pain occurs at the lateral opening of the sinus tarsi (Fig. 41.1b). The pain is often more severe in the morning and improves on warming up.

Forced passive inversion and eversion may both be painful. The most appropriate aid to diagnosis is to monitor the effect of injection of a local anaesthetic agent into the sinus tarsi under fluoroscopy (Fig. 41.23).

Treatment consists of relative rest, NSAIDs, electrotherapeutic modalities, subtalar joint mobilisation and taping to correct excessive pronation if present. If conservative management is unsuccessful, injection of corticosteroid and local anaesthetic agents may help resolve the inflammation.

### Complex regional pain syndrome type 1

Complex regional pain syndrome (CRPS) type 1, formerly known as RSD (Chapters 5, 6 and 7), may occasionally complicate ankle injury. Initially, it appears that the patient with a 'sprained ankle' is improving but then symptoms begin to relapse. The patient complains of increased pain, swelling recurs and the skin may become hot or, more frequently, very cold. There may also be localised sweating, discoloration and hypersensitivity.

As early treatment substantially improves the prognosis in CRPS type 1, early diagnosis is imperative. Initial radiographs are normal. Later, patchy demineralisation occurs and this can be seen as regions of decreased opacity on plain radiograph and areas of increased uptake on bone

scan or increased signal on MRI.<sup>38</sup> Tests of sympathetic function may confirm the diagnosis.<sup>38</sup>

It is most important that the specific nature of the condition be explained to the patient as it may be very painful, even at rest. It remains difficult to treat and there have been few controlled treatment trials for established CRPS type 1.<sup>39</sup> Physiotherapy may play a role<sup>40</sup> and ultrasound and hydrotherapy may facilitate range of movement exercises. Gabapentin, an anticonvulsant with a proven analgesic effect in various neuropathic pain syndromes, has shown mild efficacy as treatment for pain in patients with CRPS

type 1.<sup>41</sup> As CRPS type 1 is associated with regional osteoclastic overactivity (excessive bone turnover, as shown by increased uptake on radionuclide bone scan), a bisphosphonate medication (alendronate) was trialled in 39 patients.<sup>42</sup> In contrast to placebo-treated patients, all of the alendronate-treated patients had substantially reduced pain and improved joint mobility as early as the fourth week of treatment.

If the pain does not settle, chemical or surgical blockade is indicated. However, a Cochrane systematic review failed to support this therapy for relieving pain.<sup>43</sup> CRPS type 1 remains a very difficult condition to treat.

# Ankle pain

with KAREN HOLZER and JON KARLSSON

*Dance is the hidden language of the soul.*

Martha Graham, dancer and choreographer, 1894–1991

Sportspeople, particularly ballet dancers, footballers, basketballers and high jumpers, may complain of ankle pain that is not related to an acute ankle injury (Chapter 41). Clinical management of such 'overuse' injuries is simplified if the presentations are further divided into:

- medial ankle pain
- lateral ankle pain
- anterior ankle pain
- posterior ankle pain: defined in this book as the 'Achilles region' (Chapter 40).

It is important to note that clinically, patients often present with combinations of pain, such as anterolateral ankle pain in soccer players. In those circumstances, the systematic clinical approach outlined in this chapter still aids in diagnosis and management.

## MEDIAL ANKLE PAIN

Although there are numerous causes of medial ankle pain, the most common is tendinopathy, in particular of the tibialis posterior tendon, and to a lesser degree the flexor

hallucis longus tendon. Another important cause of medial ankle pain is tarsal tunnel syndrome, where the posterior tibial nerve is compressed behind the medial malleolus. This may present as medial ankle pain with sensory symptoms distally. Posterior impingement syndrome of the ankle can also present as medial ankle pain (Chapter 40).

The causes of medial ankle pain are listed in Table 42.1. The anatomy of the region is illustrated in Figure 42.1.

## History

In patients with medial ankle pain there is usually a history of overuse, especially running or excessive walking (tibialis posterior tendinopathy), toe flexion in ballet dancers and high jumpers (flexor hallucis longus tendinopathy) or plantarflexion in dancers and footballers (posterior impingement syndrome). In the case of tibialis posterior tendinopathy, pain may radiate along the line of the tendon to its insertion on the navicular tubercle, or in tarsal tunnel syndrome the arch of the foot. Associated sensory symptoms such as pins and needles or numbness

**Table 42.1 Causes of medial ankle pain**

Common	Less common	Not to be missed
Tibialis posterior tendinopathy	Medial calcaneal nerve entrapment	Navicular stress fracture (Chapter 43)
Flexor hallucis longus tendinopathy	Calcaneal stress fracture	Complications of acute ankle injuries (Chapter 41)
	Tarsal tunnel syndrome	Complex regional pain syndrome type 1 (following knee or ankle injury) (Chapter 5)
	Talar stress fracture	
	Medial malleolar stress fracture	
	Posterior impingement syndrome (Chapter 40)	
	Referred pain from lumbar spine	

(a)

(b)

**Figure 42.1** Medial aspect of the ankle (a) Surface anatomy (b) Anatomy of the medial ankle

may suggest tarsal tunnel syndrome. Crepitus is commonly associated with flexor hallucis longus and occasionally tibialis posterior tendinopathy.

## Examination

Careful palpation and testing of resisted movements is the key to examination of this region.

1. Observation
  - a. standing
  - b. walking
  - c. supine
2. Active movements
  - a. ankle plantarflexion/dorsiflexion
  - b. ankle inversion/eversion
  - c. flexion of the first metatarsophalangeal joint

3. Passive movements
  - a. as for active
  - b. subtalar joint
  - c. midtarsal joint
  - d. muscle stretches
    - i. gastrocnemius
    - ii. soleus
4. Resisted movement
  - a. inversion (Fig. 42.2a)
  - b. first toe flexion; check for crepitation (Fig. 42.2b)
5. Functional tests
  - a. hop
  - b. jump
6. Palpation
  - a. tibialis posterior tendon (Fig. 42.2c)
  - b. flexor hallucis longus; behind the medial malleolus
  - c. navicular tubercle
  - d. ankle joint
  - e. midtarsal joint
  - f. Achilles tendon
7. Special tests
  - a. Tinel's test (Fig. 42.2d)
  - b. sensory examination; especially for nerve entrapment of the calcaneal branches (Baxter's nerve) (Fig. 42.2e)
8. biomechanical examination (Chapter 8)
9. lumbar spine examination (Chapter 29).

## Key outcome measures

The key patient-reported outcome measures (PROMs) used in ankle pain are shown in Table 42.2.

(a)

**Figure 42.2** Examination of the patient with medial ankle pain (a) Resisted movement—inversion (tibialis posterior)

(b)

(d)

(c)

(e)

**Figure 42.2 (cont.)** (b) Resisted movement—toe flexion (flexor hallucis longus) (c) Palpation—tibialis posterior tendon. The tibialis posterior tendon is palpated from posteromedial to the medial malleolus to its insertion at the navicular tubercle (d) Special tests—Tinel's test. Tapping over the posterior tibial nerve in the tarsal tunnel may reproduce symptoms (e) Special tests—sensory examination especially for nerve entrapment of the calcaneal branches (Baxter's nerve). (See also Chapter 43, and refer to Figure 43.7.)

## Investigations

Plain radiograph is indicated when the following conditions are suspected:

- Posterior impingement: to confirm the presence of either a large posterior process of the talus/fracture of the posterior process of the talus or an os trigonum. A lateral view with the foot in a maximally plantarflexed position (posterior impingement view) can be useful to determine if bony impingement is occurring.
- Anteromedial impingement: anteroposterior views may reveal osteophytes with joint narrowing between the

medial talus and medial malleolus, or the anteromedial aspect of the medial tibial plafond.

- Stress fracture of the medial malleolus: often a delayed diagnosis, and as such sclerosis and/or a fracture line may be seen.

Ultrasound can assist in the diagnosis of tibialis posterior or flexor hallucis longus tenosynovitis or tendinopathy. MRI assists in the diagnosis of most medial ankle conditions including impingements, tenosynovitis and tendinopathies, and bony injuries.

Nerve conduction studies may be performed if tarsal tunnel syndrome is suspected. However nerve conduction studies are seldom diagnostic.

**Table 42.2 Patient-reported outcome measures for the ankle****Generic foot and ankle pain measures*****Foot and Ankle Ability Measure (FAAM)<sup>1</sup>***

- Self-administered questionnaire evaluating difficulty with activities of daily living (ADL) and sporting activities for patient with foot and ankle pain
- Two subscales: ADL and Sports subscales
- 29 items (21 on difficulty with ADL, 8 on difficulty with sporting activities)
- Score range: 0–100 for each subscale
- Test-retest reliability:
  - ADL subscale: 0.89
  - Sports subscale: 0.87
- Construct validity:
  - ADL subscale: SF-36<sup>1</sup> PF subscale and PCS subscale: both 0.84<sup>1</sup>
  - Higher ADL subscale scores for healthy athletes (M=100, SD=0) compared to patients with chronic ankle instability (M=88, SD=7.7)
  - Sports subscale: SF-36<sup>1</sup> PF subscale and PCS subscale: 0.78 and 0.80 respectively<sup>1</sup>
  - Higher Sports subscale scores for healthy athletes (M=99, SD=3.5) compared to patient with chronic ankle instability (M=76, SD=12.6)
- Minimal detectable change (MCD95%):
  - ADL subscale: 5.7
  - Sports subscale: 12.3
- Minimal clinically important difference (MCID):
  - ADL subscale: 8
  - Sports subscale: 9\* (\* as determined with optimal sensitivity/specificity in ROC curve)
- Developed and validated in American English, cross-culturally validated to Brazilian Portuguese,<sup>3</sup> Dutch,<sup>4</sup> German,<sup>5</sup> Italian,<sup>6</sup> Japanese,<sup>7</sup> Korean,<sup>8</sup> Persian,<sup>9</sup> Thai<sup>10</sup> and Turkish<sup>11</sup>

***Oxford Ankle Foot Questionnaire<sup>12, 13</sup>***

- Self-administered questionnaire evaluating disability in children with foot and ankle problems (5–16 years of age)
- 15 items (6 on physical domain, 4 on school and play domain, 4 on emotional domain and 1 on footwear)
- Score range:
  - Physical domain: 0–24 (0–100 if transformed to)
  - School and Play domain: 0–16 (0–100 if transformed to %)
  - Emotional domain: 0–16 (0–100 if transformed to %)

**Ankle Joint Functional Assessment Tool**

- Self-administered questionnaire evaluating ankle function
- Score ranges from 0–48 (48 = full function)
- Developed in American English; no validation studies were found

**Tibialis posterior tendinopathy**

The tibialis posterior tendon is the largest and most anterior structure that passes behind the medial malleolus (Fig. 42.1b). It then divides and sends attachments to the navicular tuberosity, the cuboid, cuneiforms, bases of the second to fourth metatarsals and the spring ligament.

The functions of the tibialis posterior include:

- inversion of the subtalar joint
- dynamic stabilisation of the hindfoot against valgus (eversion) forces
- support of the medial longitudinal arch
- locking the transverse tarsal joints, thus allowing the gastrocnemius to support heel raise, and assisting the Achilles tendon in plantarflexion of the ankle.

**Causes**

Acute injuries of the tibialis posterior tendon are rare. Thus, tibialis posterior tendinopathy is usually related to overuse and is most often seen in middle-aged women, and in ballet dancers. It comes on slowly, and is not self-limiting.

1. Overuse, often related to:
  - a. excessive walking, running or jumping
  - b. excessive subtalar pronation. This increases eccentric tendon loading during supination for toe-off
2. Acute:
  - a. direct trauma–laceration
  - b. indirect trauma–eversion ankle sprain, ankle fracture
  - c. acute avulsion fracture

### 3. Inflammatory conditions:

- a. tenosynovitis secondary to rheumatoid arthritis and seronegative arthropathies.

Chronic tendinopathies are characterised by collagen disarray and interstitial tears, and may eventually lead to total tendon rupture.

### Clinical features

The clinical features of tibialis posterior tendinopathy are as follows.

- Medial ankle pain often arising from behind the medial malleolus and extending towards the medial midfoot to the insertion of the tendon at the navicular bone.
- Swelling is very unusual in the early stages and if present may suggest a substantial tendon injury or an underlying seronegative arthropathy. In the later stages, however, swelling is more pronounced and is often diffuse around and below the medial malleolus.
- Tenderness along the tendon is usual, most prominent posterior and inferior to the medial malleolus or at the insertion onto the navicular bone.
- Crepitus is only occasionally present.
- Resisted inversion (Fig. 42.2a) will elicit pain and relative weakness compared with the contralateral side.
- A single heel raise test viewed from behind will reveal lack of inversion of the hindfoot, and if severe the patient may have difficulty performing a heel raise. In the normal ankle, the calcaneus moves into varus position during a single heel raise; in patients with tibialis posterior tendinopathy, this does not happen and the heel remains in the valgus position.

### Investigations

MRI (Fig. 42.3) or ultrasound may confirm the diagnosis and reveal the extent of tendinosis, including the presence of tears. MRI is the imaging modality of choice for the evaluation of tibialis posterior tendinopathy dysfunction. MRI has a sensitivity of 95%, a specificity of 100% and an accuracy of 96% in identifying disorders of the tendon.<sup>64</sup> It also has the ability to recognise injuries associated with longer-term tibialis posterior dysfunction, such as spring ligament failure, sinus tarsi inflammation and midfoot degeneration.

### Treatment

In milder cases conservative treatment is recommended; however, in more severe cases surgery may be required. Frequently the patient presents with an acute painful tendon, termed a 'reactive tendinopathy' which should be treated with rest, ice and non-steroidal anti-inflammatory drugs (NSAIDs) in the initial phase. Once the pain

and inflammation has settled, treatment includes the following.

- Deep soft tissue therapy to the tibialis posterior muscle.
- Footwear: a stability shoe is recommended and often the wearing of an orthoses to control excessive pronation.
- Progressive concentric and eccentric tendon loading exercise program once the inflammation has settled (Fig. 42.4).

### PRACTICE PEARL

Corticosteroid injections should never be used in the management of tibialis posterior tendinopathy due to poor long-term outcomes and an increased risk of total tendon rupture.

The use of platelet rich plasma (PRP) injections has no biological rationale and no trial evidence (see also Chapter 17).

Surgery is recommended if there is tendon rupture (Chapter 41) or if conservative management fails to settle the condition. In the case of tenosynovitis, a synovectomy may be performed, while in cases of severe tendinopathy or tendon rupture a reconstruction may be required. There is often need for large corrective surgical treatment. This treatment is directed towards correct alignment of the heel, and may include tendon transfer, calcaneus osteotomy, and/or midfoot corrective osteotomy/arthrodesis.

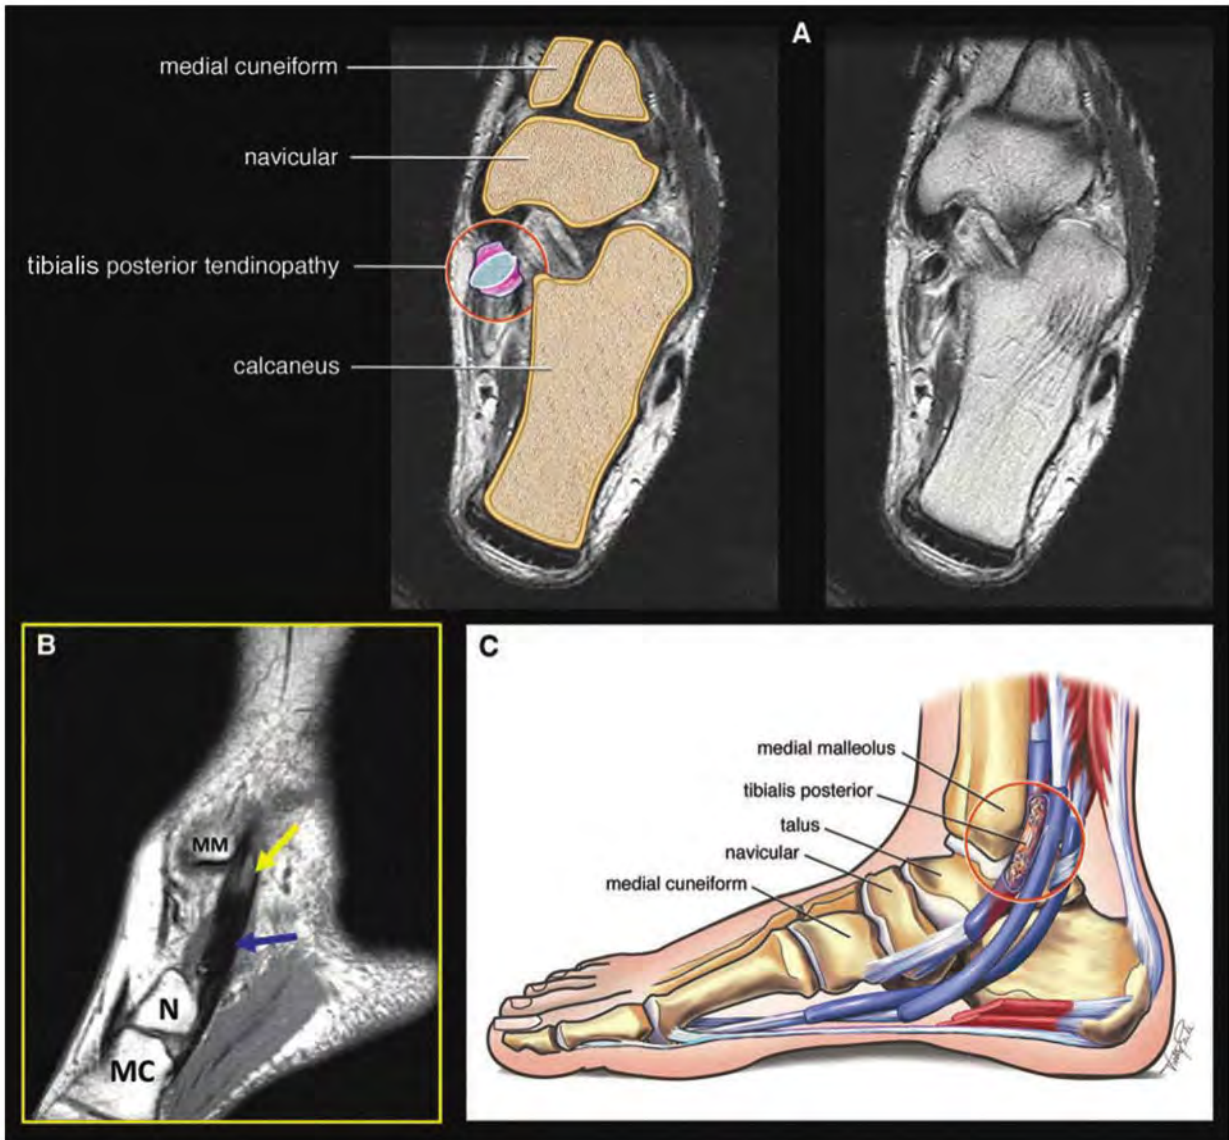

One major problem with the management of tibialis posterior tendinopathy is the long time from injury to final treatment which can result from delayed presentation or delay in diagnosis.

### Flexor hallucis longus tendinopathy

The flexor hallucis longus (FHL) tendon flexes the big toe and assists in plantarflexion of the ankle. It passes posterior to the medial malleolus, and runs between the two sesamoid bones to insert into the base of the distal phalanx of the big toe.

### Causes

FHL tendinopathy may occur secondary to overuse, a stenosing tenosynovitis, a pseudocyst or tendon tear. The tendon tear may be partial or total. A common cause is overuse in a ballet dancer, as dancers repetitively go from flat-foot stance to the *en pointe* position when extreme plantarflexion is required. Wearing shoes that are too big and require the athlete to 'toe-grip' may also result in flexor hallucis longus tendinopathy.

**Figure 42.3** Tibialis posterior tendinopathy (a) Axial view showing tendon surrounded by area of oedema (b) Sagittal view showing abnormal (yellow arrow) and normal (blue arrow) tendon appearance (c) Anatomy

This condition is often associated with posterior impingement syndrome (Chapter 40) as the flexor hallucis tendon lies in a fibro-osseous tunnel between the lateral and medial tubercles of the posterior process of the talus. Enlargement or medial displacement of the posterior process of the talus or os trigonum compresses the flexor hallucis longus at the point where the tendon changes direction from a vertical course dorsal to the talus to a horizontal course beneath the talus (Fig. 42.5). This can cause tendon thickening and may result in 'triggering' of the tendon with loud and painful crepitation, as a consequence of partial tearing and

subsequent healing of the tendon with excessive scar tissue production.

### Clinical features

The clinical features of FHL tendinopathy are as follows.

- Pain is on toe-off or forefoot weight-bearing (e.g. rising in ballet), maximal over the posteromedial aspect of the medial malleolus and the calcaneus around the sustentaculum tali.
- Pain landing from jumps (key differentiator from posterior impingement syndrome)

**Figure 42.4** Eccentric exercises—tibialis posterior. Patient stands on the edge of a step and drops down into eversion, eccentrically contracting the tibialis posterior muscle

- Pain may be aggravated by resisted flexion (Fig. 42.2b) or passive stretch into full dorsiflexion of the hallux.
- Prominent crepitus in the sheath of flexor hallucis longus
- In more severe cases, there may be 'triggering' of the first toe, both with rising onto the ball of the foot (e.g. in ballet) and in lowering from this position. Triggering occurs when the foot is placed in plantarflexion and the athlete, unable to flex the hallux, is able to extend the interphalangeal or metatarsophalangeal joints of the toe with forcible active contraction of the FHL. A snap or pop (crepitus) occurs in the posteromedial aspect of the ankle when this happens. Subsequent passive flexion or extension of the interphalangeal joint produces a painless snap posterior to the medial malleolus.

### Investigations

MRI and ultrasound may both reveal pathology. However, the diagnosis is primarily based on clinical signs as the correlation between imaging findings and symptoms is often limited. The characteristic MRI sign (Fig. 42.6) in the case of tendon pathology, such as partial rupture, is abrupt fluid cut-off in the tendon sheath; excessive fluid is found located around a normal-appearing tendon proximal to the fibro-osseous canal.<sup>65</sup>

### Treatment

In the acute phase, treatment may include:<sup>65</sup>

- ice
- avoidance of activities that stress the flexor hallucis longus tendon (e.g. dancer working at the barre but not rising *en pointe*)
- flexor hallucis longus strengthening and stretching exercises

**Figure 42.5** Flexor hallucis longus tendinopathy showing the tendon irritated near the medial malleolus

- soft tissue therapy to the proximal muscle belly
- correction of subtalar joint and 1st MTP joint hypomobility with manual mobilisation and orthoses
- control of excessive pronation during toe-off with tape or orthoses—this may be helpful but is difficult to achieve in dancers.

### PRACTICE PEARL

To prevent recurrences of FHL tendinopathy, the dancer should focus on slightly reducing the amount of hip turnout thus ensuring that the weight is directly over the hip, avoiding hard floors, and using firm, well-fitting pointe shoes, so that the foot is well supported and no additional strain is placed on the tendon. Technique correction is important in ballet dancers as the tendinopathy arises not only from excessive ankle eversion or inversion with pointe work, but also from proximal weakness, such as poor trunk control.<sup>66</sup>

If symptoms persist after consultation with an expert ballet clinician, surgical treatment should be considered when persistent synovitis or triggering prevents dancing. Arthroscopic surgery involves exploration of the tendon and release of the tendon sheath with a posterior approach. The fibrous band around the tendon is cleaned off and the tendon released. Progressive return to ballet after such surgery takes in the order of 2–3 months.

### Tarsal tunnel syndrome

Tarsal tunnel syndrome occurs as a result of entrapment of the posterior tibial nerve in the tarsal tunnel where

**Figure 42.6** Flexor hallucis longus tendinopathy. Axial short tau inversion recovery (STIR) MRI demonstrates a large amount of fluid along the flexor hallucis longus at the level of the myotendinous junction (arrow)

the nerve winds around the medial malleolus.<sup>67</sup> It may also involve only one of its terminal branches distal to the tarsal tunnel. In such cases, the clinical presentation is pain in the medial part of the heel and sensory disturbance in the same region.

### Causes

In approximately 50% of cases, the cause of tarsal tunnel syndrome is idiopathic. It may also occur as a result of trauma (e.g. inversion injury to the ankle, direct blow to the ankle with significant bleeding) or overuse associated with excessive pronation. Other less common causes include:

- ganglion
- talonavicular coalition
- varicose veins
- synovial cyst
- lipoma
- accessory muscle—flexor digitorum accessorius longus
- tenosynovitis; often associated with arthritis (sero-negative rheumatoid arthritis)
- fracture of the distal tibia or calcaneus.

### Clinical features

The clinical features of tarsal tunnel syndrome are as follows.

- Poorly defined burning, tingling or numb sensation on the plantar aspect of the foot, often radiating into the toes.
- Pain is usually aggravated by activity and relieved by rest. The location of the pain can be diffuse and poorly defined.
- In some patients, the symptoms are worse in bed at night, and relieved by getting up and moving, or massaging the foot.
- Swellings, varicosities or thickenings may be found on examination around the medial ankle or heel.
- A ganglion or cyst may be palpable in the tendon sheaths around the medial ankle.
- Tenderness in the region of the tarsal tunnel is common.
- Tapping over the posterior tibial nerve (Tinel's sign) may elicit the patient's pain and very occasionally cause fasciculations; however, this 'classic' sign is not commonly seen.
- There may be altered sensation along the arch of the foot.
- The distribution of the sensory changes in the foot needs to be differentiated from the typical dermatomal distribution of S1 nerve root compression.

### Investigations

Nerve conduction studies should be performed.<sup>68, 69</sup> These not only help to confirm the diagnosis but they can also guide the surgeon as to the location of the nerve compression. However, it must be borne in mind that tarsal tunnel syndrome is primarily a clinical diagnosis and nerve conduction studies are negative in approximately 50% of patients. Ultrasound or MRI may be required to assess for a space-occupying lesion as a cause of the syndrome. A plain radiograph and, if required, a computed tomography (CT) scan should be performed in the case of excessive pronation or if a tarsal coalition is suspected.

### Differential diagnoses

Differential diagnoses include entrapment of the medial and/or lateral plantar nerves (or both), plantar fasciopathy, intervertebral disc degeneration and other causes of nerve inflammation or degeneration. The diagnosis of tarsal tunnel is often difficult and the symptoms and signs are often vague.<sup>70</sup> This is important to bear in mind, at least before deciding on surgical intervention.

### Treatment

Non-surgical treatment should be attempted in those with either an idiopathic or biomechanical cause. If neurodynamic tests prove positive, then appropriate

gliding treatments are indicated (Chapter 17). If excessive pronation is present, initially taping, and if successful an orthosis, may be required.

Surgical decompression of the posterior tibial nerve and its branches may be indicated in selected cases, but only after both the diagnosis and site of nerve entrapment have been confirmed.

#### PRACTICE PEARL

Surgery should be reserved as the last resort, if all other treatment fails, symptoms are severe and the clinician is confident of mechanical pressure on the nerve. Results of surgery have not been encouraging,<sup>71</sup> with a high perioperative complication rate.<sup>72</sup>

### Medial malleolar stress fracture

Medial malleolar stress fractures are rare, but should be considered in runners or footballers presenting with persistent medial ankle pain aggravated by activity.<sup>73</sup> Although the fracture line is frequently vertical from the junction of the tibial plafond and the medial malleolus, it may arch obliquely from the junction to the distal tibial metaphysis.

#### Clinical features

Athletes with medial malleolus stress fractures typically present with anterior and medial ankle pain that progressively increases with running and jumping activities. The onset of pain may be acute or gradual. Examination reveals tenderness overlying the medial malleolus, frequently in conjunction with a mild ankle effusion.

#### Investigations

In the early stages, X-rays may be normal, but with time a linear area of hyperlucency may be apparent, progressing to a lytic area and fracture line (Fig. 42.7a). If the X-ray is normal, an MRI is recommended (Fig. 42.7b).

#### Treatment

For most fractures 4–6 weeks NWB in a CAM boot is required. Following fracture healing, the practitioner should assess biomechanics and footwear. A graduated return to activity follows and usually takes around 12 weeks.<sup>74</sup> In the case of complete fracture, surgical intervention with internal screw fixation (percutaneous screw fixation) followed by immobilisation in plaster for 3 weeks and air-cast for a further 3 weeks is advisable. A recent systematic review showed that non-operative and

(a)

(b)

**Figure 42.7** Medial malleolar stress fracture (a) X-ray showing sclerotic line (arrow) through medial malleolus indicating a stress fracture (b) MRI. Fat suppressed T2-weighted image showing bright T2 signal (arrow) at the site of the stress fracture

operative interventions have proven to be successful with regard to healing and return to play for medial malleolar stress fractures in the recreational and competitive athlete.<sup>75</sup> However, early operative intervention can possibly create a higher likelihood of early healing, decrease in symptoms, and return to play.

### Medial calcaneal nerve entrapment

The medial calcaneal nerve is a branch of the posterior tibial nerve arising at the level of the medial malleolus or below, and passing superficially to innervate the skin of the heel. Occasionally it may arise from the lateral plantar

nerve, a branch of the posterior tibial nerve. It has been theorised that a valgus hindfoot may predispose joggers to compression of this nerve branch. This nerve entrapment is often termed 'Baxter's nerve' (see Chapter 43).

### Clinical features

Entrapment or irritation of the nerve causes burning pain over the infero-medial aspect of the calcaneus, which often radiates into the arch of the foot, and is aggravated by running. Examination reveals tenderness over the medial calcaneus and a positive Tinel's sign. There is frequently associated excessive pronation of the hindfoot.

### Investigations

The diagnosis may be difficult to establish. Nerve conduction studies can be helpful, and injection of local anaesthetic at the point of maximal tenderness with a resultant disappearance of pain will help confirm the diagnosis.

### Treatment

Treatment involves minimising the trauma to the nerve with a change of footwear or the use of a pad over the area to protect the nerve. If this is not successful, injection of corticosteroid and local anaesthetic into the area of point tenderness may be helpful. If this fails to settle, other treatment options include radiofrequency denervation (RFD) of the nerve and surgical decompression.<sup>76</sup>

### Other causes of medial ankle pain

Two conditions that generally cause foot pain, but may present as medial ankle pain, are stress fractures of the calcaneus and the navicular bone (Chapter 43). Referred pain from neural structures may occasionally present as medial ankle pain. Entrapment of the medial plantar nerve (Chapter 43) generally causes midfoot pain, but may present as medial ankle pain.

## LATERAL ANKLE PAIN

Non-traumatic lateral ankle pain is generally associated with a biomechanical abnormality. The two most common diagnoses are peroneal tendinopathy and sinus tarsi syndrome. The causes of lateral ankle pain are listed in Table 42.3. The anatomy of the region is illustrated in Figure 42.8.

### Examination

Examination is as for the patient with acute ankle injury (Chapter 41) with particular attention to testing resisted eversion of the peroneal tendons (Fig. 42.9a) and careful palpation for tenderness, swelling and crepitus (Fig. 42.9b).

## Peroneal tendinopathy

The most common overuse injury causing lateral ankle pain is peroneus brevis tendinopathy. The peroneus longus and peroneus brevis tendons cross the ankle joint within a fibro-osseous tunnel, posterior to the lateral malleolus (Fig. 42.8a). The peroneus brevis tendon inserts into the tuberosity on the lateral aspect of the base of the fifth metatarsal. The peroneus longus tendon passes under the plantar surface of the foot to insert into the lateral side of the base of the first metatarsal and medial cuneiform. The peroneal tendons share a common tendon sheath proximal to the distal tip of the fibula, after which they have their own tendon sheaths. The peroneal muscles serve as ankle dorsiflexors in addition to being the primary evertors of the ankle.

### Causes

Peroneal tendinopathy may occur either as a result of acute or recurrent ankle inversion injuries, or as an overuse injury. Soft footwear may predispose to the development of peroneal tendinopathy.

Common causes of an overuse injury to the peroneal tendons include:

- excessive eversion of the foot, such as occurs when running on a cambered surface<sup>77</sup>
- excessive pronation of the foot
- secondary to tight ankle plantarflexors (most commonly soleus) resulting in excessive load on the lateral muscles
- excessive loading of the peroneals (e.g. dancing, basketball, volleyball).

An inflammatory arthropathy may promote peroneal tenosynovitis and subsequent peroneal tendinopathy. Peroneal tendinopathy may also be due to the excessive pulley action and abrupt change in direction of the peroneal tendons at the lateral malleolus. In some cases, peroneal tendinopathy is correlated with peroneal tendon instability in the retromalleolar groove of the lateral malleolus.

There are three main sites of peroneal tendinopathy:

1. posterior to the lateral malleolus (most common)
2. at the peroneal trochlea
3. at the plantar surface of the cuboid.

### Clinical features

The athlete commonly presents with:

- lateral ankle or heel pain which is aggravated by activity and relieved by rest
- local tenderness of the peroneal tendons, sometimes associated with swelling and crepitus (a true paratenonitis)

**Table 42.3** Causes of lateral ankle pain

Common	Less common	Not to be missed
Peroneal tendinopathy Sinus tarsi syndrome	Impingement syndrome <ul style="list-style-type: none"> <li>• Anterolateral</li> <li>• Posterior</li> </ul> Recurrent subluxation/dislocation of peroneal tendons Stress fracture of the talus Referred pain <ul style="list-style-type: none"> <li>• Lumbar spine</li> <li>• Peroneal nerve</li> <li>• Superior tibiofibular joint</li> </ul>	Stress fracture of the distal fibula Cuboid syndrome Complex regional pain syndrome type 1 (following knee or ankle trauma)

**(a)****(b)****Figure 42.8** Lateral aspect of the ankle (a) Anatomy of the lateral ankle (b) Sinus tarsi**(a)****(b)****Figure 42.9** Examination of the patient with lateral ankle pain (a) Resisted movement—eversion (peroneal muscles) (b) Palpation—the peroneal tendons are palpated for tenderness and crepitus

- painful passive inversion and resisted eversion, although in some cases eccentric contraction may be required to reproduce the pain
- calf muscle tightness
- excessive subtalar pronation or stiffness of the subtalar or midtarsal joints that is demonstrated on biomechanical examination.

### Investigations

MRI is the recommended investigation and shows characteristic features of tendinopathy—increased signal and tendon thickening (Fig. 42.10)—and may show longitudinal tears.<sup>78</sup> If MRI is unavailable, ultrasound provides similarly good results. If an underlying inflammatory arthropathy is suspected, blood tests should be obtained to assess for rheumatological and inflammatory markers.

**Figure 42.10** Peroneal tendinopathy. MRI showing oedema around the peroneus longus (bracket) and peroneus brevis (arrowheads)

### Treatment

Treatment initially involves:

- rest from weight-bearing and loading activities; the use of a controlled ankle motion (CAM) boot may be required
- if a reactive tendinopathy is present, NSAIDs and regular icing
- soft tissue therapy to the peroneal muscles
- mobilisation of the ankle, subtalar and midtarsal joints
- footwear assessment: the use of lateral heel wedges or orthoses may also be required to correct biomechanical abnormalities
- strengthening exercises: should be introduced once the pain and inflammation has settled and should include resisted eversion (e.g. rubber tubing, rotagym), especially in plantarflexion as this position maximally engages the peroneal muscles.

PRP injections may be considered as an adjunct to a comprehensive rehabilitation program; however, there is currently little supporting evidence. In severe cases, or with failure of conservative management, surgery may be required, which may involve a synovectomy, tendon debridement, or repair of the tendon in case of longitudinal rupture.<sup>79</sup> If peroneal tendinopathy is associated with tendon instability, ligament reconstruction should address the instability of the tendon at the same time as the tendon is repaired.

### Sinus tarsi syndrome

The sinus tarsi (Fig. 42.8b) is a small osseous canal running from an opening anterior and inferior to the lateral malleolus in a posteromedial direction to a point posterior to the medial malleolus. The interosseous ligament occupies the sinus tarsi and divides it into an anterior portion, which is part of the talocalcaneonavicular joint, and a posterior part, which represents the subtalar joint. It is lined by a synovial membrane and in addition to the ligament it contains small blood vessels, fat and connective tissue.

The sinus tarsi contains abundant synovial tissue that is prone to synovitis and inflammation when injured. An influx of inflammatory cells may result in the development of a low-grade and long-standing inflammatory synovitis. Although injury to the sinus tarsi may result from chronic overuse secondary to poor biomechanics (especially excessive pronation), approximately 70% of all patients with sinus tarsi syndrome have had a single or repeated inversion injury to the ankle. It may also occur after repeated forced eversion to the ankle, such as high jump take off. Other causes of sinus tarsi syndrome may include chronic inflammation in conditions such as gout, inflammatory arthropathies and osteoarthritis.

### Clinical features

The symptoms of sinus tarsi syndrome include:

- pain which may be poorly localised and vague but is most often centred just anterior to the lateral malleolus
- pain that is often more severe in the morning and may diminish with exercise
- pain that may be exacerbated by running on a curve in the direction of the affected ankle; the patient may also complain of ankle and foot stiffness, a feeling of instability of the hindfoot and occasionally of weakness
- difficulty—often marked—walking on uneven ground
- full range of pain-free ankle movement on examination but the subtalar joint may be stiff
- pain on forced passive eversion of the subtalar joint; forced passive inversion may also be painful due to damage to the subtalar ligaments
- tenderness of the lateral aspect of the ankle at the opening of the sinus tarsi and occasionally also over the anterior talofibular ligament; there may be minor localised swelling.

### Investigations

MRI may show an increased signal and fluid in the sinus tarsi, but is not often helpful. The most appropriate diagnostic test is injection of 1 mL of a short-acting local anaesthetic agent (e.g. 1% lignocaine [lidocaine]) into the sinus tarsi; ideally this should be done using fluoroscopy to ensure correct location (Fig. 42.11). In

**Figure 42.11** Diagnostic local anaesthetic injection under fluoroscopic guidance. The needle is introduced into the lateral opening of the sinus tarsi with the foot in passive inversion. The needle should be directed medially and slightly posteriorly. Corticosteroid can be added if treatment required

**Figure 42.12** Mobilisation of the subtalar joint is performed by medial-to-lateral transverse glide of the calcaneus on the talus

sinus tarsi syndrome, this injection will relieve pain so that functional tests, such as hopping on the affected leg, can be performed comfortably (for diagnosis). An ankle radiograph may be performed to exclude degenerative changes of the subtalar joint.

### Treatment

Surgery is rarely indicated. Non-surgical management includes:

- relative rest
- short-term use of NSAIDs and ice
- mobilisation of the subtalar joint; this is essential (Fig. 42.12)
- direct infiltration of the sinus tarsi with corticosteroid (Fig. 42.11)
- correction of footwear and biomechanics
- proprioception and strength training.

### Anterolateral impingement

Repeated minor ankle sprains or a major sprain involving the anterolateral aspect of the ankle may cause anterolateral impingement. An inversion sprain to the anterior talofibular ligament may promote synovial thickening. Usually this is subsequently resorbed, but sometimes this is incomplete and the residual tissue becomes hyalinised and moulded by pressure from the articular surfaces of the lateral aspect of the talus and lateral malleolus, where it may be trapped during ankle movements. A meniscoid lesion thus develops in the anterolateral gutter. Another postulated cause of anterolateral ankle impingement is chondromalacia of the lateral wall of the talus with an associated synovial reaction.

### Clinical features

The classic presentation is pain at the anterior aspect of the lateral malleolus and an intermittent catching sensation in the ankle in an athlete with a previous history of ankle inversion injuries.

Examination may reveal tenderness in the region of the anteroinferior border of the fibula and anterolateral surface of the talus. End-range dorsiflexion, such as in a lunge position, is often reduced and painful. Proprioception may be poor.<sup>80</sup>

### Investigations

Clinical assessment is more reliable than MRI to diagnose this lesion.<sup>81</sup> An arthroscopic examination confirms the diagnosis.

### Treatment

In milder cases corticosteroid injection into the anterolateral gutter combined with physiotherapy and correction of biomechanics may be helpful. In more severe cases arthroscopic removal of the fibrotic, meniscoid lesion is required. Results after arthroscopic removal of the impinged tissue are encouraging and soccer players often return to sport after a short period (3–4 weeks) of rehabilitation. Surprisingly for a condition that limits dorsiflexion, it takes ballet dancers about 3 months to regain full pointe position (plantarflexion) after this operation.

### Posterior impingement syndrome

Posterior impingement syndrome sometimes presents as lateral ankle pain, but more commonly as pain in the posterior ankle (Chapter 40).

### Stress fracture of the talus

Stress fractures of the posterolateral aspect of the talus have been described in track and field athletes, triathletes, Australian rules footballers,<sup>82</sup> elite female gymnasts<sup>83</sup> and a soccer player.<sup>84</sup>

### Causes

These stress fractures may develop secondary to excessive subtalar pronation and plantarflexion, resulting in impingement of the lateral process of the calcaneus on the posterolateral corner of the talus. In pole vaulters, this injury is usually acute and is attributed to 'planting' the pole too late.

### Clinical features

The main symptom is that of lateral ankle pain of gradual onset, made worse by running and weight-bearing. Clinical

**Figure 42.13** Stress fracture of the talus (arrowheads) demonstrated by coronal CT scan

examination reveals marked tenderness and occasionally swelling in the region of the sinus tarsi or posterior aspect of the ankle.

### Investigations

Typical CT scan appearance is shown in Figure 42.13. MRI will also reveal the fracture, with the STIR sequence being most helpful (see Chapter 15).

### Treatment

Treatment requires 6–8 weeks non weight-bearing immobilisation and then a supervised graduated rehabilitation. In elite athletes, when a rapid recovery is required, or in the case of failure of non-surgical management, surgical removal of the lateral process has been performed.

#### PRACTICE PEARL

As talar stress fractures are frequently associated with excessive pronation, biomechanical correction with orthoses is required before activity is resumed.

### Referred pain

A variation of the slump test (Chapter 15) with the ankle in plantarflexion and inversion can be performed to detect increased mechanosensitivity in the peroneal nerve. If the test is positive, this position can be used as a glide or stretch in addition to soft tissue therapy to possible areas of restriction (e.g. around the head of the fibula).

## ANTERIOR ANKLE PAIN

Pain over the anterior aspect of the ankle joint without a history of acute injury is usually due to either tibialis anterior tendinopathy or anterior impingement of the ankle. The surface anatomy of the anterior ankle is shown in Figure 42.14.

### Anterior impingement of the ankle

Anterior impingement of the ankle joint (anterior tibiotalar impingement) is a condition in which additional soft or bony tissue is trapped between the tibia and talus during dorsiflexion. This may be the cause of chronic ankle pain or may result in pain and disability persisting after an ankle sprain. Although this syndrome has been called 'footballer's ankle', it is also seen commonly in basketballers and ballet dancers.

Anterior impingement occurs secondary to the development of exostoses (bone spurs) on the anterior rim of the tibia and on the upper anterior surface of the neck of talus (Fig. 42.15). The exostoses were initially described in ballet dancers and thought to be secondary

**Figure 42.14** Surface anatomy of the anterior ankle showing tendons

**Figure 42.15** X-ray showing bony exostosis on the anterior talus

to a traction injury of the joint capsule of the ankle that occurs whenever the foot was repeatedly forced into extreme plantarflexion. Subsequently, the development of the exostoses has been attributed to direct osseous impingement during extremes of dorsiflexion, as occurs with kicking in football and the *plié* (lunge) in ballet. As these exostoses become larger, they impinge on overlying soft tissue and cause pain.

Ligamentous injury and instability following ankle inversion injuries may also result in anterior ankle impingement; it has been shown that the distal fascicle of the anterior inferior tibiofibular ligament may impinge on the anterolateral aspect of the talus.<sup>85</sup>

### Clinical features

The patient complains of:

- anterior ankle pain, which initially starts as a vague discomfort
- pain ultimately becomes sharper and more localised to the anterior aspect of the ankle and foot, especially on dorsiflexion of the foot
- pain that is worse with activity, particularly with running, descending *plié* (lunge) in classical ballet, kicking in football or other activities involving dorsiflexion.

As the impingement develops, the patient complains of ankle stiffness, a limitation of *plié*, and in athletes a loss of take-off speed.

Examination reveals tenderness along the anterior margin of the talocrural joint. If the exostoses are

(a)

(b)

**Figure 42.16** The anterior impingement test (a) The patient lunges forwards maximally and, if this reproduces the pain, the test is positive and suggests the diagnosis of anterior impingement (b) The same position is used to take a lateral X-ray. A positive test reveals bone-on-bone impingement (arrowed) when the patient adopts the lunge position that reproduces pain

large, they may occasionally be palpable. Dorsiflexion of the ankle is restricted and painful. The anterior impingement test (Fig. 42.16a), where the patient lunges forwards maximally with the heel remaining on the floor, reproduces the pain.

### Investigations

Lateral X-rays in flexion and extension show both exostoses and abnormal tibiotalar contact. Ideally performed weight-bearing in the lunge position, bone-on-bone impingement confirms the diagnosis (Fig. 42.16b).

### Treatment

In milder cases, non-surgical treatment consists of a heel lift, rest, modification of activities to limit dorsiflexion, NSAIDs and manual therapy, including accessory anteroposterior glides of the talocrural joint at the end of range of dorsiflexion. Taping or orthoses may help control the pain if they restrict ankle dorsiflexion or improve joint instability, which has been shown to contribute to the development of anterior impingement.<sup>86</sup>

More prominent exostoses may require arthroscopic removal. The clinical results after arthroscopic removal are encouraging, and the majority of patients become pain-free with increased range of ankle motion.<sup>87-89</sup>

### Tibialis anterior tendinopathy

The tibialis anterior tendon is the primary dorsiflexor of the foot, in addition to adducting and supinating (inverting) the foot. It passes medially over the anterior ankle joint and runs to insert into the medial and plantar aspects of the medial cuneiform bone and the adjacent base of the first metatarsal.

### Causes

Tendinopathy of the tibialis anterior may result from overuse of the ankle dorsiflexors secondary to restriction in joint range of motion, as may occur with a stiff ankle. It may also be due to downhill running, playing racquet sports involving constant change of direction, or with excessive tightness of strapping or shoelaces over the tibialis anterior tendon.

### Clinical features

The main symptoms are pain, swelling and stiffness in the anterior ankle. These symptoms are aggravated by activity, especially running, and walking up hills or stairs. On examination, there is localised tenderness, swelling and occasionally crepitus along the tibialis anterior tendon, especially over the anterior joint line. There is pain on resisted dorsiflexion and eccentric inversion. Long-standing and non-treated tendinopathy may eventually lead to partial or even total rupture of the tendon (under the extensor retinaculum).

### Investigations

Ultrasound or MRI may be used to confirm the diagnosis and assess the severity of the tenosynovitis/tendinopathy.

### Treatment

Treatment involves:

- rest from weight-bearing and loading activities
- the use of a CAM boot, if required

- if reactive tendinopathy present, NSAIDs and regular icing in the short term
- soft tissue therapy focusing on the tibialis anterior muscle in conjunction with ankle and subtalar joint mobilisation
- reducing running stride length; taking shorter steps decreases the functional length of the tibialis anterior and subsequently reduces the pull of the muscle on the tibia
- correction of biomechanics with the use of footwear and orthoses, if required

- eccentric strengthening and proprioception, required once the pain has settled.

In case of partial or total rupture, surgical reconstruction may be required.

### **Anterior inferior tibiofibular ligament (AITFL) injury**

This injury is discussed in Chapter 41 because it results from an acute ankle injury (and often a fracture). If missed, it will present as persistent pain and loss of function after an ankle sprain.

# Foot pain

with KARL LANDORF, STEPHEN SIMONS, CHRISTOPHER JORDAN and  
MICHAEL RATHLEFF

*Plantar fasciitis sucks. It feels like you have needles underneath your feet while you're playing.*

Joakim Noah, NBA Chicago Bulls, 2013

Injuries to the foot, both acute and chronic, can be extremely challenging for the clinician, largely due to the complex anatomy (Figs 43.1 and 43.2). If the foot is considered in its three distinct regions (Fig. 43.1)—the rearfoot (calcaneus and talus), the midfoot (the navicular proximally and medially, the cuboid laterally, and the cuneiforms distally and medially), and the forefoot (the metatarsals and phalanges)—the bony anatomy is greatly simplified. Soft tissue anatomy can then be superimposed on the regional division of the foot (Figs 43.2c-e).

In this chapter we will consider the three different clinical presentations:

- rearfoot pain (mainly the heel)
- midfoot pain
- forefoot pain.

### REARFOOT PAIN

The most common cause of rearfoot (inferior heel) pain is plantar fasciopathy/fasciitis, often mistakenly referred

to as 'heel spur'. This condition occurs mainly in runners and the older adults, and may be associated with a biomechanical abnormality, such as excessive pronation or supination.<sup>1</sup> Another common cause of heel pain is fat pad syndrome or fat pad contusion. This is also known as a 'bruised heel' or a 'stone bruise'.

Less common causes of heel pain are stress fracture of the calcaneus and conditions that refer pain to this area such as tarsal tunnel syndrome or medial calcaneal nerve entrapment (Chapter 42). Causes of rearfoot pain are listed in Table 43.1.

### History

The pain of plantar fasciopathy is usually of insidious onset, whereas fat pad damage may occur either as a result of a single traumatic episode (e.g. jumping from a height onto the heel) or from repeated heel strike (e.g. on hard surfaces with inadequate heel support). Plantar fasciopathy pain is typically worse in the morning, improves with exercise at first and is aggravated by standing.

**Table 43.1 Causes of rearfoot and inferior heel pain**

Common	Less common	Not to be missed
Plantar fasciopathy (fasciitis) Fat pad contusion	Calcaneal stress fracture Medial calcaneal nerve entrapment (Chapter 42) Lateral plantar nerve (Baxter's nerve) entrapment Tarsal tunnel syndrome (Chapter 42) Talar stress fracture (Chapter 42) Retrocalcaneal bursitis (Chapter 40)	Spondyloarthropathies Osteoid osteoma Complex regional pain syndrome type 1 (after knee or ankle injury)

## Examination

Examination of the rearfoot is shown in Figure 43.3. The windlass (or Jack's) test (passive dorsiflexion of the first metatarsophalangeal joint that provokes pain) is a quick and highly specific test for the plantar fascia (Fig. 43.3c).<sup>2</sup>

Biomechanical assessment is an important component of the examination and should include ankle, subtalar and

midtarsal joint range of motion. Also assess function of the forefoot and first metatarsophalangeal (MTP) joint range of motion. Examine footwear, looking for asymmetrical wear of the sole which may indicate differences in function between left and right sides.

## Investigations

Radiographs only contribute to the clinical work-up of rearfoot pain in a small proportion of cases. It may reveal a calcaneal spur which is associated with increased risk of heel pain. Plain radiograph is generally normal in stress

**(a)****(b)**

**Figure 43.3** Examination of the rearfoot (a) Palpation—medial process of calcaneal tuberosity. Palpate plantar fascia attachment (b) Palpation—heel fat pad

**(c)**

**Figure 43.3 (cont.)** (c) The windlass (or Jack's) test—passive dorsiflexion of the first metatarsophalangeal joint

fractures of the calcaneus, but if the injury has been present for many weeks, there may be a line of sclerosis (increased opacity).

Magnetic resonance imaging (MRI) is the investigation of choice for stress fracture. MRI and ultrasound can each confirm the presence of plantar fasciopathy. MRI reveals increased signal intensity and thickening at the attachment of the plantar fascia to the calcaneus at the medial calcaneal tuberosity, often with oedema in the

adjacent bone. Ultrasound reveals a characteristic region of hypoechogenicity.

### Patient-reported outcome measures

There are a number of patient-reported outcome measures (PROMs) which are relevant for patients with foot pain. Combined Foot and Ankle PROMs have been described in Chapter 42. The foot specific PROMs are shown in Table 43.2.

**Table 43.2 Patient-reported outcome measures for the foot**

#### Foot Function Index (FFI)

- Self-administered questionnaire evaluating pain, disability and activity restrictions
- 23 items (9 on pain, 9 on disability and 5 on activity limitation)
- Score range 0–100 for all subscales (100 = maximal impairment)<sup>3</sup>
- Test-retest reliability:
  - Total score, ICC = 0.87<sup>3</sup>
  - Pain subscale, ICC = 0.70<sup>3</sup>
  - Disability subscale, ICC = 0.84<sup>3</sup>
  - Activity limitation subscale, ICC = 0.81<sup>3</sup>
- Construct validity:
  - Pain subscale: SF-36: bodily pain subscale: –0.61; physical component summary scale: –0.45<sup>4</sup>
  - Disability subscale: SF-36: physical component summary scale: –0.67; physical functioning: –0.69; role-physical: –0.62; bodily pain: –0.64<sup>4</sup>
  - Activity limitation subscale: physical component summary scale: –0.53; physical functioning: –0.55; role-physical: –0.64; social functioning: –0.57<sup>4</sup>
  - Total score: SD-36; physical component summary scale: –0.64;<sup>5</sup> AOFAS, Hallux Metatarsophalangeal-Interphalangeal Scale: –0.81
- Developed and validated in American English<sup>3</sup> and there is a revised-FFI version available with 34 items<sup>6</sup>
- The original FFI was cross-culturally validated to Danish,<sup>7</sup> French,<sup>8</sup> German,<sup>9</sup> Italian,<sup>10, 11</sup> Korean,<sup>12</sup> Spanish<sup>13</sup> and Taiwan Chinese<sup>14</sup>

#### Rowan Foot Pain Assessment Questionnaire

- Self-administered questionnaire evaluating pain in sensory, affective and cognitive dimensions
- 36 items (16 on the sensory, 10 on the affective and 10 on the cognitive dimension)
- Score ranges from 0–5 for each subscale
- Test-retest reliability:
  - Sensory subscale: Spearman's  $\rho = 0.88^{15}$
  - Affective subscale: Spearman's  $\rho = 0.93^{15}$
  - Cognitive subscale: Spearman's  $\rho = 0.82^{15}$
- Construct validity:
  - Sensory subscale: FFI<sub>pain</sub> = 0.88<sup>15</sup>
  - Affective subscale: FFI<sub>pain</sub> = 0.69<sup>15</sup>
  - Cognitive subscale: FFI<sub>pain</sub> = 0.70<sup>15</sup>
- Developed and validated in English

#### Rowan Foot Pain Assessment Questionnaire

- Self-administered questionnaire evaluating foot pain, foot function, footwear and general foot health
- 13 items (4 items on foot pain, 4 items on foot function, 3 items on footwear, 2 items on general foot health)
- Score range 0–100 (100 = no health problem)

- Test-retest reliability:
  - Foot pain: ICC = 0.86
  - Foot function: ICC = 0.92
  - Footwear: ICC = 0.74
  - General foot health: ICC = 0.78
- MCID:
  - Foot pain: 13<sup>16</sup>
  - Foot function: 7<sup>16</sup>
  - Footwear: 2<sup>16</sup>
  - General foot health: 0<sup>16</sup>
- Developed and validated<sup>17</sup> in Australian English; cross-culturally validated to Brazilian Portuguese<sup>18</sup> and Spanish<sup>19</sup>

#### Rewan Foot Pain Assessment Questionnaire

- Self-administered questionnaire evaluating walking, hygiene, nail care, foot pain, worry/concern QoL and general foot status
- 6 items + 1 visual analogue scale (VAS) regarding foot status
- 6 items score range: VAS Score range 0–100 (100 = best possible foot health)
- Construct validity:
  - Walking: EQ-5D<sup>mobility</sup>: 0.54; EQ-5D<sup>usual activities</sup>: 0.45; EQ-5D<sup>pain/discomfort</sup>: 0.49<sup>20</sup>
  - Hygiene: EQ-5D<sup>self-care</sup>: 0.58<sup>20</sup>
  - Nail care: EQ-5D<sup>self-care</sup>: 0.37<sup>20</sup>
  - Foot pain: EQ-5D<sup>pain/discomfort</sup>: 0.40<sup>20</sup>
  - Worry/concern: EQ-5D<sup>anxiety/depression</sup>: 0.21<sup>20</sup>
  - Quality of life: EQ-5D<sup>mobility</sup>: 0.54, EQ-5D<sup>usual activities</sup>: 0.34<sup>20</sup>
- Developed and validated in British English

### Plantar fasciopathy (formerly called ‘plantar fasciitis’)

Plantar fasciopathy (also known as plantar heel pain or plantar fasciitis/fasciosis) is an overuse condition of the plantar fascia at its attachment to the calcaneus.

#### PRACTICE PEARL

The histology is of degenerative changes at the plantar fascia enthesis, including a deterioration of collagen fibres, increased secretion of ground substance proteins, focal areas of fibroblast proliferation and increased vascularity.<sup>21–23</sup>

The plantar fascia consists of type 1 collagen and has common tendinopathy traits, hence we recommend using the term ‘fasciopathy’ rather than the former ‘plantar fasciitis’. Plantar fasciopathy is the most common cause of plantar heel pain, which has an estimated prevalence of 4–7%.<sup>24, 25</sup> It commonly affects very physically active people (e.g. runners) or people with high amounts of standing occupational work (who may also have a high BMI). Through this section we try to differentiate between the two groups and discuss how treatment strategies might be tailored to each overarching group.

### Risk factors

Only one true prospective study has investigated risk factors for plantar fasciopathy. The study was conducted in a cohort of 166 runners followed over 5 years.<sup>26, 27</sup> The study found the overall incidence of plantar fasciopathy over the 5-year period to be 31%. Four risk factors that were significantly associated with an increased risk of plantar fasciopathy: varus knee alignment (OR 5.63); use of spiked athletic shoes (OR 5.49); cavus foot posture (OR 5.52); and greater number of days of practice per week (OR 2.59). High BMI was not a risk factor for developing plantar fasciopathy in this cohort of runners with low BMIs. This suggests that high training volumes that increase load or vertical force on the plantar fascia may increase a runner’s risk of plantar fasciopathy which fits well with the belief that it is an overuse type injury.

### Weight and BMI

One of the most common findings is that patients with plantar fasciopathy have a high BMI, although many of the studies that contribute to this evidence are cross-sectional.<sup>27</sup> Increased mechanical load due to higher BMI is a plausible source of increased plantar fascial stress. However, an important point is that high BMI was not a risk factor in the study in runners,<sup>26</sup> which may suggest that a high BMI increases risk in more sedentary people and in people with occupational work that requires many hours of standing, particularly on harder surfaces.

### Alignment of the foot

Cross-sectional studies that have investigated the association between foot type and plantar fasciopathy provide conflicting evidence.<sup>27</sup> One prospective study found that runners with a cavus foot have a higher risk of plantar fasciopathy, but cross-sectional research fails to identify a strong link between foot type and plantar fasciopathy.<sup>26</sup> It may be that in some patient types (e.g. those with standing work and high BMI), foot type is important. Nevertheless, a recent systematic review found that overall, the evidence supporting associations for foot and ankle range of motion and strength, kinematic and kinetic factors, and foot posture was either inconsistent or inconclusive.<sup>27</sup>

### Training volume

Plantar fasciopathy in the younger, athletic population is associated with activities that cause a dose-dependent repetitive stress to the plantar fascia, such as running.<sup>26, 28</sup> Accordingly, one of the most important management strategies in these cases may be to adjust training volume and educate the patient with plantar fasciopathy to adjust training load for a period.

### Standing work

People who spend the majority of their work day on hard surfaces and on their feet may be at higher risk for developing plantar fasciopathy.<sup>27</sup> This has only been shown in cross-sectional data, but it fits well with the proposition that high mechanical loads may increase an individual's risk of developing plantar fasciopathy. This may have implications for occupational interventions (more in the section on treatment).

### Flexibility and strength

Plantar fasciopathy may be associated with decreased flexibility of the ankle joint and hamstrings, as well as decreased plantar flexion peak torque. Likewise, patients with plantar fasciopathy may have significantly lower toe flexor strength. It is unknown if this is a cause or an effect of longstanding plantar fasciopathy.<sup>27</sup> However, these findings may be important as treatment may need to address these strength and flexibility deficits.

Plantar fasciopathy may be associated with tightness in the proximal myofascial structures, especially the calf, hamstring and gluteal regions. Tightness in these muscle groups can alter foot biomechanics.<sup>29</sup>

### Clinical features

The pain related to plantar fasciopathy is usually of gradual onset and felt classically on the inferior medial aspect of the heel. Initially, it is worse in the morning when getting out of bed (referred to as 'first-step pain') and decreases

with activity, only to return with an ache post-activity. Periods of inactivity during the day are generally followed by an increase in pain as activity is recommenced. As the condition becomes more severe, the pain may be present when standing and worsen with activity. Some patients may also experience atypical pain when non weight-bearing, for example, when they go to bed at night.

Examination reveals pain or tenderness along the medial tuberosity of the calcaneus, and this may extend some centimetres along the medial and central components of the plantar fascia. Stretching the plantar fascia via dorsiflexion of the hallux, such as during the windlass test, may reproduce pain and may assist with palpation of the plantar fascia (Fig. 43.3c).

### Investigations

If the patient has the classic history and examination findings, and there is no other suggestion of a 'red flag' (Chapter 7 and Table 43.1), then medical imaging or other investigations are not indicated. Further investigation is recommended however, if pain is particularly persistent without responding to treatment (e.g. >1 month, raising suspicion of other pathologies; Table 43.1) or if the nature of the pain is atypical for plantar fasciopathy (acute onset of pain, persistent pain even at rest, systemic symptoms, night pain). Blood tests may be warranted to rule out inflammatory arthritis, which can cause symptoms in the heels, although frequently symptoms will be more widespread. The primary imaging modalities that are useful include plain radiographs, ultrasound and MRI.

Plain radiographs, primarily the lateral view (Fig. 43.4a) are mainly used to investigate for the presence of a plantar calcaneal spur. The radiograph appearance of 'calcaneal spur' is eight times more likely in patients with plantar fasciopathy compared to those without plantar fasciopathy.<sup>30</sup> However, calcaneal spurs are also common in people without heel pain, and the presence of a spur does not indicate that this is the cause of pain. Plain radiographs of both feet are useful as they may show spurs bilaterally and allow comparison between feet in the situation of unilateral symptoms. Fractured spurs have also been reported, and although the findings may be subtle, plain radiographs can be used in the first instance to investigate whether a spur has, indeed, fractured.<sup>31</sup> Lastly, plain radiographs can be used to rule out other bone pathology (e.g. bone cysts).

Ultrasound is particularly useful for detecting pathological changes within the plantar fascia itself. Ultrasound may reveal thickening, hypoechogenicity and heterogeneity, delamination and tears (Fig. 43.4b). A systematic review and meta-analysis found that patients with plantar fasciopathy are 105 times more likely to have a fascia greater than 4.0 mm thick and 204 times

more likely to have hypoechogenicity compared to controls without fasciopathy.<sup>30</sup> Ultrasound can also be used to assess for other soft tissue pathologies associated with plantar fasciopathy, such as tissue change within the plantar fat pad, myopathies (e.g. of the deeper intrinsic musculature) and neuroma (e.g. of the medial calcaneal nerve).

MRI is the investigation of choice if there are atypical symptoms and if a wider selection of tissues (e.g. bone) are of interest. Similar to ultrasound, MRI will detect thickening of the plantar fascia, as well as heterogeneity, delamination and tears (Fig. 43.4c). MRI signs of plantar fasciopathy include hyperintensity within and around the plantar fascia, and delamination and tears within the plantar fascia. MRI is also useful for determining acute versus more chronic pathological change via the intensity of the signal on sagittal fat-suppressed short tau inversion recovery (STIR)/T2 images (lower signal signifying more chronic pathology). In addition, there is some evidence to suggest that a subsection of patients with plantar

fasciopathy have bone marrow oedema on MRI, and this may be associated with atypical symptoms such as night pain.<sup>32</sup> MRI can also identify stress fractures of the calcaneus. Finally, MRI is particularly useful for detecting other soft tissue pathologies that may be associated with a painful heel, including soft tissue tumours, medial tendinopathy and plantar fat pad pathology.

### Treatment

Treatment is often multi-faceted and generally starts with conservative interventions, progressing to more invasive interventions if conservative care fails to improve the condition. Treatment can be thought of in terms of three

(a)

(b)

(c)

**Figure 43.4** (a) Lateral plain radiograph highlighting a large plantar calcaneal spur (b) Ultrasound scan highlighting a thickened plantar fascia (0.902 cm), heterogeneity and hypoechogenicity within the plantar fascia (deep hypoechogenicity representative of a tear within the fascia) (c) MRI of plantar fasciopathy. Sagittal fat-suppressed T2-weighted MRI demonstrates thickening of the plantar fascia and hyperintense signal in the adjacent perifascial soft tissues (arrows). There is bone marrow oedema in the calcaneal attachment (arrowhead)<sup>33</sup>

(c) IMAGING IN SPORTS-SPECIFIC MUSCULOSKELETAL INJURIES 2016, P. 528. ALI GUERMAZI, FRANK W ROEMER, MICHEL D CREMA. © SPRINGER INTERNATIONAL PUBLISHING SWITZERLAND 2016. WITH PERMISSION OF SPRINGER

tiers, which essentially equate to short-, medium- and long-term options.<sup>34</sup> The tiers also relate to the complexity, cost and invasiveness of the intervention. The following interventions are listed, taking into account evidence from two systematic reviews, unless otherwise indicated.<sup>35, 36</sup> The evidence is summarised in Table 43.3.

#### First tier/short term

Minimise the aggravating activity and educate the patient about the potential causes of their heel pain. If the patient is a runner, it is essential that you also discuss training loads, and regression and progression of their training volumes. The following is some of the generic advice that we give to patients.

- You should not begin to run before your heel has been pain-free for 4 weeks and you can walk 10 km without pain during the walk or the morning after.
- If you need to wear dress shoes, you might consider using soft silicone gel heel pads or contoured prefabricated foot orthoses in your shoes.
- It is important that you decrease or avoid activities that cause your heel pain to worsen.
- When you want to start activities again, you should be careful and progress slowly.

If your patient is a factory worker with many hours of standing work each day, it is important that you discuss potential options on how to decrease the number of hours of standing per day. The following points of

advice are generic and should be individualised to the patient.

- Advise the patient to wear appropriate footwear (offering both cushioning for the heel and support for the rearfoot and midfoot). Although there is little evidence for footwear, it is a good starting point for long-term treatment.<sup>36, 41</sup>
- Two types of taping have been advocated. The first is low-Dye taping (Fig. 43.5a), which involves the application of rigid tape to the plantar aspect of the foot with the aim of supporting the plantar fascia.<sup>37, 38</sup> This is sometimes augmented with the second type, calcaneal taping (Fig. 43.5a).
- Recommend appropriately contoured prefabricated foot orthoses.<sup>39, 40</sup>
- Provide strengthening exercises for proximal muscle groups (e.g. tibialis posterior and hip abductors/external rotators).
- A silicone gel heel pad may be beneficial (Fig. 43.5b) although the evidence is unclear.
- Recommend stretching of the plantar fascia<sup>42-44</sup> (Fig. 43.5c), gastrocnemius and soleus.
- Suggest self-massage with a frozen bottle or golf ball (Fig. 43.5d). This is commonly used but there is no supporting evidence.
- Suggest soft tissue therapy (minimal evidence), both to the plantar fascia (Fig. 43.5e) and proximal myofascial regions including calf, hamstrings and gluteals.<sup>45</sup>

**Table 43.3 Evidence table**

Interventions	
Conservative	Non-conservative
<b>Likely to be beneficial</b> <ul style="list-style-type: none"> <li>• Taping (e.g. low-Dye): limited evidence for up to 1 week</li> <li>• Customised and prefabricated foot orthoses (up to 12 months): note that there is no difference between customised and appropriately contoured prefabricated orthoses</li> </ul>	<b>Likely to be beneficial</b> <ul style="list-style-type: none"> <li>• Corticosteroid injection (short-term effects): ultrasound-guided injections have been found to be more effective than placebo</li> </ul>
<b>Unknown effectiveness</b> <ul style="list-style-type: none"> <li>• Heel pads</li> <li>• Night splints</li> <li>• Stretching exercises</li> </ul>	<b>Unknown effectiveness</b> <ul style="list-style-type: none"> <li>• Corticosteroid injection plus local anaesthetic (short term)</li> <li>• Extracorporeal shock wave therapy</li> <li>• Surgery</li> </ul>
<b>Likely to be ineffective or harmful</b>	<b>Likely to be ineffective or harmful</b> <ul style="list-style-type: none"> <li>• Corticosteroid injection (long-term effects)</li> <li>• Corticosteroid injection plus local anaesthetic injection (long-term effects)</li> </ul>

Note: No evidence from high-quality systematic reviews is available for dry needling, strengthening exercises, weight loss and non-steroidal anti-inflammatory drugs (NSAIDs) so they have not been included in this table.

(f)

(g)

**Figure 43.5 (cont.)** (f) Corticosteroid injection (g) Strasbourg sock

- Recommend the use of non-steroidal anti-inflammatory drugs (NSAIDs)<sup>46</sup>
- Advise the patient to lose weight. Although there is no evidence for weight loss as being effective, it is biologically plausible that it may be effective given that plantar fasciopathy is highly associated with increased BMI.

#### Second tier/medium term

The following are recommended second-tier interventions.

- Dry needling of related lower limb muscles is effective.<sup>47</sup>
- Customised foot orthoses may be considered; although there is no evidence that customised foot orthoses are more beneficial than appropriately contoured prefabricated foot orthoses.
- Corticosteroid injection (Fig. 43.5f): evidence supports the use of corticosteroid injection for pain relief in the short term (4–6 weeks).<sup>35, 48, 49</sup> Ultrasound-guided injections were more effective than palpation-guided injections.<sup>50</sup> It should always be combined with other treatments such as stretching, foot orthoses or other evidence-based treatments to prevent recurrence. There is some concern that corticosteroid injections are associated with an increased risk of rupture and fat pad atrophy.<sup>51, 52</sup> However, this is likely related to the solubility and duration of the corticosteroid. Lateral plantar nerve injury is a potential adverse event.<sup>53</sup>
- High-load strength training consisting of unilateral heel-raises with a towel inserted under the toes to further activate the windlass mechanism may potentially be effective for longstanding cases of plantar fasciopathy. This has been evaluated in one RCT.<sup>54</sup>

#### Third tier/long term

The following are recommended third-tier interventions.

- Night splints<sup>55–57</sup> or a Strasbourg sock (Fig. 43.5g) should be considered for patients with pain of over 6 months in duration, although the evidence is unclear and some patients will not tolerate them. One RCT found this to be effective in reducing pain that had been present for more than 6 months.<sup>1</sup>
- Extracorporeal shockwave therapy (ESWT) may be of benefit for longstanding cases, although the evidence is still unclear and it may cause substantial pain for some patients while being applied.<sup>35, 58</sup>
- As the evidence for surgery is unclear and of low quality, it should only be considered in severe longstanding cases that do not respond to any of the evidence-based treatments available. Surgical options include plantar fasciotomy ± nerve release, plantar fasciectomy with neurolysis of the nerve to the abductor digiti quinti muscle,<sup>59</sup> and minimally invasive endoscopic plantar fascia release.<sup>60, 61</sup>

#### Fat pad contusion

The heel fat pad, elastic fibrous tissue septa separated by closely packed fat cells, absorbs the shock of heel strike. Contusion can occur acutely after a fall onto the heels from a height, but is more common chronically because of poor heel cushioning or repetitive stops, starts and changes in direction.

The patient often complains of marked heel pain, particularly during weight-bearing activities. The pain is felt laterally in the heel due to the pattern of heel strike, which may help differentiate this condition from plantar fasciopathy. Examination reveals tenderness in

the posterolateral heel region. MRI often demonstrates oedematous changes in the fat pad, with ill-defined areas of decreased signal intensity on T1-weighted images that increase in signal intensity on T2-weighted images.

The patient should avoid aggravating activities. NSAIDs or paracetamol (acetaminophen) may provide short-term pain relief. Athletes can maintain cardiovascular fitness by cross-training with low-impact activities such as cycling and swimming. Training on soft surfaces can assist athletes with returning to sport.

As the pain settles, the use of a silicone gel heel pad (Fig. 43.5b) and good footwear are important as the athlete resumes activity. A well-fitting heel counter in athletic footwear can reduce shear stress and tension in the fat pad.<sup>62</sup> Heel-lock taping (see Fig 41.11b) will often provide symptomatic relief.

### Calcaneal stress fracture

Calcaneal stress fracture is the second most common tarsal stress fracture. It occurs at either the upper posterior margin of the calcaneum or adjacent to the medial tuberosity, at the point where calcaneal spurs occur. First described among the military as a marching injury (Chapter 45), calcaneal stress fractures occur in runners, ballet dancers and jumping athletes.

Patients give a history of insidious onset of heel pain that is aggravated by weight-bearing activities, especially running. Examination should include viewing the patient perform the causative activity if feasible (i.e. gait analysis in a runner). Palpation reveals localised tenderness over the medial or lateral aspects of the posterior calcaneus and pain that is reproduced by squeezing the posterior aspect of the calcaneus from both sides simultaneously.

### Investigations

Plain radiography is often normal, but may show a typical sclerotic appearance on the lateral radiograph, parallel to the posterior margin of the calcaneus (Fig. 43.6a). Stress injury was only visible in 15% of plain radiographs.<sup>63</sup> The majority of calcaneal stress fractures are posterior. MRI reveals an area of high signal on a T2-weighted image (Fig. 43.6b).

Use the level of pain to guide how much the patient must reduce activity. If pain is marked, a short period of non weight-bearing may be required. Soft heel pads can contribute to immediate pain relief. Weight-bearing can be reintroduced gradually once pain settles.

As with every training-related injury, assess sport technique to determine if abnormal biomechanics may have contributed to the injury. If indicated, prescribe rigid or soft orthoses. Expert foot clinicians consider that joint mobilisation and stretching of the calf muscles and plantar fascia contribute to recovery.

(a)

(b)

**Figure 43.6** (a) Plain radiograph appearance of a calcaneal stress fracture. The white arrowheads indicate typical sclerotic appearance (b) T2-weighted MRI showing characteristic appearance<sup>33</sup> of a stress fracture

### First branch of lateral plantar nerve (Baxter's nerve) entrapment

An overlooked cause of rearfoot pain is entrapment of the first branch of the lateral plantar nerve (Fig. 43.7). This

**Figure 43.7** The lateral plantar nerve. The nerve is one of three terminal branches of the posterior tibial nerve arising distal to the tarsal tunnel

terminal branch of the posterior tibial nerve arises distal to the tarsal tunnel and it can become trapped between the deep fascia of the abductor hallucis longus and the medial caudal margin of the quadratus plantae muscle.<sup>64</sup>

Pain radiates to the medial inferior aspect of the heel and proximally into the medial ankle region. Patients do not normally complain of numbness in the heel or foot. Often confused with plantar fasciopathy, the two conditions were shown to coexist in 52% of patients with this nerve entrapment.<sup>65</sup>

Examination is nonspecific with maximal tenderness at the plantar medial heel just proximal to the plantar fascia. A Tinel's sign at this location may reproduce pain. Theoretically, the condition is associated with 'subtle weakness of fifth toe abduction'<sup>66</sup> and atrophy to the abductor digiti quinti muscle, although this is an example of a clinical test that would have very low sensitivity if tested formally (Chapter 14). Some authors claim that atrophy can be identified on MRI or ultrasound exam.<sup>67, 68</sup>

In the clinic, a diagnostic injection with local anaesthetic, ideally performed using ultrasound to identify the nerve, can increase the clinician's confidence in the diagnosis (increased positive likelihood ratio, Chapter 14).<sup>69</sup> Referral for nerve conduction tests may be helpful for diagnosis and to determine the location of compression in the lateral plantar tunnel, Baxter's nerve or more proximally in the tarsal tunnel.<sup>67</sup> This is particularly important if surgery is being considered.

Treatment consists of using soft-soled shoes, heel cups or arch support, tape or an orthosis for athletes with excessive pronation. A corticosteroid injection, best ultrasound-guided as described earlier, may be helpful. Radiofrequency denervation of the nerve may give short-to medium-term pain relief. Surgical release would be indicated if conservative measures have failed.<sup>64</sup>

## MIDFOOT PAIN

The midfoot consists of the three cuneiform bones, the cuboid and the navicular bones as well as the surrounding soft tissues (Figs 43.1 and 43.2). The most common cause of midfoot pain is midtarsal joint sprain after ankle injury, but the most important cause of midfoot pain is stress fracture of the navicular bone. Tendinopathy of the extensor tendons is another common cause of midfoot pain. The causes of midfoot pain are listed in Table 43.4.

**Table 43.4** Causes of midfoot pain in order of importance (clinical relevance)

Common	Less common	Not to be missed
Navicular stress fracture	Cuneiform stress fracture	Lisfranc's joint injury (fracture or dislocation)
Midtarsal joint sprain	Cuboid stress fracture	Osteoid osteoma
Lisfranc joint injury (sprain)	Stress fracture base second metatarsal	Complex regional pain syndrome type 1 (after knee or ankle injury)
Tibialis posterior tendinopathy	Extensor tendinopathy	Referred pain
Plantar fascia strain	Peroneal tendinopathy	
	Abductor hallucis strain	
	Cuboid syndrome	
	Tarsal coalition (in adolescents)	
	Köhler's disease (in young children)	
	Accessory navicular bone	

### Clinical approach to midfoot pain

Acute midfoot pain results from a sprain of the midtarsal joint or plantar fascia. Gradual pain is a sign of overuse injury, such as extensor tendinopathy, tibialis posterior tendinopathy or navicular stress fracture. In most conditions, pain is well localised to the site of the injury, but in navicular stress fracture, pain is poorly localised.

Examination involves palpation of the area of tenderness and a biomechanical examination to detect factors that predispose to injury. Examination of the midfoot is shown in Figure 43.8.

(a)

(b)

**Figure 43.8** Examination of the midfoot (a) Palpation—N spot. The proximal dorsal surface of the navicular is tender when a stress fracture is present (b) Palpation—extensor tendons. These may be tender as they pass under the extensor retinaculum

### Investigations

If there is a clinical suspicion of a stress fracture of the navicular or a cuneiform, plain radiographs are indicated. This rarely reveals a fracture, even if one is present, but it is useful to rule out tarsal coalition, to show bony abnormalities such as talar beaking (osteophytes at the talonavicular joint) and accessory ossicles, and to exclude bony tumours. MRI should be performed if X-ray fails to reveal a stress fracture.

### Navicular stress fracture

Stress fractures of the navicular are among the most common stress fractures seen in the athlete, especially in sports that involve sprinting, jumping or hurdling.<sup>70</sup> The stress fracture commonly occurs in the middle third of the navicular bone (Fig. 43.9). This site is a relatively avascular 'watershed area' of bone as the blood supply comes from the lateral and medial sides of the navicular. This is thought to contribute to poor healing of these stress fractures.

Spikes in training load are thought to be the most common cause of navicular stress fractures. It is likely that the navicular bone is jammed between the talus proximally and the cuneiforms distally. Many clinicians speculate that reduced ankle dorsiflexion may cause excessive midfoot dorsiflexion and thus increase the load at the talonavicular joint with subsequent failure of the slightly concave proximal lip of the navicular at that site.<sup>71</sup>

### Clinical features

The onset of symptoms is usually insidious, consisting of a poorly localised midfoot ache associated with activity. The pain typically radiates along the medial aspect of the

**Figure 43.9** Navicular stress fractures occur at a characteristic proximal site on the bone. This N-spot corresponds with the point of tenderness on palpation

longitudinal arch or the dorsum of the foot. The symptoms abate rapidly with rest, unfortunately often contributing to diagnostic delays. Examination reveals localised tenderness at the N-spot: the proximal dorsal portion of the navicular.<sup>72</sup> If palpation confirms tenderness over the N-spot, particularly when compared to a symmetric location on the contralateral foot (Fig. 43.8a), the athlete should be considered to have a navicular stress fracture until proven otherwise.

#### PRACTICE PEARL

The pain of navicular stress fracture is often poorly localised.

The astute clinician assesses the patient for factors that predispose to the condition, such as tarsal coalition, excessive pronation and restricted ankle dorsiflexion. Any factors that need to be corrected should be attended to at the appropriate time in the management program (see below).

#### Investigations

Plain radiographs lack sensitivity to detect navicular stress fractures.<sup>72</sup> MRI (Fig. 43.10a) is the investigation of choice. Computed tomography (CT) scan can further clarify the morphology of this fracture (Fig. 43.10b and c). Poor positioning of the patient's foot and scanning with slice thickness >2 mm can lead to a navicular stress fracture being missed on CT scan.<sup>73</sup>

(a)

#### Management of navicular bone stress injuries

We consider treatment according to whether the diagnosis is: 1. stress reaction; 2. typical (uncomplicated) stress fracture; and 3. complicated stress fracture (e.g. delayed diagnosis, delayed union). (See also Chapter 4–Bone stress injuries.)

##### Stress reaction

If a patient has only had symptoms for a relatively short time (days, <2 weeks), he or she may not have a full

(b)

(c)

**Figure 43.10** Navicular stress fracture (a) T2-weighted MRI showing bone marrow oedema (b) CT scan showing undisplaced fracture (arrow) (c) CT scan showing more extensive Y-shaped fracture

stress fracture but only a stress reaction. A positive MRI combined with a normal CT scan (skilfully executed, as mentioned in the previous section) confirms the diagnosis of navicular stress *reaction* (no cortical breach). This can be treated with weight-bearing relative rest which means the patient can take weight through the part but cannot play sport. This is generally done by having the patient wear a CAM boot for 1–3 weeks until pain is absent and the N-spot is no longer tender. This is then followed by a graduated return to activity (aim for increases in the acute:chronic workload to be <1.1 or 10%) over 2–3 months (Chapter 12).

### Typical stress fracture

In the majority of cases, patients who present with midfoot pain and navicular tenderness have a frank stress fracture visible on both MRI and CT scan. Remember that bone pathology (failure) begins before the patient feels pain, so day 1 of pain is not day 1 of relative excessive load and microfractures (which precede frank stress fracture).

#### PRACTICE PEARL

**The typical non-displaced stress fracture should be treated with absolute non weight-bearing.**

Non weight-bearing can be achieved with patient education and a rigid fibreglass boot.<sup>72</sup> This period of non weight-bearing is ideally carried through a *minimum* of 6 weeks but many clinicians recommend 8 weeks so as to lower the risk of recurrence.

At the end of the period of non weight-bearing immobilisation, the boot should be removed and the N-spot palpated for tenderness. Generally, the N-spot will be non-tender; however, if tenderness is present, the patient should have a further 2 weeks of non weight-bearing immobilisation. Management is primarily based on the clinical assessment, as there is poor CT and MRI correlation with clinical union of the stress fracture (Fig. 43.11).<sup>70, 74</sup>

Following removal of the boot, it is essential for a skilled clinician to mobilise the stiff ankle and the subtalar and midtarsal joints. The calf muscles require soft tissue therapy and a progressive strengthening program. This rehabilitation must precede return to running.

Activity must begin gradually, slowly building up to full training over a period of 6 weeks. Return to sport often takes 3 months in the ideal case where the athlete has maintained fitness with cross-training and meets all his or her rehabilitation landmarks smoothly. Taking 4 months to return to play is within normal limits for this injury.<sup>75</sup> Note that even if a patient rested for 8 weeks

**Figure 43.11** Imaging of navicular stress fracture does not necessarily mirror clinical recovery. This CT scan of a 26-year-old runner shows that the fracture line is still evident (arrow) but the patient had returned pain-free to all competition and had no further recurrences of stress fracture

(without any injury), it would take 3 months to return to a high level of training merely to avoid spiking training loads.<sup>76</sup>

#### PRACTICE PEARL

**WARNING: A recipe for navicular disaster is for the patient to think that 'non weight-bearing' is merely an aspirational goal or a guideline. Countless athletes have had their careers ruined by navicular stress fracture recurrence. The fracture is notorious for non-union if the first treatment attempt is a failure.<sup>72</sup>**

### Complicated stress fracture

Often, patients with a stress fracture of the navicular present after a long period of pain or after a period of weight-bearing rest. There is no evidence to suggest these patient should have immediate surgical treatment. Patients who have been unsuccessfully treated with weight-bearing rest or short-term boot immobilisation should undergo non weight-bearing immobilisation for 8 weeks. This method of

treatment is associated with an 80% successful return-to-sport rate and may be successful even in cases where the patient has had longstanding (>6 months) pain.<sup>70, 74</sup>

Failure of rigorous conservative treatment is an indication for surgery. Which type of surgery is best has not been tested. Some surgeons favour internal fixation, others prefer to excise the fracture and perform a bone graft. As the fracture involves a joint surface (proximal navicular, at the talonavicular joint; Fig. 43.10) surgery is not universally successful.

A 2010 systematic review and meta-analysis found no significant difference between non weight-bearing conservative treatment and surgical treatment in terms of pain reduction.<sup>74, 77</sup>

### Midtarsal joint sprains

Themidtarsal joint (Chopart's joint) consists of the talonavicular and calcaneocuboid joints. Other joints in themidtarsal area are the naviculocuneiform, cuboid cuneiform and intercuneiform joints. Injuries to themidtarsal joints are most commonly seen in gymnasts, jumpers and footballers.

Individual ligamentous sprains to themidtarsal joints are uncommon and if they occur usually affect the dorsal calcaneocuboid or bifurcate ligament, comprising the calcaneonavicular and calcaneocuboid ligament.

### Dorsal calcaneocuboid ligament injury

Patient presents with pain in the lateral midfoot following an inversion injury. Examination reveals localised tenderness and swelling at the dorsolateral aspect of the calcaneocuboid joint. Stress inversion of the foot elicits pain.

Plain radiography is required to exclude fracture and MRI may confirm the diagnosis. Taping may provide additional support while orthoses may help to de-load the painful ligaments. A joint sprain can sometimes lead to secondary joint inflammation. This generally responds well to NSAIDs but if inflammation persists the patient may benefit from a corticosteroid injection into the painfulmidtarsal joints.

### Bifurcate ligament injuries

Injuries to the bifurcate ligament may be associated with fractures to the anterior process of the calcaneus secondary to violent dorsiflexion, forceful plantarflexion and inversion injuries (Chapter 41). Patients present with lateral midfoot pain and swelling, usually following an ankle sprain or injury. Examination reveals local tenderness and occasionally swelling overlying the ligament, with pain elicited at the site with simultaneous forefoot supination and plantarflexion.

Plain radiograph may reveal a fracture of the anterior process of the calcaneus but it can miss one, so never rely on X-ray to rule out a fracture. An MRI scan can be used to confirm the joint/ligament sprain. If a fracture is present, a CT scan may be required for further assessment (see Fig. 41.17).

Treatment is similar to the dorsal calcaneocuboid sprain mentioned previously. If a non-displaced or mildly displaced fracture of the anterior process of the calcaneum is present, 4 weeks immobilisation is required. If the fracture is displaced, surgery is required.

### Lisfranc joint injuries

The eponymous Lisfranc joint refers to the tarsometatarsal joints: the bases of the five metatarsals with their corresponding three cuneiforms and cuboid (Fig. 43.12). The spectrum of injuries of the Lisfranc joint complex ranges from partial sprains with no displacement, to complete tears with separation (diastasis) of the first and second metatarsal bones and, depending on the severity, different patterns of tarsal and metatarsal displacement (Fig. 43.13).

#### PRACTICE PEARL

Be alert! Although Lisfranc joint injuries ('midfoot sprains') are not common in the general population, they are the second most common foot injury in athletes. In sport, they generally occur via low-velocity indirect force.

**Figure 43.12** Ligamentous attachments of the Lisfranc joint articulation

**Figure 43.13** Lisfranc joint injury classification system

Lisfranc joint fracture-dislocation is rare in sport, but, because of its disastrous consequences if untreated, the diagnosis must be considered in all cases of 'midfoot sprain' in the athlete.

### Causes

There are two main mechanisms of injury.

- **Direct.** This injury is relatively uncommon and occurs as a simple crush injury to the tarsometatarsal joint region. There is no specific pattern of damage or distinctive appearance with a direct injury.
- **Indirect.** This mechanism is more common and generally occurs secondary to a longitudinal force sustained while the foot is plantarflexed and slightly rotated. There are three common injury situations: longitudinal compression (Fig. 43.14); a backward fall with the foot entrapped; and a fall on the point of the toes.<sup>78</sup>

The extent of the damage depends on the severity of the injury. In milder injuries, the weak dorsal tarso-metatarsal ligaments are ruptured; with more severe injuries, there may also be fractures of the plantar aspect of the metatarsal base, or the plantar capsule may rupture and the metatarsal may displace dorsally. Thus, a fracture

**Figure 43.14** Mechanism of injury to Lisfranc joint—longitudinal compression

at the plantar base of a metatarsal can be a clue to a subtle Lisfranc joint injury.

### Clinical features

A patient with Lisfranc joint injury may complain of midfoot pain and difficulty weight-bearing, following an acute injury by the mechanisms described above. Pain is classically aggravated by forefoot weight-bearing—the patient is unable to run on the toes and feels pain on the push-off phase of running (and sometimes during walking) and on calf raises. Often the presentation may be delayed, and the patient presents with ongoing midfoot pain and swelling, aggravated by running.

#### PRACTICE PEARL

Midfoot pain that persists for more than 5 days post injury should raise suspicion of a Lisfranc joint injury.

Examination reveals:

- tenderness with or without swelling on the dorsal midfoot, often with associated bruising in this region
- pain with combined eversion and abduction of the forefoot while the calcaneus is held still
- plantar medial ecchymosis may be observed in a delayed diagnosis<sup>79</sup>
- neurovascular examination is mandatory as the dorsalis pedis artery can be compromised in the initial injury or by subsequent swelling of the foot.<sup>78</sup>

### Investigations

Plain weight-bearing radiographs are recommended. Diastasis between the first and second metatarsal bases of greater than 2 mm. (Fig. 43.15a) suggests a Lisfranc joint injury, although in patients with a metatarsus adductus a 3 mm separation may be normal. In such cases, it is essential to take comparative weight-bearing X-rays of the non-injured side, as a difference in diastasis of greater than 1 mm between the two sides is considered diagnostic.

Other radiological signs that may indicate an injury to the Lisfranc joint include a 'fleck sign', which appears as a fleck fracture near the base of the second metatarsal or medial cuneiform or, in the lateral view, either dorsal displacement of the metatarsal bases relative to the tarsus or flattening of the medial longitudinal arch. However, a dislocation may reduce spontaneously, and the foot may appear normal on plain X-rays despite severe soft tissue disruption. There was a high correlation between rupture or grade II sprain of the plantar ligament between the first cuneiform and the bases of the second and third metatarsals, and true midfoot instability.

If injury is suspected, and X-ray is normal, both CT (Fig 43.15b) and MRI (Fig 43.15c) can help the clinician make the diagnosis. MRI is more sensitive and specific than CT to demonstrate all the components of the Lisfranc complex.<sup>80, 81</sup>

Static and dynamic ultrasound examination of the dorsal cuneiform metatarsal (C1-M2) ligament is a sensitive indicator of stable or unstable sprains. Thickening to this ligament without joint space widening is consistent with a grade 1 sprain. Absence of this ligament and joint space wider than 2.5 mm, plus increased spacing upon weight-bearing, suggests Lisfranc ligament tear.<sup>82</sup>

### Treatment

The treatment of a Lisfranc joint injury depends on the degree of instability present.<sup>83</sup> In grade I injuries, where there is no instability (diastasis), conservative management is recommended with non weight-bearing in a CAM boot or Aircast® for 6 weeks. The goal of this treatment is to restore the integrity of the tarsometatarsal ligaments and

(a)

**Figure 43.15** Lisfranc fracture–dislocation (a) Plain radiograph

hence the stability of the midfoot. Following removal of the cast, mobilisation of the ankle and a calf-strengthening program are required. Orthoses may be needed to correct the intrinsic alignment of the foot and to support the second metatarsal base. A graded return to activity is required. Recovery time from diagnosis to activity return is prolonged, often requiring 3–4 months of total treatment.<sup>79</sup>

Due to instability, injuries of grade II or greater severity require surgical reduction and fixation. This may be performed percutaneously or, in more difficult cases, an open operation may be needed. There has also been consideration for primary arthrodesis as opposed to open reduction internal fixation (ORIF); however, this is a less-preferred method.<sup>84</sup> In the situation of a delay in diagnosis, similar treatment protocols are required, however grade II or grade III Lisfranc injury is a significant injury that has a much better prognosis if managed correctly initially, rather than being salvaged once there is prolonged joint malalignment and non-union.

(b)

(c)

**Figure 43.15 (cont.)** (b) CT scan showing fractures of middle and lateral cuneiforms (arrows) with 0.30 cm of diastasis in the Lisfranc joint (c) Axial STIR MRI highlights torn Lisfranc ligament (arrow) and associated cuboid and metatarsal base contusion (arrowhead)<sup>33</sup>

(c) IMAGING IN SPORTS-SPECIFIC MUSCULOSKELETAL INJURIES, 2016, P. 660: ALI GUERMAZI, FRANK W ROEMER, MICHEL D CREMA. © SPRINGER INTERNATIONAL PUBLISHING SWITZERLAND 2016. WITH PERMISSION OF SPRINGER

A delay in diagnosis has been associated with a poor outcome, a prolonged absence from sport, and chronic disability due to ligamentous instability of the tarsometatarsal joint.

### Tibialis posterior tendinopathy (distal pain presentation)

Tibialis posterior tendinopathy is described in the previous chapter on ankle pain (Chapter 42), but tendinopathy at the distal insertion of the tendon into the navicular may present primarily as medial foot pain. In younger patients, the accessory ossicle, the os navicularis (Fig. 43.16), may be avulsed. This requires orthoses and gradual return to activity. Surgery is rarely indicated as the tibialis posterior has a complex insertion into all bones of the foot.

### Less common causes of midfoot pain

#### First tarsometatarsal joint pain

A prominent first metatarsal-cuneiform joint may cause pain to the dorsomedial midfoot. Most often, constricting shoelaces or excessively tightly fitting shoes will compress a dorsally protuberant first tarsometatarsal joint. The prominent base of the first metatarsal may be anatomically determined or developed due to degenerative changes at the joint. Dorsal cutaneous nerve compression can also result from this prominent dorsal bump. Suggested treatments focus to reduce pressure at this site. Modified lacing patterns, shoes with soft leather through the midfoot,

**Figure 43.16** The os navicularis (arrow)

and accommodative padding around the bump can all be attempted before more aggressive treatments. Surgery may be required to remove persistently painful bony exostoses.

### Extensor tendinopathy

The extensor (dorsiflexor) muscles of the foot comprise the tibialis anterior, extensor hallucis longus and brevis, as well as extensor digitorum longus and brevis. Tibialis anterior tendinopathy is the most common tendinopathy occurring in the extensor muscles of the foot. Tendinopathies of the extensor hallucis longus and brevis and extensor digitorum longus and brevis muscles are rare.

The tibialis anterior muscle eccentrically controls plantarflexion and eversion of the foot at heel strike and its tendon is therefore susceptible to overuse injury. Tendinopathy generally occurs because of excessive training load in relation to background preparation. Experienced clinicians believe that stiffness of the first MTP joint and midfoot joints may contribute.

Generally, after a period of overuse, the patient with extensor tendinopathy complains of burning or aching medial midfoot pain. Examination may reveal tenderness, often with mild swelling, at the insertion of the tibialis anterior tendon at the base of the first metatarsal and the cuneiform. Pain may be elicited by passive plantar flexion combined with eversion, abduction and dorsiflexion. This is otherwise known as the tibialis anterior passive stretch (TAPS) test.<sup>85</sup> Resisted dorsiflexion and eccentric inversion may also exacerbate symptoms. Functional assessment may reveal excessive heel strike or over-striding during running. Both ultrasound and MRI may reveal swelling of these tendons and exclude the presence of a degenerative tear.

Popular clinical treatment includes relative rest and soft tissue therapy to the extensor muscles. Extensor muscle strengthening is advocated as is the case with other tendinopathies. The underlying precipitating cause needs to be addressed. If this is load, then training load needs to be considered. Local treatment may include mobilisation of the first ray, and tarsometatarsal and midtarsal joints, if the first MTP joint and midfoot is stiff. Modification of running technique may be required (reduce stride length) and footwear may need to be replaced.

### Peroneal tendinopathy

Peroneal tendinopathy is an overuse injury of the peroneal tendons associated with running, dancing and in those with chronic lateral ankle instability. The management of this condition is described in Chapter 42.

### Abductor hallucis strains

Abductor hallucis strains result in pain along the medial longitudinal arch and are often associated with excessive pronation. The abductor hallucis tendon is tender to

palpate. Treatment consists of local electrotherapeutic modalities and taping.

### Cuboid syndrome

The renowned physiotherapist from the American Ballet Theatre in the 1990s, Peter Marshall, brought this condition to the mind of clinicians who specialise in foot pain.<sup>86, 87</sup> Marshall argued that due to excessive traction of the peroneus longus, the cuboid becomes 'subluxated'. The term 'subluxated' is still challenging, 35 years after Marshall used it; certainly there have never been imaging changes captured to confirm subluxation or dislocation. Cuboid syndrome may also manifest following an acute plantarflexion and inversion ankle injury, and is common among professional ballet dancers. Pain is experienced with lateral weight-bearing. Most patients with this syndrome have excessively pronated feet but it is also seen in patients with lateral ankle instability.

The peroneus longus subluxates the cuboid bone so that the lateral aspect is rotated dorsally and medially. There may be a visible depression over the dorsal aspect of the cuboid. Treatment involves a single manipulation to reverse the subluxation.<sup>88</sup> The cuboid should be pushed upwards and laterally from the medial plantar aspect of the cuboid, as shown in Figure 43.17. In the largest case series, athletes returned to sport immediately following cuboid manipulation without any recurrences.<sup>89</sup>

### Stress fracture of the cuboid

Stress fractures of the cuboid are uncommon and occur secondary to compression of the cuboid between the calcaneus and the fourth and fifth metatarsal bones when exaggerated plantarflexion is undertaken with or without inversion. Diagnosis is often delayed due to non-specific signs or symptoms clinically and typically normal plain radiography. MRI is the preferred choice of imaging (Fig. 43.18).<sup>90, 91</sup> Treatment of the uncomplicated stress fracture requires non-weight-bearing for 4–6 weeks, followed by a graduated return to activity.

### Stress fracture of the cuneiforms

Stress fractures of the cuneiform bones are quite rare. We reported one in 1993 and have seen less than a handful between us since then.<sup>92</sup> Theoretical risk factors are large body habitus, plantar fascia injury,<sup>93</sup> overuse and altered gait pattern. Limited weight-bearing rest is treatment for medial cuneiform stress fractures; however, stress fractures of the intermediate cuneiform require surgical reduction and fixation for adequate healing.<sup>94</sup>

### Köhler's disease

Köhler's disease, or osteochondritis of the navicular, is found in children aged 2–8 years (Chapter 44).

**Figure 43.17** Manipulation of the cuboid in a superior and lateral direction in cuboid syndrome

### Tarsal coalition

Congenital fusions of the foot bones usually present as midfoot pain. Tarsal coalitions may be osseous, cartilaginous (synchondrosis), fibrous (syndesmosis) or a combination. The estimated prevalence is 1–2%, although a recent CT and cadaver dissection study found 12.7%.<sup>95</sup> A fibrous coalition is relatively mobile and therefore may not cause any pain on limited motion. As fibrous or cartilaginous coalitions ossify during adolescence, rearfoot or midfoot joint range of motion decreases, placing additional stress on the talocrural (ankle) joint. Accounting for 90% of coalitions, the two most common tarsal coalitions occur at the calcaneonavicular joint and the talocalcaneal joint; 50–60% occur bilaterally.

Clinical presentation usually occurs during the adolescent/young adult years coinciding with ossification of the cartilaginous coalitions and more vigorous sports and physical activity.<sup>96</sup> Patients can also present after minor trauma such as an ankle sprain that does not clinically improve (Chapter 41). Because tarsal coalition causes subtalar restriction, adjacent joints may function abnormally and thus the patient presents with

**Figure 43.18** MRI demonstrating stress fracture cuboid (arrow)<sup>33</sup>

IMAGING IN SPORTS-SPECIFIC MUSCULOSKELETAL INJURIES, 2016, P. 659, ALI GUERMAZI, FRANK W ROEMER, MICHEL D CREMA.

© SPRINGER INTERNATIONAL PUBLISHING SWITZERLAND 2016. WITH PERMISSION OF SPRINGER

joint spurs and symptoms remote from the coalition (Fig. 43.19).

Examination usually reveals limited range of subtalar and midtarsal joint movement that may be painful at end range. Plain radiographs remain the initial test of choice and are the most useful diagnostic tool for osseous coalitions. A Harris-Beath view may detect a talocalcaneal coalition. A complete C-sign seen on a lateral X-ray is highly correlated with bony talocalcaneal coalition (Fig. 43.19), although the absence of this sign does not rule out the possibility of this condition.<sup>97</sup> CT scan provides the most complete diagnostic imaging for bony tarsal coalition, while MRI can identify fibrous coalition.

Asymptomatic cases do not require treatment. For symptomatic cases, initial conservative management includes a period of relative rest to allow inflamed joints to settle. NSAIDs may provide a short-term palliative effect as can paracetamol (acetaminophen). Orthoses may alter biomechanics favourably but they can also eliminate

**Figure 43.19** Radiograph showing talocalcaneal coalition (black arrows) with a continuous cortical line, the C-sign, joining the talus and sustentaculum tali, and talar beaking (white arrow) that results from abnormal subtalar movement

movement at joints that provide motion so they need to be considered carefully and their effects monitored. Corticosteroids are mentioned in sports medicine texts but we do not see a compelling case in tarsal coalition.<sup>96</sup>

Surgery may be required for recalcitrant or disabling pain. As always, an experienced subspecialist foot surgeon is likely to provide better advice and have superior clinical outcomes compared to a general orthopaedic surgeon who is essentially unfamiliar with the intricacies of the procedure or its postoperative rehabilitation.

## FOREFOOT PAIN

Forefoot problems that can severely compromise dancers' and athletes' performance include stress fractures and soft tissue injuries such as the plantar plate tear. Common problems that are far more significant in a competitive athlete's life than in a 'weekend warrior' include corns, calluses and nail problems. Causes of forefoot pain are listed in Table 43.5 and that list guides the order in which we discuss the conditions in the chapter.

### Clinical perspective

Accurate diagnosis in the forefoot often requires the clinician to combine the evidence from a careful history (mechanisms, time course), with careful palpation and understanding of the limitations of investigations (e.g. Morton's neuroma will likely come with a normal MRI).

### History

Most causes of forefoot pain result from training errors and thus have an insidious onset. Occasionally, acute forefoot pain may result from a sprain of the first MTP joint ('turf toe'). Sensory symptoms may indicate that a neuroma is present.

### Examination

The key to examination of the patient with forefoot pain is precise palpation to identify the site of maximal tenderness. Biomechanical examination is necessary.

**Table 43.5** Causes of forefoot pain

Common	Less common	Not to be missed
Stress fracture of the neck of metatarsals I–IV	Stress fracture of the great toe	Referred pain
Stress fracture of the base of the second metatarsal	Joplin's neuritis	
Fractures of the fifth metatarsal	Freiberg's osteochondritis	
MTP joint synovitis	Toe clawing	
First MTP joint sprain ('turf toe')	Subungual haematoma	
Hallux limitus	Subungual exostosis	
Hallux valgus ('bunion')		
Sesamoid injuries including stress fracture		
Plantar plate tear		
Morton's neuroma		
Corns, calluses		
Plantar wart		
Onychocryptosis (ingrown toenail)		

1. Observation (Fig. 43.20a)
2. Palpation:
  - (a) metatarsals (Fig. 43.20b)
  - (b) first MTP joint (Fig. 43.20c)
  - (c) sesamoid bone of the foot (Fig. 43.20d)
  - (d) space between third and fourth metatarsal (Fig. 43.20e)

### Investigations

Plain radiographs may show evidence of a healing stress fracture or acute fracture, the presence of hallux abducto-valgus, hallux limitus or a subungual exostosis. MRI may confirm the diagnosis of a stress fracture. Both MRI and ultrasound have limited utility to identify a neuroma<sup>98</sup> (see section on Morton's neuroma below).

### Stress fractures of the neck of metatarsals I–IV

Stress fractures of the metatarsals are the second most common stress fractures of all.<sup>99</sup> Training errors (sudden

increase in load, change in training conditions or footwear) or poor biomechanics can load the forefoot to failure.<sup>100</sup> Fatigue of the gastrocnemius muscle increases forefoot loading.<sup>101, 102</sup>

**Figure 43.20** Examination of the patient with forefoot pain (a) Observation for the presence of obvious abnormalities (e.g. hallux abducto-valgus, claw toes, Morton's foot, plantar warts, onychocryptosis, corns, callus) (b) Palpation—metatarsals (c) Palpation—first MTP joint (d) Palpation—sesamoid

(e)

**Figure 43.20 (cont.)** (e) Palpation—space between third and fourth metatarsal

The most common metatarsal stress fracture is at the neck of the second metatarsal. This occurs in the pronating foot, when the first ray is dorsiflexed and the second metatarsal becomes subjected to greater load. The second metatarsal is also susceptible to stress fracture in the case of a Morton's foot, where the second ray is the longest ray (Fig. 43.21). The base of the second metatarsal is firmly fixed in position next to the cuneiform bones, further increasing the likelihood of fracture. Stress fracture of the second metatarsal is common in ballet dancers. Stress fractures of the other metatarsals also occur, particularly in the third metatarsal if it is longer than the second.

Plain radiograph is not sensitive to detect early stress fractures but may reveal a radiolucent line or periosteal thickening if the fracture has been present for a few weeks (Fig. 43.22). MRI is the investigation of choice.

The management of most stress fractures is straightforward, involving rest from weight-bearing aggravating activities for approximately 4 weeks, and addressing any

underlying contributing factors. If the patient is required to be on his or her feet excessively, the use of a CAM boot may be required for 1-2 weeks until pain settles.

The athlete should be allowed to recommence activity when he or she does not experience pain when walking and there is no local tenderness at the fracture site. A graduated exercise program should be instituted to return the athlete to full training and competition. Orthoses may

**Figure 43.21** Morton's foot with the first ray shorter than the second. The patient with a metatarsal stress fracture complains of forefoot pain aggravated by activity such as running or dancing. The pain is not severe initially but gradually worsens with activity. Examination reveals the presence of focal tenderness overlying the metatarsal

**Figure 43.22** Stress fracture of the second metatarsal. X-ray appearance—arrow points to new bone formation at the site of the stress fracture. This ballet dancer's metatarsal displays generalised cortical hypertrophy

be required to control abnormal foot mechanics; however, it is still unclear from current research whether orthoses can prevent metatarsal stress fractures.<sup>103</sup> Any instability during forefoot weight-bearing may predispose to the development of a stress fracture. Intrinsic and extrinsic foot muscle strengthening exercises may help prevent recurrence.

#### PRACTICE PEARL

Two metatarsal stress fractures require special treatment: fractures of the base of the second metatarsal and the stress fracture in the Jones position of the fifth metatarsal.

#### Special metatarsal stress fracture: base of the second MT

An unusual fracture of the base of the second metatarsal (Fig. 43.23a) involving the joint occurs in ballet dancers.<sup>99, 104–106</sup> The fracture can sometimes be seen on plain X-ray (Fig. 43.23b), however MRI is the investigation of choice (Fig. 43.23c). This fracture should be treated by having the dancer remain non weight-bearing on crutches until tenderness settles, usually at least 4 weeks. The differential diagnosis of proximal second metatarsal stress fracture is chronic joint synovitis.

These stress fractures may be associated with Achilles tightness, low bone mass and high training loads.<sup>107</sup>

Clinicians expert in managing metatarsal fractures advocate soft tissue therapy to the calf muscles in addition to strengthening of all foot muscles including the peroneals.

#### Fractures of the fifth metatarsal

Ever since Sir Robert Jones described<sup>108</sup> in 1902 a fracture 2 cm from the base of the fifth metatarsal that he himself sustained (while maypole dancing!), there has been considerable confusion regarding the different types of fractures and their definitions. For many years, fractures at the base of the fifth metatarsal were simply divided into avulsion fractures of the tuberosity, and all others, which were collectively known as Jones fractures.

In 1993, Lawrence and Botte were the first to introduce a classification distinguishing three different fracture types based on mechanism of injury, fracture location, treatment options and outcome.<sup>109</sup> They described the 'Jones fracture' being located more proximally, and assigned it at the level of the entire fourth-fifth intermetatarsal articulation

(a)

**Figure 43.23** (a) Stress fracture of the base of the second metatarsal

(b)

(c)

**Figure 43.23 (cont.)** (b) Stress fracture of the base of the second metatarsal involving the joint. The fracture line (arrowhead) extends to the second tarsometatarsal joint (c) MRI of stress fracture (arrow) at base of second metatarsal. This is a common site of stress fractures in ballet dancers<sup>33</sup>

(c) IMAGING IN SPORTS-SPECIFIC MUSCULOSKELETAL INJURIES 2016, P. 659, ALI GUERMAZI, FRANK W ROEMER, MICHEL D CREMA. © SPRINGER INTERNATIONAL PUBLISHING SWITZERLAND 2016. WITH PERMISSION OF SPRINGER

(Zone 2). The location formerly known as 'Jones fracture' at the proximal diaphysis was renamed as 'diaphyseal stress fracture' (Zone 3). Fractures to the most proximal part of the fifth metatarsal were named 'tuberosity avulsion fracture' (Zone 1).

Still today, the most common classification of fractures to the proximal fifth metatarsal bone is into 'tuberosity avulsion fractures' (Zone 1), 'Jones fractures' (Zone 2) and 'diaphyseal stress fractures' (Zone 3) as shown in Figure 43.24a.

### Fracture of the tuberosity

The fracture of the tuberosity at the base of the fifth metatarsal (Fig. 43.24b) has been described in Chapter 41 and is usually an avulsion injury that results from an acute ankle sprain. This uncomplicated fracture does well

treated with weight-bearing as tolerated with an elastic wrap circumferentially placed around the midfoot.<sup>110</sup>

### Jones fracture

The fifth metatarsal fracture at the level of the articulation of the fourth and fifth metatarsals (Zone 2) is the Jones fracture (Fig. 43.24c). A Jones fracture may occur as the result of an acute plantarflexion/inversion mechanism or a medially directed force on a planted foot, and thus create an acute fracture. There may be a history of prodromal symptoms suggesting that the fracture may occur in an area already suffering bone stress. In Ekstrand's UEFA study of professional footballers with fifth metatarsal fractures, 45% reported pain on the lateral side of the foot prior to the acute fracture.<sup>111</sup>

In 1984, Torg proposed managing these fractures on the basis of a radiographic (Fig. 43.24c) classification into three types.<sup>112</sup>

- Type 1: acute fractures characterised by a narrow fracture line and absence of intramedullary sclerosis.
- Type 2: those with delayed union, with widening of the fracture line and evidence of intramedullary sclerosis.
- Type 3: those with non-union and complete obliteration of the medullary canal by sclerotic bone.

Jones fractures can be treated operatively or non-operatively. In the 1990s, most Jones fractures were managed non-operatively with 6–8 weeks of non-weight-bearing.

However, there is now compelling evidence for screw fixation (Fig. 43.24d) of Jones fractures in sports medicine. Superior outcomes include both faster return to play (as early as 2–4 weeks) and fewer recurrences compared with cast treatment.<sup>113–115</sup> The average time to return to sport following primary screw fixation is 7.5 weeks.<sup>116</sup>

Non-union may occur with this type of fracture because of the location of the nutrient artery (Fig. 43.24e).<sup>115</sup>

**Figure 43.24** (a) Anatomical locations of the different types of proximal fifth metatarsal fractures. Zone 1 tuberosity avulsion fractures, Zone 2 Jones fractures and Zone 3 diaphyseal stress fractures (b) Fracture of the tuberosity of the fifth metatarsal (c) Jones fracture at the level of the fourth–fifth metatarsal articulation

(d)

Re-fractures as a result of screw failure are fortunately uncommon, but are most likely to occur soon after return to full unrestricted sport. Re-fractures and non-unions are best treated with a large, 5.5 mm or larger, solid screw and bone grafting.<sup>117</sup> The average time to return to sport following revision is 12 weeks. Early return to sport may predispose the athlete to re-fracture<sup>118</sup> and it may be wise to wait for full radiographic healing before return to sport.<sup>119</sup>

(g)

### Stress fracture of the diaphysis

Diaphyseal stress fractures occur distal to the intermetatarsal articulation (Zone 3) in the diaphysis of the bone (Fig. 43.24f and g). Similarly to Jones fractures, these fractures are prone to non-union and treatment with screw fixation (Fig. 43.24d) has been found to both reduce the incidence of non-union and result in improved return-to-sport times (6.9 weeks compared to 14.5 weeks in a non-operative group).<sup>114</sup>

### Spiral fracture (distal third)

An acute spiral fracture of the distal third of the fifth metatarsal is seen, especially in dancers who suffer this fracture when they lose their balance while on demi pointe and roll over the outer border of the foot—the ‘fouetté fracture’ (Fig. 43.25). Non-displaced fractures may be treated with a plastic cast shoe, short leg walking boot or firm-soled shoe with weight-bearing as tolerated. Fractures that are displaced more than 3–4 mm or angulated more than 10° in the sagittal plane should be reduced.<sup>110</sup>

Approximately 25% of individuals who sustain a fifth metatarsal fracture—of any kind—continue to have some non-limiting pain up to one year later. Despite this low-level pain there were no functional impairments in a cohort of patients prospectively followed for one year.<sup>120</sup>

### MTP joint synovitis

MTP joint synovitis (commonly referred to as ‘metatarsalgia’) is a common painful condition occurring most frequently in the second, third and/or fourth MTP joints, or isolated in the first MTP joints. Tenosynovitis of the flexor tendon sheath is a potential differential diagnosis.<sup>121</sup>

The synovium of the MTP joints becomes painful, usually due to excessive pressure over a prolonged period. It is often related to:

- pes cavus or high-arched foot
- excessive pronation of the foot
- clawing or hammer toes
- tight extensor tendons of the toes
- prominent metatarsal heads
- Morton’s foot (Fig. 43.21): there is a shortened first metatarsal, which results in weight going through the second MTP joint.

The patient complains of pain aggravated by forefoot weight-bearing, particularly in the midstance and propulsion phases of walking. Pain onset is usually gradual.

Examination reveals local tenderness on palpation. Pain is aggravated by passive forced flexion of the toe. The V sign is sometimes seen in the early stages of metatarsal

**Figure 43.25** Spiral fracture of the distal fifth metatarsal

joint synovitis. A separation of the toes can create a V shape that may indicate underlying dysfunction.<sup>122</sup>

There may be an associated skin lesion (e.g. a callus) over the plantar surface of the affected joint due to the excessive load. This injury may be caused by uneven distribution of load, especially with excessive pronation.

Treatment involves addressing the most likely biomechanical contributing factors, as well as providing

symptomatic relief. Padding to redistribute weight from the painful areas can provide short-term relief. Footwear that has adequate midsole cushioning is essential. NSAIDs may be helpful and corticosteroid injection is occasionally required. The joint is injected via the dorsal surface, while longitudinal traction is placed on the toe to open the joint space.

### First MTP joint sprain ('turf toe')

A sprain to the first MTP, otherwise known as a 'turf toe', is a common injury occurring in athletes in which the plantar capsule and ligament of the first MTP joint is damaged. The classic mechanism of injury is usually that of a forced hyperextension to the first MTP joint, although occasionally a plantarflexion injury to the joint may result in this injury.

Turf toe injuries are classified on the basis of their severity into grade I (mild), grade II (partial plantar capsule and ligament disruption) and grade III (complete plantar capsule and ligament disruption) (Table 43.6). Grade III injuries are often associated with injury of other structures such as the plantar plate or the flexor hallucis longus/flexor hallucis brevis tendons.<sup>123</sup>

Predisposing risk factors include:

- competing or training on artificial turf
- pes planus or excessive pronation
- decreased pre-injury ankle range of motion
- decreased pre-injury MTP range of motion
- soft flexible footwear.

The athlete usually complains of localised pain, swelling and occasional redness at the first MTP joint following a 'bending' injury to the joint. The pain is classically aggravated by weight-bearing or movement of the big toe.

Examination reveals localised swelling and tenderness at the first MTP joint. In mild injuries plantar or plantar medial tenderness is present; in more severe injuries, dorsal tenderness occurs. Passive plantarflexion and dorsiflexion of the first MTP joint are generally painful and there may be a reduction in the range of movement in both directions. Passive gliding of the joint in a dorsal to plantar direction can be used to evaluate the plantar plate. Resisted plantarflexion and dorsiflexion can be used to evaluate the integrity of the flexor and extensor tendons.<sup>123</sup>

Plain radiographs are generally unremarkable, although occasionally small periarticular flecks of bone are noted, most likely indicating avulsion of the MTP capsule or ligamentous complex. If injury to the plantar plate is suspected, lateral views in forced dorsiflexion can be used. This view may demonstrate a lack of distal sesamoid excursion, which is indicative of complete disruption of the plantar ligament structures.<sup>123</sup> MRI may be appropriate for elite athletes with grade II and III injuries to outline the extent of ligamentous, osseous and cartilage damage.<sup>124</sup>

Treatment consists of ice, NSAIDs, electrotherapeutic modalities and decreased weight-bearing for at least 72 hours. Additional treatment may include taping (Fig. 43.26) and the use of stiff-soled shoes or a CAM walker boot to protect the first MTP joint from further injury. Treatment of the various grades of injury is summarised in Table 43.6. Recovery from grade I and II turf toe injury generally takes 3–4 weeks. Surgical indications for grade III injuries include:<sup>123</sup>

- large capsular avulsion and vertical instability
- retraction of sesamoids
- loose body
- chondral injury.

A possible long-term sequel to this injury is the development of hallux limitus, discussed in the next section.

**Table 43.6** Turf toe grading and treatment

Grade	Description/Findings	Treatment	Return to play
I	Attenuation of plantar structures Localised swelling Minimal ecchymosis	Symptomatic	Return as tolerated
II	Partial tear of plantar structures Moderate swelling Restricted motion due to pain	Walking boot Crutches as needed	Up to 2 weeks May need taping on return to play
III	Complete disruption of plantar structures Significant swelling/ecchymosis Hallux flexion weakness Frank instability of hallux MTP	Long-term immobilisation in boot or cast OR Surgical reconstruction	6–10 weeks depending on sport and position Likely need taping on return to play

ADAPTED FROM MCCORMICK AND ANDERSON<sup>123</sup> REPRODUCED WITH PERMISSION OF JOURNAL OF CLINICAL SPORTS MEDICINE

**Figure 43.26** Taping to protect an injured first MTP joint

### Hallux limitus

Hallux limitus refers to restriction in dorsiflexion of the hallux at the first MTP joint secondary to exostoses or osteoarthritis of the joint. Often the term 'hallux rigidus' is used to describe the final progression of hallux limitus as ankylosis of the joint occurs.

The primary role of the hallux is to enable dorsiflexion of the first metatarsal during the propulsive phase of gait. Approximately 60° of dorsiflexion is required for normal gait. Limitation of this range of motion results in problems with gait. Normal dorsiflexion is achieved via the action of peroneus longus, which helps to stabilise and maintain plantarflexion of the first ray.<sup>125</sup>

There is some evidence that the following may contribute to development of hallux limitus:

- trauma: secondary to chondral damage
- excessive load: via absolute loading or due to excessive pronation of the foot which increases the stresses on the joint and promotes development of exostoses
- repetitive weight-bearing dorsiflexion of the first MTP joint
- autoimmune arthropathy or metabolic conditions (e.g. rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, gout)<sup>125</sup>
- hypermobile first ray (e.g. reduced plantarflexion of the first ray can increase compressive forces in the joint during propulsion).<sup>125</sup>

The main symptom is usually pain around the first MTP joint—often described as a deep aching sensation. Pain is aggravated by walking, especially in high heels, or activities involving forefoot weight-bearing. Dorsal joint hypertrophy can cause footwear to impinge on the joint and may lead

to pain secondary to skin or soft tissue irritation. In patients with longstanding hallux limitus, a distinct shoe wear pattern is seen: the sole demonstrates wear beneath the second MTP joint and the first interphalangeal joint.

Examination reveals tenderness over the dorsal aspect of the first MTP joint, often with palpable dorsal exostoses. There is a painful limitation of joint motion. Some with this condition may develop chronic subungual haematoma due to repetitive compensatory dorsiflexion in the interphalangeal joint.<sup>125</sup>

Plain radiographs display the classic characteristics of degenerative osteoarthritis and the degree of degeneration. Features include joint space narrowing, sclerosis of the subchondral bone plate, osteophytic proliferation, flattening of the joint, sesamoid displacement and free bony fragments.

Conservative management consists of an initial reduction in activity, NSAIDs, a corticosteroid injection as adjuvant therapy, passive joint mobilisation before the joint fully fuses, correction of abnormal biomechanics with orthoses and/or footwear, and dynamic splinting.<sup>126</sup> Conservative treatment often fails when hallux dorsiflexion is less than 50°.

If conservative treatment fails, cheilectomy (resection of all bony prominences of the metatarsal head and base of the proximal phalanx) is required. Occasionally, arthroplasty of the first MTP joint is indicated.

### Hallux valgus

Hallux valgus refers to static subluxation of the first MTP joint. It is characterised by valgus (lateral) deviation of the great toe and varus (medial) deviation of the first metatarsal (Fig. 43.27). Bony exostoses develop around the first MTP joint, often with an overlying bursitis. In severe cases, exostoses limit first MTP joint range of motion and cause pain with the pressure of footwear. Hallux valgus is common, affecting 23% of adults aged between 18 and 65 years.<sup>127</sup> It is more common in women. Although it is more common in older athletes, it can also develop in adolescence.<sup>128</sup>

The development of hallux valgus appears to occur secondary to a combination of intrinsic (genetic) and extrinsic causes. There is some evidence for an association of the condition with:

- constricting footwear (e.g. high heels)
- excessive pronation: increased pressure on the medial border of the hallux, resulting in deformation of the medial capsular structures
- increased length of the first metatarsal and hallux<sup>129</sup>
- trauma to the medial and plantar ligament complex and medial sesamoid bone<sup>123</sup>
- others including cystic degeneration of the medial capsule, Achilles tendon contracture, neuromuscular disorders and collagen-deficient diseases.

**Figure 43.27** Hallux valgus

In the early phases, hallux valgus is often asymptomatic but as the deformity develops, pain arises at the medial eminence. The pain is typically relieved by removing shoes or by wearing soft, flexible, wide-toed shoes. Blistering of the skin or development of an inflamed bursa over the medial eminence may occur. In severe deformity, lateral metatarsalgia may occur due to the diminished weight-bearing capacity of the first ray.

Examination reveals the hallux valgus deformity often with a tender swelling overlying the medial eminence. Plain radiographs can image both the severity of the deformity and the degree of first MTP joint degeneration.

Initial treatment involves appropriate padding and footwear to reduce friction over the medial eminence. Correction of foot function with orthoses is essential. In more severe cases, surgery may be required to reconstruct the first MTP joint and remove the bony exostoses.

Minimally invasive surgical techniques for hallux valgus have been developed.<sup>130</sup> Orthoses are often required after surgery and gait re-education is needed to restore normal weight-bearing through the first ray.<sup>131</sup>

## Sesamoid injuries

The first MTP joint consists of the metatarsophalangeal joint and two regularly occurring sesamoid bones, that play a significant role in great toe function. Embedded within the two tendons of the flexor hallucis brevis, the sesamoids:

- functionally lengthen the first metatarsal
- protect the tendon of flexor hallucis longus
- transfer weight-bearing from the lateral to the medial aspect of the forefoot.

Bipartite sesamoids occur in approximately 30% of individuals and are bilateral 25% of the time.

The sesamoid bones can suffer stress fracture, sesamoiditis ('chondromalacia'), acute fracture, osteochondritis, osteoarthritis and bursitis.<sup>132</sup> Sesamoid stress fractures may occur in many sporting activities, but particularly in basketball players, tennis players and dancers. Most sesamoid abnormalities involve inflammatory changes and osteonecrosis. The medial sesamoid is more frequently affected. Injury may be caused by landing after a jump, increased forefoot weight-bearing activities (e.g. sprinting and dancing) or after traumatic dorsiflexion of the hallux. Pronation and progressive hallux valgus positioning may cause lateral displacement or subluxation of the sesamoids within the plantar grooves of the first metatarsal. This subluxation of the sesamoids may lead to erosion of the plantar aspect of the first metatarsal, resulting in pain underneath the first metatarsal head and arthritic changes reminiscent of patellofemoral pathology.

The patient complains of pain with forefoot weight-bearing and may display a supinated antalgic gait to avoid painful toe-off. Examination reveals marked local tenderness and swelling overlying the medial or lateral sesamoid. Movement of the first MTP joint is usually painful and often restricted. Resisted plantar flexion of the great toe is weak and painful.

Plain radiographs for this bone require an anteroposterior (AP), lateral and axial sesamoid view but radiographs are often not diagnostic for stress injury. They may show an acute fracture or bony sclerosis of sesamoid necrosis. MRI is often required to detect early stress fractures or more specific pathologies as mentioned above.

Recent onset or mild cases of sesamoid pain are traditionally treated with load modification, ice and possibly NSAIDs. Appropriate accommodative padding can partially relieve direct pressure to the sesamoids (Fig. 43.28). Orthoses can include this accommodation within the cushioning layer of the device. A carefully placed corticosteroid injection may provide pain relief for those athletes who must delay a rest period but it is not recommended. Ideal initial treatment of sesamoid

**Figure 43.28** Sesamoiditis—padding

stress fractures includes a several-week period of non weight-bearing in a boot or short leg cast. The duration is determined by frequent examination awaiting resolution of tenderness by firm palpation.

Gradual return to full weight-bearing can be bridged by using a highly curved stiff shoe or rocker bottom shoe. Transition to athletic activities should also be assisted

with the previously discussed orthosis which unloads the first MTP and places the foot into a laterally directed supinated position thereby reducing the toe-off force through the first MTP.

Non-operative management is preferable, but a few cases will fail this approach. Surgical fixation or sesamoidectomy is reserved for these recalcitrant few. Sesamoidectomy does risk developing hallux deformities. A recent surgical series estimated approximately 12 weeks to return to sport.<sup>133</sup>

## Plantar plate tear

with KENT SWEETING

Tears of the plantar plate may be the most common cause of pain under the second MTP joint, though it can occur at any of the MTP joints. It is also referred to as pre-dislocation syndrome, crossover toe deformity and floating toe syndrome. A fibrocartilaginous thickening of the MTP joint (Fig. 43.29a), the plantar plate:

- stabilises the MTP joint
- assists in the windlass mechanism due to its attachment to the plantar fascia
- resists hyperextension of the MTP joint
- absorbs compressive loads.

The second MTP joint is most likely to be affected as it is the longest metatarsal and has unopposed lumbricals and no plantar interossei insertions. Plantar plate tears usually result from repetitive overload from abnormal forefoot loading patterns resulting from hallux valgus, excessive pronation, short first metatarsal or long second metatarsal. The tear usually arises from the base of the proximal phalanx.<sup>134</sup>

The athlete usually complains of localised pain under the MTP joint. Swelling may be present, extending to the dorsal aspect of the joint. Neuroma-like symptoms may be experienced by patients due to irritation of the plantar digital nerve from the localised oedema.

(a)

**Figure 43.29** (a) Anatomy of the MTP joint demonstrating the plantar plate

(b)

**Figure 43.29 (cont.)** (b) Modified Lachman's anterior-posterior drawer test. The metatarsal head is stabilised and the proximal phalanx is dorsally translocated. A 2 mm or 50% joint displacement is a positive sign of plantar plate laxity (c) Taping. Plantarflexion strapping of the digit

Examination reveals pain at the base of the proximal phalanx which may be aggravated by dorsiflexion of the joint. In relaxed stance, a dorsiflexion deformity of the toe may be noted. This is often accompanied by a crossover deformity. The modified Lachman's test (anterior-posterior drawer) can also be utilised. The metatarsal head is stabilised and the proximal phalanx is dorsally translocated (Fig 43.29b). A 2 mm or 50% joint displacement is a positive sign of plantar plate laxity.

Ultrasound may reveal a hypoechoic defect in the plantar plate, usually at the distal attachment. Historically arthrography was used to demonstrate synovial hypertrophy and extravasation of dye into the flexor tendon sheath. Today, MRI is helpful to demonstrate a tear of the plantar plate. There is increased signal intensity within the plate, along with a loss of continuity.<sup>135</sup>

Treatment initially consists of ice, NSAIDs, relative rest, plantarflexion strapping of the digit (Fig 43.29c) and accommodative padding to reduce loads under the affected MTP joint. Orthoses and a stiff-soled shoe or rocker bottom shoe are also required. Some clinicians consider an extra-articular corticosteroid injection may also be useful but there have been no quality trials of this treatment. Primary repair of the plantar plate with or without a flexor tendon transfer may be required in patients that fail to respond to conservative measures.

(c)

### Corns and calluses

Excessive pressure on the skin may cause hypertrophy of the squamous cell layer of the epidermis, which manifests as corns and calluses. In the feet, corns and calluses result from uneven weight distribution and thus indicate abnormal foot biomechanics or poorly fitting footwear.

Treatment involves the removal of circumscribed corns and diffuse areas of callus with a scalpel, the wearing of well-fitting footwear and, if abnormal foot mechanics are present, orthoses. Petroleum jelly over the corn or callus and on the outside of the sock can also help.

### Morton's interdigital neuroma

So-called Morton's neuroma is not a true neuroma, but a swelling of nerve and scar tissue arising from compression of the interdigital nerve, usually between the third and fourth metatarsals (Fig. 43.30a). Excessive pronation contributes to metatarsal hypermobility and impingement of the interdigital nerve.

The patient complains of pain radiating into the toes, often associated with pins and needles, and numbness. A clicking sensation may be noticed. Pain is increased by forefoot weight-bearing activities and with narrow-fitting footwear, and is often relieved by removing the shoes.

(a)

(b)

**Figure 43.30** Morton's neuroma (a) Location of nerve entrapment in Morton's neuroma (b) Plantar metatarsal padding

Examination reveals localised tenderness and, in cases of extensive chronic proliferation, there may be a palpable click on compression of the metatarsal heads. Web space tenderness and toe tip sensation deficit may be present.<sup>136</sup>

Diagnostic confirmation with imaging can be performed for chronic cases considering surgical management. MRI demonstrating a neuroma greater than 5 mm is generally significant. Ultrasound has emerged as a viable technique to diagnose and distinguish an interdigital nerve from an intermetatarsal bursa.<sup>137, 138</sup>

Treatment consists initially of ice to alleviate acute tenderness. Plantar metatarsal padding to subtly separate the metatarsals and shoes with a wide toe box are used to reduce the side-to-side compression of the metatarsals (Fig. 43.30b). However, in chronic cases, little improvement is seen with padding. Intrinsic and extrinsic foot muscle strengthening exercises are indicated to maintain or improve the transverse arch and control of foot pronation. The use of orthoses is essential if excessive pronation is present.

Various interventions have been proposed.<sup>139</sup> Injection of corticosteroid and local anaesthetic agents in conjunction with the padding may provide lasting relief. An ultrasound-guided corticosteroid injection via a distal interdigital approach provided at least 9 months significant relief of symptoms for the majority of patients.<sup>140</sup> Injection with alcohol is also an option.<sup>141, 142</sup>

If the patient obtains no relief, radiofrequency ablation of the nerve appears to be a promising new therapy.<sup>143</sup> Recently, sonographically guided cryoneurolysis improved four of five Morton's neuroma patients.<sup>144</sup>

Surgical management is quite successful for those cases not responding to conservative care. Pain relief remains the principal goal of treatment; however, a resected neuroma will result in permanent numbness and this needs to be discussed with the patient prior to surgery. Decompression by neurolysis has been described as a successful intraoperative decision to preserve the nerve in some cases.<sup>145</sup>

### Plantar warts

The papovavirus causes plantar warts when it enters the skin. The warts can be particularly painful on weight-bearing. They should be differentiated from corns. Applying lateral pressure or pinching will be painful in warts, whereas corns are more painful with direct pressure. Gentle paring with a scalpel will also reveal the characteristic appearance of a plantar wart with fine black dots within a defined margin of white or brown tissue.

Plantar warts are best treated with chemical solutions containing salicylic acid. The overlying hyperkeratosis should be removed weekly to allow the chemicals to penetrate the wart. Blistering and abscess formation occur and require debridement with a scalpel and the application of a dressing.

## Onychocryptosis

Onychocryptosis (ingrown toenail) arises from abnormal nail growth or poor nail cutting. Patients often present in acute pain with tenderness on gentle palpation. Nails are often infected. Treatment with local and oral antibiotic therapy is required. Conservative treatment involves elevating the offending corner of the nail plate from the soft tissue, cutting a small 'V' into the middle of the nail distally (to take pressure off the edges) and stretching the soft tissue away from the nail with a cotton bud.

Surgical management consists of resection of the outer aspect of the nail to prevent the nail border injuring the soft tissue. Resection involves anaesthetising the toe and removing the nail border with appropriate nail splitters and forceps. All abnormal tissue is removed and the nail matrix treated with phenol to prevent regrowth.

## Less common causes of forefoot pain

### Stress fracture of the great toe

Stress fractures of the proximal phalanx of the great toe have been reported in adolescent athletes.<sup>99, 146</sup> Stress fractures in the distal phalanx can occur in ballet dancers. There appears to be an association with hallux valgus. Treatment involves a period of non weight-bearing rest of 4–6 weeks followed by graduated return to activity.

### Joplin's neuritis

Joplin's neuritis involves compression and irritation of the dorsal medial cutaneous nerve over the first metatarsal and first MTP joint. It usually occurs because of irritation from footwear and is common in patients with hallux abducto-valgus or exostoses around the first MTP joint.

The patient complains of pain radiating along the first ray into the hallux. Wearing appropriate footwear and using foam and felt to redistribute the load from the affected area generally provides relief. Orthoses may be required to prevent excessive pronation.

### Freiberg's osteochondritis

Freiberg's disease or osteochondritis of the metatarsal head affects adolescents between the ages of 14 and 18 years (Chapter 44). The metatarsal head appears fragmented on radiograph. Offloading of the metatarsal heads using padding and orthoses is essential to prevent permanent metatarsal head flattening that may predispose to adult osteoarthritis.

## Toe clawing

Toe clawing occurs secondary to short, tight long flexor tendons (Fig. 43.31). During the propulsive phase of gait, the long flexors contract to stabilise the toes. In the unstable foot, these long flexors contract excessively during the propulsive phase and the toes claw the surface in an attempt to maintain stability.

Clawing of toes does not result in pain itself but excessive pressure on the prominent joints and ends of toes often causes painful skin lesions.<sup>88</sup>

## Subungual haematoma

Subungual haematoma occurs when direct trauma or repetitive pressure from footwear leads to bleeding under the toenails. Pain arises from increased pressure under the nail and the nails appear black. The nail may eventually loosen from the nail bed.

Treatment of an acute subungual haematoma involves using a heated needle or paperclip to perforate the nail and release the collection of blood. Cover with a small dressing. Correctly fitting footwear and appropriate lacing techniques may prevent recurrence.

## Subungual exostosis

A subungual exostosis develops because of direct trauma. The patient presents with pain on direct pressure to the nail. The nail plate may be displaced from the nail bed due to elevation from the exostosis. Treatment requires the wearing of loose-fitting footwear, appropriate cutting of the nail and padding. Surgery may be required to remove the bony exostosis.

PART C

# Practical sports medicine

# The younger athlete

with NEBOJSA POPOVIC, BOJAN BUKVA, NICOLA MAFFULLI and DENNIS CAINE

*Youth is full of sport, age's breath is short; Youth is nimble, age is lame; Youth is hot and bold, age is weak and cold; Youth is wild, and age is tame.*

William Shakespeare (1564–1616) 'Crabbéd Age and Youth'

Participation in youth (i.e. child and adolescent) sports is popular and widespread. Many youngsters train year-round and specialise in their sports in childhood, and during adolescence some may reach peak performance and compete nationally or internationally. It is not uncommon for preteens to train 20 or more hours each week at regional training centres in tennis or gymnastics, to compete in triathlons, or for youngsters as young as 6–8 years of age to play organised hockey or soccer and travel with select teams to compete against other teams of similar calibre. Thus, knowledge about specific physiologic characteristics, management of orthopaedic conditions, injury prevention guidelines, and information regarding non-orthopaedic concerns is imperative to all individuals involved in the healthcare of young athletes.

### THE YOUNG ATHLETE IS UNIQUE

Engaging in sports activities at a young age has numerous health benefits, but also involves risk of injury. Indeed, the young athlete may be particularly vulnerable to sport injury due to the physical and physiological processes of growth. Injury risk factors that are unique to the young athlete include specifics of the musculoskeletal system such as an immature skeleton, nonlinearity of growth, maturity-associated variation, the adolescent growth spurt and the response to skeletal injury.<sup>1</sup> Young athletes might also be at increased risk because of immature or underdeveloped coordination, skills and perception, in addition to psychological issues. Although problems do not ordinarily arise at normal levels of activity, the more frequent and intense training and competition of young

athletes today may create conditions under which this susceptibility exerts itself.

### Nonlinearity of growth

The normal growth pattern is nonlinear; that is, differential growth of the body segments (head, trunk and lower extremities) occurs throughout growth and influences body proportions accordingly.<sup>2</sup> At birth, the relative contribution of head and trunk to total stature is highest and declines through childhood into adolescence. Thus, the child is characterised by a proportionally larger head and trunk, and shorter legs compared to an adult. In some events, for example rodeo 'mutton busting', one can anticipate that a young 'top-heavy' child would be at increased risk of falling off a sheep compared to an older child with proportionally longer legs.

One of the features of the child's skeleton is the existence of the epiphyseal growth zones (physis). It has traditionally been divided into four zones: the resting or germinal zone, the proliferation zone, the zone of hypertrophy and the zone of enchondral ossification, which is continuous with the metaphysis (Fig. 44.1).

In each segment of the young skeleton, for example the femur or humerus, the contribution to growth of distal and proximal parts are not equal. This is the concept of the 'fertile physis'. The proximal part of the humerus and distal part of the femur contribute much more in skeletal growth, an important factor in the treatment approach after skeletal injuries.

It could also be argued that under a given physical load, for example over a distance run, a child's locomotor

(a)

(b)

**Figure 44.1** (a) Anatomy of the physis (b) Different parts of the growing bone—the metaphysis, epiphysis, diaphysis and epiphyseal plate

apparatus would be exposed to greater stress: hence to a higher risk of overuse injury than that of an adult. Yet, often child athletes progress rapidly to training regimens, skills and stunts that were originally introduced and intended for more mature individuals.

### Maturity-associated variation

Maturity-associated variation depends on the sex of the young athlete. In general, girls are more mature than boys at a given age. Early-maturing boys have structural, functional and performance advantages in sports requiring size, strength and power over late maturers.

#### PRACTICE PEARL

Children of the same chronological age may vary considerably in biological maturity status, and individual differences in maturity status influence measures of growth and performance during childhood and adolescence.<sup>2</sup>

Chronological age (CA) may add yet another dimension of individual variation given that most youth sports are categorised by CA. Within a single age group (e.g. 12 years of age), the child who is 12.9 years of age is likely to be taller, heavier and stronger than the child who is 12.0 years of age, even though both are classified as 12 years of age. The fear is that an unbalanced competition between early and late-maturing and/or older and younger boys in contact sports such as martial arts and wrestling contributes to at least some of the serious injuries in these sports. A matching system based on physical attributes, although logistically difficult to implement, may be beneficial to equalising competition, to maintaining interest in participation, and to reducing potential for injury.<sup>3</sup>

### Unique response to skeletal injury

Often, the mechanism of injury in young athletes and adult athletes is the same. However, there are some significant differences in the type of injuries sustained by children and adolescents because of the differences in the structure of growing bone compared with adult bone. The different components of growing bone are indicated in Figure 44.1b.

The differences between growing and adult bone (Fig. 44.2) are summarised below.

- The periosteum is thicker in children and has considerable healing potential.
- The articular cartilage of growing bone is a thicker layer than in adult bone and can remodel.

**Figure 44.2** Contrasting features of growing bone (left) and adult bone (right)

- The junction between the epiphyseal plate and the metaphysis in children is vulnerable to disruption, especially from shearing forces.
- Tendon attachment sites—apophyses—are cartilaginous plates that, in children, provide a relatively weak cartilaginous attachment, predisposing to the development of avulsion injuries.
- The cortex of long bones in children is more resilient and elastic than adult bone, withstanding greater deflection without fracture. Thus, children tend to suffer incomplete fractures of the greenstick type, which do not occur in adults.
- During the adolescent growth spurt, structural changes in physeal cartilage occur that result in a thicker and more fragile epiphyseal plate.<sup>4</sup> Studies of the incidence of physeal fractures indicate an increased occurrence of fractures during pubescence.<sup>5,6</sup>
- It has been proposed that the adolescent growth spurt may also increase susceptibility to physeal injury by causing an increase in muscle-tendon tightness about the joints and loss of flexibility.<sup>7</sup> However, this concept is controversial.<sup>8</sup>
- The vascular supply is different especially in very young athletes.

As a result of these differences, a particular mechanism of injury may result in different pathological conditions in the younger athlete compared with the mature adult. The younger athlete is more likely to injure cartilage and bone or completely avulse an apophysis than to have a significant ligament sprain or tendinopathy. Some examples of different injuries in children and adults that are the result of similar mechanisms are shown in Table 44.1.

#### PRACTICE PEARL

**Younger athletes have a greater healing potential than adult athletes.**

### MANAGEMENT OF MUSCULOSKELETAL CONDITIONS

In children, traumatic injuries may result in fractures of the long bones or the growth plates, or soft tissue damage. Strong, incoordinate muscle contractions are more likely to lead to an avulsion fracture at the site of attachment of the muscle or tendon rather than to a tear of the muscle or tendon itself.

The osteochondroses are a group of conditions affecting secondary ossification centres of the growing bones. Although the aetiology of the osteochondroses is not well understood, non-articular osteochondroses may well be related to overuse (Table 44.2).

Each of the following common paediatric injury presentations are discussed in this chapter: acute fractures, shoulder pain, elbow pain, wrist pain, back pain or postural abnormality, hip pain, knee pain, painless abnormalities of gait and foot pain.

#### Acute fractures

Fractures occur in the young athlete due to the line of weakness between the epiphyseal plate and the formed bone, the relative weakness of apophyseal cartilage compared with the musculotendinous complex, and the direction and strength of the force. Four types of fractures are seen in the younger athlete: metaphyseal, physeal, diaphyseal and apophyseal avulsion fractures.

#### Metaphyseal fractures

Metaphyseal fractures occur especially in the forearm and lower leg. The most common type of fracture seen is a buckling of one side of the bone. The management of metaphyseal fractures in children depends on age, gender, the degree and plane of displacement, and the distance from the joint. The treatment usually simply consists of cast immobilisation and complications are very rare. Occasionally, angular or rotational deformity is present and requires open reduction and internal fixation.

**Table 44.1 Comparison of injuries that occur with similar mechanisms in children and adults**

Site	Mechanism	Injury in adult	Injury in child
Thumb	Valgus force as in 'skier's thumb'	Sprain of ulnar collateral ligament	Fracture of proximal phalangeal physis (usually Salter–Harris type III)
Distal interphalangeal joint of finger	Hyperflexion injury	Mallet finger	Fracture of distal phalangeal epiphysis Salter–Harris (type II or III)
Hand	Punching injury as in boxing	Fracture of metacarpal head	Fracture of metacarpal epiphysis Salter–Harris (type II)
Shoulder	Fall on point of shoulder	Acromioclavicular joint sprain	Fracture of middle third of clavicle epiphysis
	Abduction and external rotation force	Dislocated shoulder	Fracture of proximal humeral epiphysis Salter–Harris (type I or II)
Thigh/hip	Acute flexor muscle strain or extensor strain	Quadriceps strain or hamstring strain	Apophyseal avulsion of anterior inferior iliac spine or ischial tuberosity
Knee	Overuse injury	Patellar tendinopathy	Osgood–Schlatter disease or Sinding–Larsen–Johansson disease
	Acute trauma (e.g. skiing) injury	Meniscal or ligament injury	Fractured distal femoral or proximal tibial epiphysis, avulsion of tibial spine
Ankle	Acute inversion	Lateral ligament sprain	Salter–Harris type I or II fracture of tibia or fibula
Heel	Overuse	Achilles tendinopathy	Sever's disease

**Table 44.2 Types of osteochondroses**

Type	Condition	Site
Articular	Perthes' disease	Femoral head
	Kienböck's disease	Lunate
	Köhler's disease	Navicular
	Freiberg's disease	Second metatarsal
	Osteochondritis dissecans	Medial femoral condyle, capitellum, talar dome
Non-articular	Osgood–Schlatter disease	Tibial tubercle
	Sinding–Larsen–Johansson disease	Inferior pole of patella
	Sever's disease	Calcaneus
Physeal	Scheuermann's disease	Thoracic spine
	Blount's disease	Proximal tibia

**Physeal (growth plate) fractures**

Approximately 15% of all fractures in children involve the physis<sup>9</sup> or growth plate, and more than a third of these occur in organised sport settings. Fractures of the growth plate are of particular concern because of the dangers of interruption to the growth process via injury to the cells in the zone of hypertrophy.

Although more elaborate systems for describing acute physeal injuries are available,<sup>9</sup> the system most widely used was developed by Salter and Harris<sup>10</sup> (Fig. 44.3). Salter–Harris types I and II fractures usually heal well. However, these injuries are not as innocuous as originally described and may occasionally be associated with local growth plate closure and osseous bridging.<sup>9</sup>

**Figure 44.3** Salter–Harris classification of physeal (growth plate) fractures

Type III and IV fractures involve the joint surface as well as the growth plate and have a high complication rate. If these fractures are not recognised, they could produce permanent injury to the growth plate, resulting in growth disturbances. When recognised, accurate anatomical reduction must be performed to reduce the possibility of interference in growth and to minimise the possibility of long-term degenerative change. However, occasionally the initial insult can produce permanent growth arrest despite subsequent anatomical reduction.

Type V fractures are compressive force fractures of the physis and can lead to growth zone lesions. Type VI fractures are lesions of the periosteal attachment (Ranvier zone) and can also lead to growth zone disturbances.

Management of physeal fractures depends on the age and gender of the athlete, grade and plane of the displacement and the distance from the joint. In the paediatric population, they mostly require cast immobilisation only, or closed reduction and cast immobilisation (types I and II). Types III and IV may require percutaneous fixation using Kirschner wires.

#### PRACTICE PEARL

The common sites of physeal fractures in the younger athlete with recommended management and potential complications are shown in Table 44.3.

It is most important to recognise a physeal fracture. Radiographs should be obtained of both limbs (for comparison) if clinical features suggest growth plate injury. A normal radiograph does not exclude a growth plate fracture. A history of severe rotational or shear force with accompanying localised swelling, bony tenderness

and loss of function should be regarded as a growth plate fracture until proven otherwise. If there is any doubt regarding the diagnosis or management of these injuries, specialist orthopaedic referral is mandatory.

#### Diaphyseal fractures

Most fractures of the shaft of long bones do not involve the growth plate and metaphysis of the bone, but only the diaphysis of the long bone (especially in the forearm and lower leg). In younger athletes, fractures are often incomplete due to the thicker periosteum. They are referred to as 'greenstick' fractures. The treatment of diaphyseal fractures is usually through cast immobilisation only. Indications for surgical treatment depend on the degree of displacement, age and gender of the athlete.

#### Apophyseal (avulsion) fractures

Avulsion fractures occur at the apophyseal attachments of large musculotendinous units, that is, large tendons to bones or, less frequently, at ligament insertions. The common sites are at the attachment of the:

- sartorius muscle to the anterior superior iliac spine
- rectus femoris muscle to the anterior inferior iliac spine
- hamstring muscles to the ischial tuberosity
- iliopsoas tendon to the lesser trochanter of the femur
- gluteus medius to the greater trochanter of the femur
- anterior cruciate ligament to the tibial plateau
- patellar tendon to the tibial tubercle
- peroneus brevis to the base of the 5th metatarsal bone
- triceps to the olecranon
- forearm flexors and pronator to the medial epicondyle humerus.

In the younger athlete, apophyseal fractures are the equivalent of acute muscle strains in the adult. Instead of a tear of the muscle fibres in the mid-substance of the muscle or at the musculotendinous junction, the tendon is pulled away with its apophyseal attachment. Many patients will describe a 'pop' with the onset of discomfort. This is confirmed on plain radiographs (e.g. Fig. 30.17). Even though injury involving the apophyseal growth plate does not normally result in length discrepancy, angular deformity or altered joint mechanics, it may adversely affect training and performance as well as the long-term health of young athletes. The most common site of an avulsion fracture is the tibial tubercle at the attachment of the patella tendon, especially in football and basketball players. Radiographs should be performed in all cases.

Management depends on the degree of the displacement of the avulsed fragment of bone. It involves cast immobilisation and, in more displaced fragments, surgical reattachment. In general, apophyseal fractures around

**Table 44.3 Management and possible complications of physeal (growth plate) fractures in young athletes**

Site	Management	Potential complications
Distal radius fracture	Cast immobilisation (3–4 weeks)	Not recognised, growth disturbance
Supracondylar fracture of the elbow (undisplaced)	Sling (3 weeks)	Vascular compromise of brachial artery, median nerve damage, malalignment
Distal fibular fracture	Cast, non weight-bearing (4–6 weeks)	Growth disturbance can occur up to 18 months later
Distal tibial fracture	Cast, non weight-bearing (4–6 weeks)	Premature closure of physis can lead to angulation and leg length discrepancy
Distal femur fracture	Anatomical reduction	Greater incidence of growth discrepancies than in other fractures, Salter–Harris types I and II fractures; must be observed closely

the pelvis do not need surgical treatment because the displacement is mostly not significant and the continuity of the periosteum is preserved.

One common site of an avulsion fracture at a ligamentous attachment is at the attachment of the anterior cruciate ligament to the tibia. An acute rotational injury to the knee may present with the symptoms and signs of an anterior cruciate ligament tear. Instead of the in-substance tear common in adults, the more common injury in children is avulsion of the tibial spine or distal femoral attachment. Radiographs should be performed in all cases of acute knee injuries accompanied by haemarthrosis. Management involves surgical reattachment of the avulsed fragment and ligament.

The most commonly reported acute apophyseal sport injuries in the upper extremity involve the olecranon and medial epicondyle of the humerus. The vertebral ring apophysis is the site most often involved in the spine.

Management of avulsion fractures is identical to that for grade III tears of the muscle. It involves initial reduction of the pain and swelling, restoration of full range of motion with passive stretching and active range of motion exercises as symptoms settle, as well as a graduated program of muscle strengthening. Any biomechanical abnormalities that may have predisposed the athlete to this injury should be corrected. Reattachment is occasionally required when there is a large displacement of the avulsed fragment.

### Overuse injuries of the physis

Trends in children's and youth sports include increased numbers of participants, greater duration and intensity of training, and earlier specialisation and year-round training. Increased involvement and repetition of skills practiced at an early age and continued through the years of growth raises concern about risk of injury. In particular, there is concern that the tolerance limits of the physis (growth plate) may be exceeded by the repetitive physical loading required in

many sports, particularly during the adolescent growth spurt. Physeal growth disturbance as a result of injury can result in length discrepancy, angular deformity, or altered joint mechanics, and may cause significant long-term disability.

Physeal stress injuries are thought to develop when repetitive loading of the extremity disrupts metaphyseal perfusion which may inhibit ossification of the chondrocytes in the zone of provisional calcification. The hypertrophic zone continues to widen as the chondrocytes transition from the germinal layer to the proliferative zone. Widening of the physis may be seen radiographically, whereas physeal cartilage extension into the metaphysis has been shown with magnetic resonance imaging (MRI).

Physeal stress injuries were first recognised in baseball pitchers and are also found in other young athletes involved in overhead sports, including cricket, gymnastics, badminton, swimming and volleyball.

Treatment for physeal stress injury is straightforward: rest from loading of the extremity. However, in cases involving growth disturbance, corrective surgery may be required. Clinicians need to educate parents and coaches as to the existence of overuse physeal injury and the need for rest to ensure proper recovery and return to sport participation.

### Shoulder pain

Acute trauma to the shoulder in children may result in fracture of the proximal humerus, the clavicle or proximal humeral physis. Fractures of the acromion or the coracoid process are rare.

Dislocation of the glenohumeral joint is common in the adolescent but uncommon in the younger child. Dislocations in adolescents are associated with a high incidence of recurrence and development of post-traumatic instability. The management of acute dislocation of the shoulder is discussed in Chapter 24.

Stress fracture of the proximal humeral physis (growth plate) was first observed in young baseball pitchers, but

has since been reported in young athletes representing a variety of sports including cricket, gymnastics, badminton, swimming and volleyball.<sup>11</sup> Radiographs may show widening of the proximal humeral physis. Metaphyseal sclerosis and demineralisation or fragmentation of the epiphysis may also be present.<sup>12</sup> MRI should be performed if the X-ray is negative and clinical suspicion high. In most cases, subjects improved with rest and were able to return to their sport.

Shoulder impingement is also seen in the younger athlete. In the young athlete involved in throwing sports, the impingement is usually secondary to atraumatic instability, which develops because of repetitive stress to the anterior capsule of the shoulder joint at the end range of movement (Chapter 24). Impingement and rotator cuff tendinopathy also occur in swimmers where excessive internal rotation causes a tendency to impinge. The aetiology of these problems in throwers and swimmers is discussed in Chapters 8 and 9.

## Elbow pain

Delineating injury patterns to the elbow in children can be challenging, given the cartilaginous composition of the distal humerus and the multiple secondary ossification centres which appear and unite with the epiphysis at defined ages. The pitching motion in baseball, serving in tennis, spiking in volleyball, passing in American football, and launching in javelin throwing can all produce elbow pathology caused by forceful valgus stress, with medial stretching, lateral compression and posterior impingement.

The valgus forces generated during the acceleration phase of throwing (Chapter 8) result in traction on the medial elbow structures and compression to the lateral side of the joint. This may injure a number of structures on the medial aspect of the joint. Injuries include chronic apophysitis of the medial epicondyle, acute or chronic strain of the ulnar collateral ligament (also referred to as the medial collateral ligament) or avulsion fracture of the medial epicondylar apophysis. The ulnar nerve may also be damaged.

### PRACTICE PEARL

**Acute ulnar collateral ligament (UCL) injuries are increasing in young baseball pitchers at an alarming rate. Children who are still growing are more likely to injure the growth area of the elbow, but older adolescents are more likely to present with a frank UCL tear.**

Some young athletes have avulsion injuries where the ligament stays intact but pulls off a piece of bone. If the UCL is torn, non-operative treatment is attempted but if the ligament fails to heal, the patient often undergoes reconstructive Tommy John surgery if he or she wishes to continue throwing at a high level (Chapter 25).<sup>13</sup>

The lateral compressive forces may damage the articular cartilage of the capitellum or radial head. The long-term sequelae of these repetitive valgus forces include bony thickening, loose body formation and contractures.

Flexion contractures can occur because of repeated hyperextension. The majority of these contractures are relatively minor (less than 15°). Significant contractures (greater than 30°) should be treated with active and active-assisted range of motion exercises accompanied by a lengthy period of rest (e.g. 3 months).

Osteochondritis dissecans of the capitellum is also seen in pitchers and, more commonly, in gymnasts. Osteochondritis dissecans is a localised area of avascular necrosis on the anterolateral aspect of the capitellum. Initially, the articular surface softens and this may be followed by subchondral collapse and formation of loose bodies in the elbow. X-rays will frequently demonstrate the lesion. In cases with suspicious radiographic changes, MRI is critical to confirm the diagnosis as well as to characterise the extent and stability of the osteochondral lesion. The early stages of osteochondritis dissecans may respond well to rest. Surgical procedures include removal of loose bodies, joint debridement and fixation of stable fragments. The results of surgical management of this condition are variable.<sup>14</sup>

The younger child (under 11 years) may develop Panner's disease. This self-limiting condition is characterised by fragmentation of the entire ossific centre of the capitellum. Loose bodies are not seen in Panner's disease and surgery is not required.

## Wrist pain

Wrist pain in children may be acute or chronic. In acute conditions, it is mostly related to a distal radial fracture/epiphyseolysis or, rarely, scaphoid fracture.

Chronic dorsal wrist pain is commonly seen in gymnasts where pain is aggravated by weight-bearing with the wrist extended. The gymnast complains of tenderness over the dorsum of the hand and perhaps swelling. An often reported cause among gymnasts is a stress injury to the distal radial physis involving compromise of the metaphyseal and/or the epiphyseal blood supply.<sup>11</sup> Longstanding injuries are associated with typical radiographic changes, including widening, irregularity, haziness or cystic changes of the growth plate. Other causes of dorsal wrist pain include scaphoid impaction syndrome, dorsal impingement syndrome/capsulitis, tear of the triangular fibrocartilage complex and stress fractures.

Management of the younger gymnast with dorsal wrist pain includes relative rest, and splinting. Strengthening of the wrist flexors may also be useful in association with tape and pads to decrease hyperextension of the wrist. Most gymnasts with stress injuries involving the distal radial physis recover with rest; however, there are also

reports of stress-related premature closure of the distal radial growth plate leading to positive ulnar variance.<sup>15</sup>

Kienböck's disease of the wrist (Chapter 26) is an osteochondrosis of the lunate bone. It occurs generally in older patients (20 years old) and rarely in adolescents.

### Back pain and postural abnormalities

Younger athletes may present with pain or postural abnormalities, such as 'curvature' of the spine, or both.

#### Low back pain

Common causes of back pain in the younger athlete are similar to those in the mature adult. Minor soft tissue injuries to the intervertebral disc, the apophyseal joints and associated ligaments, and muscle strains in the paravertebral muscles usually respond well to reduction in activity. Manipulative treatment in the management of these conditions in the younger athlete is probably contraindicated.

Back pain is more common among young athletes participating in sports with high demands on the back, such as wrestling, gymnastics and American football, than other athletes or non-athletes.<sup>16</sup> Back pain in the young athlete may be associated with one or more of the following conditions: idiopathic scoliosis, spondylolysis, spondylolisthesis, disc degeneration, disc herniation, Schmorl's nodes, vertebral end-plate fracture and atypical Scheuermann's lesion (vertebral apophysitis). The spine, as with the rest of the skeleton, is at greater risk of injury during the adolescent growth spurt.<sup>16</sup>

Severe disc injuries and tumours are occasionally seen in the lumbar spine of the adolescent athlete. Biomechanical abnormalities such as leg length discrepancy, pelvic instability and excessive subtalar pronation may also indirectly lead to low back pain.

#### Idiopathic scoliosis

Idiopathic scoliosis accounts for 80% of structural scoliosis and is the most common cause of back discomfort in young athletes. Nearly 32% of adolescents with idiopathic scoliosis complain of back discomfort.<sup>17</sup> The pain is not related to the size or location of the curve and usually does not interfere with the patient's ability to perform daily activities.

Non-predictive but predisposing factors for the progression of the scoliosis before skeletal maturity include a family history of scoliosis, patient height-to-weight ratios, lumbosacral transitional anomalies, thoracic kyphosis, lumbar lordosis and spinal balance.

In general, the rate of progression of scoliosis in adulthood is much slower than that in adolescence and depends on the size of the curve once skeletal maturity has been reached.

The screening protocol for scoliosis in young athletes is the most important issue in the assessment of spine disorders. On physical examination the most common findings are: shoulder asymmetry, unequal scapular

prominence, appearance of an elevated or prominent hip, greater space between the arm and body on one side (with the arms hanging loosely on the side), head not centred over the pelvis, and a positive forward-bending test (Adam's test). A plain radiograph in anteroposterior and lateral view plays an important part in assessment.

In selecting appropriate treatment, the clinician must take into consideration the adolescent's remaining growth potential, the severity of the curve, as well as the pattern and location of the scoliosis. The available treatment choices are observation, non-surgical intervention and surgical intervention. It is imperative that clinicians know which option is appropriate for each individual patient.

Actively growing adolescents (Risser grade 2 or lower) with curves between 30° and 45° should be started on brace therapy at the time of the initial visit. In very immature patients (Risser grade 0 and pre-menarcheal if female) with curves exceeding 25° degrees, bracing should be started immediately. In most cases, growing adolescents with curves exceeding 45-50° require operative treatment (stabilisation) because other forms of treatment are ineffective to control or correct the scoliosis. Skeletally mature individuals with curves exceeding 50-55° also are at risk for curve progression and should be considered for surgical treatment.

#### Spondylolysis

Spondylolysis has received particular attention due to its high prevalence among athletes (Chapter 29). This condition may also occur in the younger athlete, particularly because of repeated hyperextension of the lumbar spine. This injury is typically seen as a result of participation in ballet, gymnastics, diving, volleyball, fast bowling in cricket and serving in tennis. The management of this condition is discussed in Chapter 29. The amount of hyperextension activity must be reduced and this may involve some alteration in technique.

There is considerable debate whether these defects in the pars interarticularis are congenital or acquired. They are probably acquired, even though this may occur at an extremely young age. A fibrous union develops across the defect and this is susceptible to injury. The presence of a pars interarticularis defect does not automatically mean that this is the cause of the patient's pain. MRI may confirm that the pars interarticularis defect is the site of an acute fracture.

#### Spondylolisthesis

Spondylolisthesis is defined as the forward slippage of one vertebra on its adjacent caudal segment (Chapter 29). Spondylolisthesis is one of the most variable conditions affecting the paediatric spine. The severity of its clinical manifestation ranges from a coincidental radiographic finding in asymptomatic patients, to a disabling deformity that produces severe postural and gait disturbances, pain

and neurologic impairment affecting the lower extremities, the bowel and the bladder. Just as the initial symptoms can vary, so does the radiographic severity of the slippage, which ranges from a few millimetres of anterior displacement to complete dislocation of L5 anteriorly over the sacrum (called *spondyloptosis*). Unabated controversy continues regarding optimal surgical treatment in severe cases.

Spondylolisthesis is divided into five types based on the radiographic findings and age at onset: the dysplastic, isthmic, degenerative, post-traumatic and pathologic types. The age of the patient and the degree of listhesis determine whether observation, non-operative management, or immediate surgical stabilisation is necessary. It has been commonly believed that the younger the patient, the greater the risk of progression of the deformity.

Low-grade spondylolisthesis (<50% slip) is treated conservatively, with surgical treatment reserved for patients with continued symptoms, disability, or in the case of juvenile onset, evidence of progressive listhesis. High-grade spondylolisthesis (>50% slip) generally requires surgical treatment. Objective opinions that reduction of the slip angle and L5 incidence correlate with better clinical outcome suggest that this is becoming the treatment of choice, although the degree of reduction is still being debated. Current expert opinion favours *partial* reduction—by postural means if possible—maintained by internal fixation as the appropriate middle ground to achieve neurologic safety, sagittal realignment and a high fusion rate.<sup>17</sup>

### Postural abnormalities

The commonest postural abnormality of the spine in the younger athlete is excessive kyphosis of the spine due to an osteochondrosis (Scheuermann's disease). This condition occurs typically in the thoracic spine, but is also seen at the thoracolumbar junction. The thoracolumbar form of Scheuermann's disease, which encompasses both the thoracic and lumbar regions of the spine, is more common in athletes than non-athletes and also is considered to be associated more frequently with back pain.<sup>16</sup> Children can present with acute pain. It usually presents in later years as an excessive thoracic kyphosis in association with a compensatory excessive lumbar lordosis.

The typical radiographic appearance of Scheuermann's disease is shown in Figure 44.4. This demonstrates irregularity of the growth plates of the vertebrae. The radiological diagnosis of Scheuermann's disease is made on the presence of wedging of 5° or more at three adjacent vertebrae.

Management is aimed at preventing progression of the postural deformity and involves a combination of joint mobilisation, massage therapy to the thoracolumbar fascia, stretching of the hamstring muscles and abdominal

**Figure 44.4** Radiographic appearance of Scheuermann's disease

muscle strengthening. A brace may be worn to decrease the thoracic kyphosis and lumbar lordosis. Surgery may be indicated if the kyphosis is greater than 50° or if signs of spinal cord irritation are present.

### Hip pain

Hip pain is a more common presenting symptom in the younger athlete than the mature adult. The causes of hip pain in the younger athlete are shown in Figure 44.5. There are a number of possible causes of persistent hip pain and decreased range of motion in the younger athlete, in addition to those seen in the older athlete such as FAI, labral tears, stress fractures and snapping hip (all discussed in Chapters 31 and 32). MRI plays an important role in the diagnosis of the young athlete with hip pain.

### Apophysitis

A number of large musculotendinous units attach around the hip joint. Excessive activity can result in a traction apophysitis at one of these sites, usually the ischial tuberosity at the attachment of the hamstring muscles, the anterior inferior iliac spine at the attachment of the rectus femoris, the anterior superior iliac spine at the attachment of the sartorius, or the iliopsoas attachment

**Figure 44.5** Causes of hip pain in children

to the lesser trochanter. Conservative therapy, including relative rest and modification of the athlete's activity level and strengthening, is usually effective.<sup>18</sup>

### Perthes' disease

Perthes' disease is an osteochondritis affecting the femoral head. Perthes' disease is usually unilateral. It typically affects children between the ages of 4 and 10 years, is more common in males, and may be associated with delayed skeletal maturation. It presents as a limp or low-grade ache in the thigh, groin or knee.<sup>19</sup> On examination there may be limited abduction and internal rotation of the hip. Radiographs vary with the stage of the disease, but may show increased density and flattening of the femoral capital epiphysis (Fig. 44.6).

Management consists of rest from aggravating activity and range of motion exercises, particularly to maintain abduction and internal rotation. The age of the child and the severity of the condition according to radiographic findings (Herring or Catarell scale) will affect the intensity of the management. For initial stages in children under 6 years of age, pain killers, and avoiding jumping and

**Figure 44.6** Radiographic appearance of Perthes' disease

running are sufficient to control the disease. In older children (over 6 years) with lateral pillar collapse of the femoral head over 50%, surgical treatment is indicated.

Various surgical techniques are used to cover the femoral head and protect it from further damage. Most frequently, femoral osteotomy or iliac augmentation techniques (or both) are used. In borderline cases, usage of orthoses is indicated. It is important for parents to prevent their children from engaging in sports that involve running and jumping, especially during the healing period of the femoral head (lasting approximately 2–3 years).

The condition usually resolves and return to sport is possible when the child is symptom-free and radiographs show some improvement. The main long-term concern is the development of osteoarthritis due to irregularity of the joint surface.

### Slipped capital femoral epiphysis

A slipped capital femoral epiphysis (SCFE) may occur in older children, particularly between 12 and 15 years,<sup>20</sup> but can also be observed in younger children. Radiographs in SCFE have a similar appearance to a Salter-Harris type I fracture.

A slipped capital femoral epiphysis is associated with endocrinological disorders, biomechanical stress on the proximal femoral physis and high body mass index (BMI). It occurs typically in overweight boys who tend to be late-maturing, and thus is of increased concern given the trend towards adolescent obesity and selection for heavy boys in sports like American football and rugby. It has also been suggested that increased physical stress associated with intense sports participation may precipitate this condition.<sup>21</sup>

The slip itself may occur suddenly or, more commonly, as a gradual process. There is sometimes associated pain, frequently in the knee, but the most common presenting symptom is a limp. Examination reveals shortening and external rotation of the affected leg. Hip abduction and internal rotation are reduced. During flexion the hip moves into abduction and external rotation.

Bilateral involvement is common (approximately 20% of cases). Slips may compromise the vascular supply to the femoral head and lead to avascular necrosis.

**Figure 44.7** Radiographic appearance of slipped capital femoral epiphysis

#### PRACTICE PEARL

Radiographs show widening and irregularity of the growth plate, cystic changes in the proximal femoral metaphysis and a line continued from the superior surface of the neck of the femur does not intersect the growth plate (Fig. 44.7).

Avascular necrosis is the most common and severe complication of a slipped capital femoral epiphysis and requires orthopaedic assessment. A gradually progressing slip is an indication for surgery. The aim is to prevent further slipping of the epiphysis by transcervical fixation using one or more cannulated screws. An acute severe slip occurs occasionally. This is a surgical emergency.

#### Irritable hip

'Irritable hip' or transitory synovitis is common in children, but should be a diagnosis of exclusion. It is often related to a respiratory, often viral, infection. The child presents

with a limp and pain that may not be well localised. Examination reveals painful restriction of motion of the hip joint, particularly in extension and/or abduction in flexion. Radiographs and blood tests are usually normal. Ultrasound may demonstrate fluid in the joint capsule and MRI can help in challenging cases.

In the majority of cases, a specific cause is never identified and the pain settles after a period of bed rest and observation.<sup>22</sup>

#### Knee pain

Knee pain, especially anterior knee pain, is a common presentation in the younger athlete. Common causes of anterior knee pain include: Osgood-Schlatter disease, Sinding-Larsen-Johansson disease, patellofemoral joint pain (Chapter 36), patellar tendinopathy (Chapter 36), and referred pain from the hip.

#### Osgood-Schlatter disease

Osgood-Schlatter disease is an osteochondritis that occurs at the growth plate of the tibial tuberosity. Repeated

**Figure 44.8** Sites of maximal tenderness in Sinding-Larsen-Johansson disease (black arrow) and Osgood-Schlatter disease (red arrow)

contraction of the quadriceps muscle mass may cause softening and partial avulsion of the developing secondary ossification centre.

This condition is extremely common in adolescents at the time of the growth spurt. It is usually associated with repeated forced knee extension, especially in sports involving running and jumping, such as basketball, football or gymnastics. Pain around the tibial tuberosity is aggravated by exercise.

Examination reveals tenderness over the tibial tuberosity (Fig. 44.8). There may be associated tightness of the surrounding muscles, especially the quadriceps. The presence of excessive subtalar pronation may predispose to the development of this condition.

The diagnosis of Osgood-Schlatter disease is clinical and radiographs are usually not required. In cases of severe anterior knee pain with more swelling than expected, a radiograph may be indicated to exclude bony tumour. Although all bone tumours are rare, the knee is a site of osteogenic sarcoma in the 10-30 year age group. The typical radiographic appearance of Osgood-Schlatter disease is shown in Figure 44.9.

**Figure 44.9** Radiographic appearance of Osgood-Schlatter disease

Osgood-Schlatter disease is a self-limiting condition that settles at the time of bony fusion of the tibial tubercle. Its long-term sequel may be a thickening and prominence of the tubercle. Occasionally, a separate fragment develops at the site of the tibial tubercle. Athletes and parents need to understand the nature of the condition as symptoms may persist up to full maturity.

### Management

Management of this condition requires activity modification. While there is no evidence that rest accelerates the healing process, a reduction in activity will reduce pain.

#### PRACTICE PEARL

As this condition occurs in young athletes with a high level of physical activity, it may be useful to suggest they eliminate one or two of the large number of sports they generally play. There is no need to rest completely. Pain should be the main guide as to the limitation of activity.

Symptomatic management via relative load reduction is key. The athlete may consider a stretching program and some massage therapy to the quadriceps muscle. Muscle strengthening can be introduced as pain allows.

Correction of any predisposing biomechanical abnormality, such as excessive subtalar pronation, is necessary. Neither injection of a corticosteroid agent nor surgery is required. Very occasionally, the skeletally mature person

may continue to have symptoms (e.g. with work-related kneeling) due to non-union. The separate fragment should then be excised.

### **Sinding-Larsen–Johansson disease**

This is a similar condition to Osgood-Schlatter disease. It affects the inferior pole of the patella at the superior attachment of the patellar tendon (Fig. 44.8). It is much less common than Osgood-Schlatter disease, but the same principles of management apply.

### **Patellar tendinopathy**

Although symptomatic tendinopathy was thought to be rare in children, Professor Jill Cook showed that patellar tendinopathy is prevalent in junior basketball players.<sup>23, 24</sup> Management is as per the tendinopathy management principles in adults (Chapter 36).

### **Referred pain from the hip**

Conditions affecting the hip, such as a slipped capital femoral epiphysis or Perthes' disease, commonly present as knee pain due to the innervation by the obturator nerve. Examination of the hip joint is mandatory in the assessment of any young athlete presenting with knee pain.

### **Popliteal cysts**

Popliteal cysts (called 'Baker's cysts') are cystic formations filled with gelatinous mass developing in the popliteal fossa. The usual presenting complaint in children is the presence of a mass at the back of the knee. The most common site of origin is the bursa of the gastrocnemius and semimembranosus muscle. The cyst often appears gradually and may be fairly large when first noticed. Occasionally, it is found after an injury. Popliteal cysts in children are usually minimally symptomatic or asymptomatic, and not related to an intra-articular pathologic process.

Physical examination reveals a firm cystic mass in the popliteal fossa, often medially located and usually distal to the popliteal crease. It is most prominent when the knee is hyperextended with the patient in a prone position. Plain radiographs and ultrasound are the imaging techniques of choice. MRI should be obtained if an atypical history or abnormal physical findings are present.

In the vast majority of cases, popliteal cysts do not require treatment. The cyst usually resolves spontaneously over a period of months to a few years. Surgical excision of a popliteal cyst is indicated only when symptoms are severe and limit the range of motion of the knee, and have not resolved with at least several months of follow-up.

### **Less common causes of knee pain**

Osteochondritis dissecans may affect the knee. This generally presents with intermittent pain and swelling

of gradual onset. Occasionally, it may present as an acute painful locked knee. This acute presentation is associated with haemarthrosis and loose body formation. Radiographs may reveal evidence of a defect at the lateral aspect of the medial femoral condyle. Osteochondritis dissecans requires orthopaedic referral for possible fixation of the loosened fragment or removal of the detached fragment.

In juvenile rheumatoid arthritis (Still's disease) of the knee, there is a persistent intermittent effusion with increased temperature and restricted range of motion. There may be a family history of rheumatoid arthritis. Investigation requires serological examination, including measuring the level of rheumatoid factor and the erythrocyte sedimentation rate and, if indicated, serological examination of joint aspirate. The child's activity should be adapted to avoid using the painful joints while exercising other body parts and promoting cardiovascular fitness.

A differential diagnosis in paediatric arthritis that is relatively rare but is increasing in the developed world is acute rheumatic fever.<sup>25</sup> As there may be no history of sore throat and carditis may be silent, the diagnosis can only be made if the practitioner maintains an index of suspicion for this condition. Investigations should include markers of inflammation (erythrocyte sedimentation rate, C-reactive protein), serology for streptococci (anti-streptolysin-O titre, anti-DNaseB titres) and echocardiography. Penicillin and aspirin taken orally remain the mainstays of management.

A partial discoid meniscus may cause persistent knee pain and swelling in the adolescent athlete. A complete discoid meniscus is characterised by a history of clunking in the younger child (approximately 4 years). There is usually marked joint line tenderness, and a palpable snapping at the joint line with flexion/extension and/or rotation. MRI will demonstrate the lesion. Arthroscopy may be diagnostic and therapeutic.

Adolescent tibia vara (Blount's disease) is an uncommon osteochondritis that affects the proximal tibial growth plate. It usually affects tall, obese children around the age of 8–10 years. It is generally unilateral and radiographs show a reduced height of the medial aspect of the proximal tibial growth plate. Surgery may be required to correct any resultant mechanical abnormality.

### **Painless abnormalities of gait**

It is not uncommon for a child to present with an abnormality of gait. The child is typically brought in by a parent who has noticed an unusual appearance of the lower limb or an abnormal gait while walking or running. The child may complain of foot pain (see below). However, in many instances, the abnormal gait is painless.

It is not sufficient to say that the child will 'grow out of it'. The child requires a thorough biomechanical

## Anterior cruciate ligament (ACL) injuries in the skeletally immature athlete

with HÅVARD MOKSNES

Instability and functional impairments following ACL tears in skeletally immature children have been increasingly recognised.<sup>26–32</sup> Intrasubstance ACL ruptures are most worrisome due to the serious long-term health effects of potential early osteoarthritis.<sup>33</sup> Furthermore, the open growth plates on both sides of the knee joint warrant particular caution before surgical interventions with ACL reconstruction are performed.<sup>34, 35</sup>

### Risk factors

It seems that boys may be more prone to rupturing their ACL before maturity, while girls have an increased risk through and after puberty,<sup>36, 37</sup> and most authors state that the incidence of these injuries is rising. However, no epidemiological studies are available with historical or new data to support this assumption. The perceived increased occurrence of ACL tears in children and adolescents may be due to higher participation and early specialisation in sports; however, it can also be caused by increased awareness and advances in diagnostic methods.

### Treatment

Treatment algorithms for ACL ruptures in skeletally immature children vary around the world.<sup>28–40</sup>

### PRACTICE PEARL

One of three different treatment algorithms is traditionally recommended to skeletally immature children after ACL injury:<sup>38, 39, 41</sup>

- a transphyseal (adult) surgical reconstruction
- non-operative treatment with active rehabilitation and an optional delayed ACL reconstruction if specific criteria are met
- a physeal-sparing ACL reconstruction.

Unfortunately, the methodological quality in research on treatment of ACL injuries in younger populations has been poor.<sup>42</sup> Thus, there is a need for adequately sized prospective multicentre studies to heighten the scientific base for which treatments should be offered to children after suffering an ACL injury. Specific decision criteria with regard to which of these algorithms a child should be recommended have not been established, and treatment decisions are traditionally based on the experiences and practice of the individual orthopaedic surgeon or institution.

### (i) Surgical reconstruction

Surgical reconstruction of the ACL in a skeletally immature patient is usually advocated to provide ligamentous knee joint stability, and to potentially protect the menisci from subsequent injury. However, surgical treatment may also damage the epiphyseal growth plates and result in various growth disturbances.<sup>34, 35, 43</sup> Furthermore, development of the graft during the remaining skeletal growth is unknown, and different authors have discussed the possibility of increased risk of re-injuries in adulthood due to impaired biomechanical properties.<sup>31, 44, 45</sup>

### (ii) Primary active rehabilitation without surgical reconstruction

Conversely, primary active rehabilitation without surgical reconstruction has been documented to give favourable functional outcomes for a majority of children who have undergone supervised active rehabilitation programs.<sup>30</sup> Still, between one-third and half of these children report a change in their preferred sports activities from level 1 to level 2 activities (e.g. abandoning pivoting sports). Studies reporting comparable numbers following surgical treatment have not yet been reported. Either way, paediatric ACL injuries should be thoroughly assessed on an individual basis and treatment algorithms should be presented in a balanced fashion to the child and his or her parents.

### (iii) Physeal-sparing ACL reconstruction

Intercondylar tibial eminence avulsion fractures involving the ACL are frequent and have long been assumed to be the most common injury involving the ACL in skeletally immature children.<sup>46</sup> Since a paper on surgical treatment of tibial spine avulsion injuries with involvement of the ACL from Roth in 1928,<sup>47</sup> consensus has developed that the majority of these injuries should be treated surgically with fixation to the bone without intervening with the epiphyseal growth plate.<sup>48, 49</sup>

### Surgery or rehabilitation?

The clinical challenges with treatment for paediatric ACL injuries are related to the weighing of risks and benefits between primary surgical treatment and primary active rehabilitation without surgical intervention.<sup>50</sup> Regardless of whether the child is advised to undergo surgical treatment or not, there is substantial support in the literature that supervised rehabilitation should be performed exhaustively through all phases before the ultimate treatment decision is taken (Chapter 35).

### Rehabilitation

Paediatric rehabilitation has to be performed in close collaboration with the parents. Exercises and goals have to be adjusted compared to traditional rehabilitation

*continued*

protocols because children are not small adults, and they cannot be expected to perform unsupervised training independently. Rehabilitation exercises are primarily focused on neuromuscular stimulation and control, with less focus on muscular strength and hypertrophy.<sup>50, 51</sup> Throughout the first two phases the child should be guarded from pivoting activities, and possibly should also wear a protective brace in school and training. Training sessions including exercises to facilitate proper alignment and adequate landing techniques have been successfully implemented in injury prevention

programs,<sup>52–54</sup> and are also recommended through phases 2 and 3 of an ACL rehabilitation protocol.

Similarly, rehabilitation after surgical interventions has to be thorough and individualised with regard to the child's physiological and psychological maturity to achieve successful outcomes. Additionally, a longer time from surgery to return to sport should be advocated as emerging data from international registries suggest that young athletes have a high risk of suffering a second ACL injury following an ACL reconstruction.<sup>55–59</sup>

assessment, which may reveal a structural abnormality. The most common biomechanical problems in children are rotational abnormalities originating from the hip and the tibia causing either in-toed or out-toed gait.

If the child is asymptomatic and biomechanical abnormalities are not marked, no treatment is indicated. If abnormalities are marked or if the child is symptomatic, management may involve physiotherapy, as well as the use of braces or night splints when the child is very young and during periods of rapid growth. In the older child, orthoses can be used to compensate for the deformity.

## Foot pain

Foot pain of gradual onset is a common presenting symptom in the younger athlete. The causes of foot pain are either acquired and congenital foot deformities such as flat feet, metatarsus adductus, clubfoot, vertical talus, pes calcaneovalgus or toe abnormalities, or osteochondroses of the foot such as Köhler's disease and Freiberg's disease. Examination of younger athletes with foot pain requires precise determination of the site of maximal tenderness.

## Sever's disease

Heel pain is a common complaint in the skeletally immature athlete. Sever originally described<sup>60</sup> this condition as an inflammatory condition to the apophysis (Sever's apophysitis). It is a self-limited disease.

The patient complains of activity-related pain and examination reveals localised tenderness and swelling at the site of insertion of the Achilles tendon. There may be tightness of the gastrocnemius or soleus muscles, and dorsiflexion at the ankle is limited. Biomechanical examination is necessary. Radiographic examination is usually not required except in persistent cases.

Management consists of activity modification so that the child becomes pain-free. The patient should be advised that the condition will typically always settle, usually within 6–12 months, but occasionally symptoms will persist for as long as 2 years. A heel raise should be inserted in shoes. Stretching of the calf muscles is also advisable.

Any biomechanical abnormalities should be corrected. Orthoses may be required. Strengthening exercises for the ankle plantarflexors should be commenced when pain-free and progressed as symptoms permit. Corticosteroid injections and surgery are contraindicated in this condition.

There is MRI evidence that this condition is not an inflammation within the apophysis, but rather is a chronic (repetitive) injury to the actively remodelling trabecular metaphyseal bone.<sup>61, 62</sup> This condition should be treated as a stress fracture with a limited period of partial or non weight-bearing<sup>61</sup> and temporary discontinuation of the offending activity.

## Tarsal coalitions

Congenital fusions of the bones of the foot may be undetected until the child begins participation in sports. The most common form is a bony or cartilaginous bar between the calcaneus and navicular bone. The second most common coalition is between the calcaneus and talus. Calcaneocuboid coalition is the least common form. There is often a family history. The adolescent may present with midfoot pain, after recurrent ankle sprains or after repetitive running and jumping. The pain may be associated with a limp.

Examination reveals restriction of subtalar joint motion. There may be a rigid flat-foot deformity. Radiographs taken at 45° oblique to the foot may confirm the diagnosis, but if these are normal and clinical suspicion persists, a CT scan or MRI should be obtained.

Management may require orthotic therapy. Surgical excision may be necessary in a young patient with severe symptoms or after failure of conservative therapy. The bony or cartilaginous bar may recur after surgery.

## Köhler's disease

Köhler's disease is a form of osteochondrosis affecting the navicular bone seen in young children, especially between the ages of 2 and 8 years, and more frequently in boys. The exact cause of Köhler's disease is not known. It has

been suggested in the literature that because of its late ossification relative to the other tarsal bones, the navicular is vulnerable to mechanical compression injury.

The child complains of pain over the medial aspect of the navicular bone and often develops a painful limp. Tenderness is localised to the medial aspect of the navicular bone. Radiographs reveal typical changes of increased density and narrowing of the navicular bone. Management in a walking cast for 6 weeks may accelerate relief of the symptoms. Orthoses should be used if biomechanical abnormalities are present. The natural history of the disease is spontaneous resolution of clinical symptoms and the radiographic abnormalities over time.

### **Apophysitis of the tarsal navicular bone**

Pain on the medial aspect of the tarsal navicular in the older child may result from a traction apophysitis at the insertion of the tibialis posterior tendon to the navicular. This condition is often associated with the presence of an accessory navicular (Fig. 43.16) or a prominent navicular tuberosity. Management involves modification of activity, local electrotherapy and NSAIDs, with orthoses to control excessive pronation if this is present.

The accessory navicular which is found in 2.5% of children can cause pain by itself. Throughout early childhood, this condition is not noticed. However, in adolescence, when the accessory navicular begins to calcify, the bump on the inner aspect of the arch becomes noticed. For most, it is never symptomatic. However, for some, there is some type of injury, whether a twist, stumble or fall, that makes the accessory navicular symptomatic.

### **Apophysitis of the fifth metatarsal**

A traction apophysitis at the insertion of the peroneus brevis tendon to the base of the fifth metatarsal is occasionally seen. Examination reveals local tenderness and pain on resisted eversion of the foot. Management consists of modification of activity, stretching and progressive strengthening of the peroneal muscles.

### **Freiberg's disease**

Freiberg's disease (infarction) is an osteochondrosis causing collapse of the articular surface and adjacent bone of the metatarsal head. It is commonly thought to be due to avascular necrosis of the metatarsal head as demonstrated by destructive radiographic changes. The second metatarsal is most commonly involved (especially in ballet dancers), the third occasionally, and the fourth rarely. It occurs most frequently in adolescents over the age of 12 years.

Standing on the forefoot aggravates pain. The head of the second metatarsal is tender and there is swelling around the second metatarsal joint. Radiographs reveal a flattened head of the metatarsal with fragmentation of the growth plate. However, these changes may lag well behind the symptoms. Isotopic bone scan or MRI are more sensitive investigations.

If Freiberg's disease is diagnosed early, management with activity modification, padding under the second metatarsal and footwear modification to reduce the pressure over the metatarsal heads may prove successful. If the symptoms persist, surgical intervention may be necessary.

### **Flat foot**

The exact incidence of flat foot in children is unknown. It is undoubtedly one of the most common 'deformities' evaluated by sports medicine clinicians. Most often, flat foot is a reflection of ligamentous laxity in the foot resulting in an abnormally low or absent arch.

In asymptomatic paediatric patients with a hypermobile flat foot, no treatment is indicated. Orthopaedic shoes, including various heel modifications, moulded heel cups, medial arch support and other orthoses, have traditionally been prescribed, even though there is no scientific evidence that such measures are efficacious.

In symptomatic patients, arch support and other orthoses may be of benefit. In some cases, where bony abnormalities caused by tarsal coalition (rigid type of flat foot) are present, surgical intervention is indicated if conservative treatment does not achieve satisfactory results.

# Military personnel

with STEPHAN RUDZKI, TONY DELANEY and ERIN MACRI

*The limbs of soldiers are in as much danger from the ardor of young surgeons  
as from the missiles of the enemy.*

Confederate surgeon Julian John Chisholm's observations on the limitations of medical care for military personnel in the American Civil War (1861–1865)

In the United States (US) Army, injuries and injury-related musculoskeletal conditions are responsible for more than 660 000 visits annually.<sup>1</sup> Injuries are the biggest cause of disability in the US Army.<sup>1</sup>

In this chapter, we discuss the principles of sport and exercise medicine that will help you provide services to a military population.

We introduce:

- the special culture of the military environment
- epidemiology of military injuries
- common military injuries with a sport and exercise medicine focus (i.e. not major trauma).

## SPECIAL MILITARY CULTURE

Clinicians who provide medical and physiotherapy care in a military setting have a challenging task. An important difference between civilian and military practice is the compulsory nature of physical training. All military recruits undergo exercise regimes that are designed not only to improve their fitness, but also to prepare them physically and psychologically for extreme environments, discomfort and pain (Fig. 45.1). Military trainees have not always had a background of physical training. Increasingly, young adults come into the military with little experience of contact sports or regular physical activity. It is challenging to bring them to a required level of strength and aerobic fitness without causing injury.

The traditional military culture generally encouraged personnel to continue exercising despite early warning signs of pain that would cause civilian athletes to stop or slow down. Many recruits conceal injuries until graduation for fear of medical 'back squadding' (recruits held back

in training) and derision from fellow recruits and their superiors. A soldier who finishes a forced march by walking on a broken ankle for 20 km with a fully weighted rucksack receives accolades and respect from peers and superiors.

Further to the drive towards pushing through pain, soldiers with a history of previous injury demonstrate an increased pain threshold—they feel less pain for a given stimulus compared to controls.<sup>2,3</sup> Pain thresholds may also be related to environmental and psychological factors

**Figure 45.1** Physical training in the military takes place within a distinct culture and environment  
ISTOCKPHOTO

(e.g. the common experience of World War II soldiers reporting no pain during the heat of battle despite severe injuries).<sup>4</sup>

As a consequence of these changes in experiencing or reporting of pain, military members often present to clinics with musculoskeletal injuries that are severe and debilitating, requiring longer periods of rehabilitation. Patients may present stoically, making it challenging to determine the true severity of pain or injury.

Because of the cultural overlay and late presentation in at least some military settings, it is common for patients to present with multiple concurrent pathologies. It is therefore very important to take a thorough history and physical examination (Chapter 14 and 15) on the initial presentation even if under time pressures. Concurrent pathology should always be considered in a patient whose progress is slow or who does not respond to treatment considered appropriate for the initial diagnosis.

## EPIDEMIOLOGY OF MILITARY INJURIES

Recruit populations have an especially high incidence of injury and attrition. In New Zealand, the injury rate for recruits was more than five times that of trained personnel.<sup>5</sup> High attrition rates represent a significant cost. An injured soldier cannot perform his or her duties even if physically fit, and a moderate level of injury can impinge on the combat readiness of individual units.

US military studies have shown that training injury incidence rates range from 120 to 144 injuries/100 soldiers/year<sup>6</sup> in infantry, special forces and ranger units and 360/100/year for Naval Special Warfare training.<sup>7</sup>

These rates are far greater than the rates of injury in wars themselves. The Watson Institute monitors the cost of war: more than 970 000 Iraq and Afghanistan veteran disability claims were registered with the US Department of Veterans Affairs as of April 2016.<sup>8</sup> Rates of musculoskeletal injury in combat are estimated at around 3 per 1000 deployed soldiers per year. However, when a group of soldiers is monitored prospectively the rate is 10 times as high.

One of the larger reports of the type of musculoskeletal injuries highlights the proportion of fractures when soldiers are in the combat setting (as distinct from the training setting when soft tissue injuries dominate) (Fig 45.2).<sup>9</sup> The most common sites of fracture are humerus, femur, tibia and fibula.

Injuries are not just a problem within a barracks setting. Non-battle injuries in US service personnel have been a major cause of medical evacuation from Iraq and Afghanistan. Referred to as DNBI (disease and non-battle injury), these conditions had an incidence rate of 130 per 1000 combat years and resulted in over 80% of the evacuations required from Afghanistan and Iraq in 2001–2012.<sup>9,11</sup> The importance of rehabilitation is underscored

**Figure 45.2** Fractures and soft tissue injuries provide the bulk of military injuries in the combat setting<sup>10</sup>  
ADAPTED FROM BELMONT ET AL.<sup>9</sup>

by the fact that >90% of these injured military personnel returned to duty. Also relevant to the sports medicine community is that 50 000 anterior cruciate ligament (ACL) injuries were sustained among almost 2 million US troops during 10 years in Afghanistan and Iraq.<sup>9</sup>

Historically, the lower limb comprised the bulk of combat injuries (Table 45.1a), but recent wars have seen an increase in spinal/trunk injuries and spinal cord injury as a result of more powerful explosives.<sup>9,17</sup> The back, knee and wrist/hand are body regions commonly affected in those medically evacuated. This pattern of military injuries (i.e. being primarily lower limb in nature) presents in contrast to the Australian civilian workplace where back injury is the most common injury (25%) followed by the hand (14.3%) and finally lower limb injuries (10.8%).<sup>18</sup> Overuse is the most common cause of military training injuries.<sup>6,7,14,15</sup>

Wearing combat body armour is a risk factor in the development of low back pain during a military deployment.<sup>19,20</sup> In a prospective cohort study of US troops who deployed to Afghanistan for 12 months, moderate or worse low back pain occurred in 22% (175/805) and there was some back pain in 77% of the soldiers. Risk of back pain was sharply increased (relative risk >4.0) if the combatant wore body armour for greater than 6 hours a day or wore equipment weighing >32 kg. The incidence of low back pain in deployed US troops increased 20 times from 1.5/1000 in 2001 to 29.8/1000 in 2010. See Chapter 29 for discussion of the biopsychosocial factors that contribute to back pain.

**Table 45.1 (a) Types and incidence of injuries by country**

Body part	US infantry <sup>12</sup>	US military <sup>13</sup>	Australian recruits <sup>14</sup>	Australian Army <sup>14</sup>	South African recruits <sup>15</sup>	New Zealand recruits <sup>4</sup>
Ankle/foot	11.6%/20.8%	13%	18.3%/11.9%			35%
Knee/lower leg	17.6%/15.1%	22%	32.1%/7.3%			16%
Low back	10.2%	20%				
Spine				15.2%		
Lower limb				39.6%	80%	
Upper limb				19.4%		

**(b) Cause of injuries by country**

Cause	US infantry <sup>12</sup>	Afghanistan/Iraq medical evacuations <sup>13</sup>	Australian recruits <sup>14</sup>	Norwegian recruits <sup>16</sup>	New Zealand recruits <sup>4</sup>
Training-related	47%	19–21%	19.2%		
Falls/jumps		18%			
Motor vehicle-related		12–16%			
Running			36.6%		28%
Obstacle course			14.6%		
Basic training				20–25%	
Acute overexertion					37%
Team sports					25%

Injuries cause disproportionate morbidity in young military populations. In a US military population, injuries accounted for 56% of sick-call diagnoses, but caused nearly 10 times the number of limited-duty days as illness. Soldiers with lower extremity running injuries spent seven times more days on a restricted duty profile than those with non-running injuries.<sup>21</sup> In outpatient clinics, 80–90% of all limited-duty days accrued by US Army trainees and infantry soldiers were the result of training-related injuries (Table 44.1b).<sup>6</sup>

### COMMON MILITARY INJURIES

The range of injury and illness facing clinicians who serve the military greatly exceeds that usually seen in civilian medicine. In the military, individuals are exposed to extremes in temperature, biological and chemical agents, and communicable diseases (e.g. sexually transmitted, tropical). Traumatic injuries can result in concussion or traumatic brain injury, spinal cord injury, limb amputation, and injuries that can affect multiple systems and often require urgent medical care. For example, significant risk for injury occurs in diving operations, including

submariner evacuation and rescue. However, the majority of the injuries tend to be related to environmental exposure (e.g. barotrauma, decompression illness, cold exposure, marine life exposure) rather than to mechanical mechanisms of injury, and thus most diving injuries are of a non-musculoskeletal nature.<sup>22, 23</sup>

Psychosocial factors can influence the recovery trajectory of military sports injuries (see also Chapter 5). Experiencing deployment can affect emotional and psychological health, even in situations of peacekeeping missions, resulting in issues ranging from fatigue and exhaustion to depression, post-traumatic stress disorder and suicidal ideation. Mental health is a major issue in military medicine and suicide rates are higher among military populations than among civilians.<sup>9</sup>

The following discussion will address musculoskeletal and sports injuries. However, maintain a broad perspective when assessing sports injuries as often these other factors present at the same time. Many 'injury' chapters (Part B) in this volume are relevant to the military population. This chapter highlights common specific military issues and treatment that is particular to this population.

**Figure 45.3** Running is a predominant source of exercise in many forces. Competition is high and environments are usually extreme compared with recreational running programs ISTOCKPHOTO

### Overuse injuries of the lower limb

There are three peaks of overuse lower limb injuries in the military. The first and greatest is among recruits, the second in trained soldiers preparing for special forces selection (Fig 45.3) and the third is older soldiers training to pass annual fitness assessments.

The most common lower limb overuse injury is leg pain due to medial tibial stress syndrome (see Chapters 4 and 38). Early identification with correction of training errors and biomechanical factors often leads to rapid resolution. Recalcitrant medial tibial stress syndrome may require customised orthoses, gait retraining and more appropriate footwear where possible.

A significant proportion of recalcitrant medial tibial stress syndrome may be due to underlying exertional compartment syndrome (see Chapter 38). We have encountered resting compartment pressures >50 mmHg (normal resting <15 mmHg) in military trainees with largely medial tibial pain and tenderness. Changes in running technique (shortening stride length, landing more towards the forefoot) decreased leg pain and increased pain-free running distance in US Army recruits

at the United States Military Academy at West Point (see Chapter 38).<sup>24-26</sup>

The incidence of stress fracture in military recruits varies from 1-30%, with female rates generally higher than male rates.<sup>15, 27-32</sup> The most common sites of stress fracture are the tibia, metatarsals, pelvis and femur.<sup>33</sup> Previous stress fracture and lower baseline levels of weekly exercise are well-recognised risk factors.<sup>32</sup> There may be genotypic predisposition.<sup>32</sup>

To prevent stress fractures, as well as other injuries, aim to have recruits enter physical training with a reasonable level of fitness (as measured by the 20 m shuttle run). The issue of fitness at entry and injuries is discussed in more detail later in this chapter. Correction of biomechanical faults, and reduction of training to 60-70% of the injury-causing load, will contribute to rapid recovery and return to full training. Complete rest is contraindicated as this leads to loss of cardiorespiratory fitness and often depression. Training should change from large marching and running volumes to cycling, rowing and swimming pool work. For more on stress fracture aetiology see Chapter 4 and for treating specific stress fractures, please see the index. Medial tibial stress syndrome, exertional compartment syndromes and bone stress injuries can coexist. All personnel presenting with lower limb injuries should be evaluated for referred pain from the spine (Chapters 5, 6 and 29).

### Blister injuries

Blister injury from endurance marching has been a major problem for infantry soldiers throughout history. Among Canadian military, there was a 43% incidence of blisters during a 56 km night march carrying an 11 kg load.<sup>34, 35</sup> High rates of blister injury occur in recruits in the US Marine Corps and US Navy.<sup>36</sup> The morbidity associated with blisters should not be underestimated.<sup>37</sup>

Blisters are caused by shear forces acting on the skin, mainly due to friction while braking. This causes a mechanical split in the skin layers, which subsequently fills with fluid. Moist (sweaty) skin is most prone to blister formation because of increased friction and softening of the hard outer layer of skin (stratum corneum).<sup>38</sup> Braking forces on the foot increase with increased rucksack load.<sup>39</sup>

Sock type reduces the incidence of blisters. During a 3-day road march in the United Kingdom (UK), soldiers wearing a nylon inner sock had fewer blisters per person than those with either a single or double woollen sock.<sup>40</sup> A study in runners suggests that an acrylic sock results in fewer and smaller blisters than a cotton sock.<sup>38</sup> A joint US military task force recommended the use of synthetic-blend socks to prevent blisters.<sup>41</sup>

In addition to type of sock, use of an inner sock can reduce the severity and associated morbidity of blister

# JOURNAL OF THE ROYAL ARMY MEDICAL CORPS

**Fig 45.4** The *Journal of the Royal Army Medical Corps* (cover shown) along with *Military Medicine* provide valuable research and education

A 2016 COVER IMAGE, COURTESY OF THE JOURNAL OF THE ROYAL ARMY MEDICAL CORPS

injuries compared to a single sock.<sup>42</sup> Foot powder does little to reduce blister incidence in recruits and may even increase the incidence of blister formation.<sup>43</sup>

Boots have traditionally been blamed for the problem of blisters, but changes in boot fit, style and composition have had little effect on blister incidence.<sup>40, 44, 45</sup> Nevertheless, the following strategies are recommended for boot fitting and blister prevention:<sup>42</sup>

- wear a sock, sock liner and insoles (if applicable)
- have a load on your back when fitting boots
- measure both feet; length and width
- fit length first
- push the foot forwards in unlaced boot; ensure 1.5 cm space behind the heel
- push the foot backwards; ensure 1.5 cm from the longest toe to the end of boot
- ensure the boot width over the arch is snug but not tight
- fit the boots at the end of a day's activity, when the foot has spread
- apply sports tape directly to the feet before a long march; this may prevent blisters

- use off-the-shelf heat-mouldable orthoses to reduce shearing loads to the sole of the foot
- reduce heel lift and blistering by tightening boot laces over the dorsum of the foot and tying a reef knot to lock the lace at the anterior ankle joint.

## Parachuting injuries

Military parachuting has the potential to cause severe injuries.<sup>46</sup> Military parachutists use static line parachutes with limited manoeuvrability. In conditions where the prevailing winds exceed 5–8 knots, the parachutist has limited ability to reduce speed on landing. Dirt landing strips and airports are hazardous landing areas. Night descents are associated with a greater rate and severity of injury.<sup>46</sup> Paratrooper body weight influences risk of injury, particularly when the drop zone is on land.<sup>47</sup> There appears to be a relatively high rate of thoracic spine injuries in military parachutists jumping with operational loads.

Military round parachutes should not be used in wind conditions over 10 knots for trainees and 13 knots for trained static line paratroopers. If the wind on a drop zone is a steady 10 knots, there is a high probability of 15–18 knot gusts every 10–15 minutes. A 20 knot wind carries a parachutist into an obstacle at four times the force of a 10 knot wind (i.e.  $F = 1/2mv^2$ ). There is often real or perceived pressure to complete training or military exercise jumps in marginal wind conditions. Most military mass parachuting injuries occur when a strong wind gust comes through after the jump has been initiated. Our experience is that the cost of aborting a jump due to wind is dwarfed by the financial and human cost of injuring highly trained paratroopers or special forces operators, many of whom will not return to pre-injury duties.

### PRACTICE PEARL

Prophylactic ankle bracing significantly reduced ankle sprains and fractures in US Army paratroopers.<sup>48</sup>

Prophylactic ankle bracing significantly reduced ankle sprains and fractures in US Army paratroopers<sup>48</sup> and it also reduced the amount of time spent on medically restricted duties.<sup>49</sup> It has been estimated that for every dollar expended on a parachute ankle brace, a saving of between US\$7–9 could be achieved in medical and personnel costs.<sup>50</sup>

## The ageing defence forces

Retirement ages are extending to 60 for full-time defence personnel and up to 65 for some reservists. With ageing, incidence of injury may increase as may risk of

central obesity, insulin resistance, hyperlipidaemia, hypertension, cardiovascular disease and neoplasia. Attention to lifestyle, exercise and diet is equally as important as in the general population.

## INJURY PREVENTION IN THE MILITARY

This chapter extends the principles of injury prevention outlined in Chapter 12 and in specific injury chapters (e.g. Chapter 35, prevention of ACL injuries) to focus on prevention in the military setting. Risk factors for injury can be divided into intrinsic (specific to an individual, e.g. age, height, foot shape, sex and body weight) or extrinsic (training errors, footwear or environmental considerations such as weather or running surface). This distinction is important in a military context because military forces must recruit from a civilian pool with a wide range of physical and athletic abilities, and seek to train these new members to achieve and maintain a standard of fitness relevant to the physical demands of the profession. There is little or no scope to select out applicants with intrinsic risk factors, as most military forces are required to take applicants from the broadest possible pool.

During recruit training, very high rates of injury lead to medical discharge and a loss of personnel. Australian recruits who developed an injury during recruit training were 10 times more likely to fail to complete training than those who were not injured.<sup>51</sup> US male recruits who were discharged during training sustained injuries three times more frequently than those not discharged; discharged females sustained injuries at twice the rate of non-discharged females.<sup>52</sup>

As it is costly to attract and process new recruits, minimising recruit attrition during basic training is an important objective for all military forces. Addressing modifiable extrinsic factors can provide the greatest yield in terms of decreasing injury levels and allowing the broadest range of entrants to successfully enter into a military career.

### Injury surveillance

Injury surveillance is the necessary precursor to injury prevention; it allows for the identification of incidence, location, nature and cause of injury. Population-based data are necessary in order to target interventions appropriately.

Ideally, military services should adopt a public health approach to injury prevention as a framework.<sup>53</sup> The public health approach is characterised by four steps:

1. surveillance
2. risk factor identification
3. intervention implementation
4. evaluation (Fig. 45.5).<sup>54</sup>

**Figure 45.5** The public health model that is appropriate for the military setting. Note the similarities with the injury prevention model outlined in Chapter 12

Surveillance data are fundamental to priority setting, but are dependent on reliable and valid data collection and dissemination. Without such data, it is nearly impossible to measure the impact of interventions.<sup>53</sup>

The aim of any military injury surveillance system should be to provide commanders with accurate and reliable information on the type, nature and cause of injury, in conjunction with well thought out strategies for injury prevention. The army dictum 'do not come to me with problems, just solutions' is especially pertinent in military settings.

The public health approach to injury prevention was utilised to identify and eliminate ACL ligament ruptures at an Australian Army Recruit Training Centre as detailed below.<sup>55, 56</sup>

1. *Surveillance*: data identified a greater than expected number of ACL ruptures occurring in an obstacle course landing area.
2. *Risk factor analysis*: rubber matting installed to provide shock absorption was causing ACL injuries due to increased friction and 'stickiness' on landing.
3. *Intervention*: removal of the rubber matting and its replacement with river pebbles.
4. *Evaluation*: no further ACL ruptures at this particular location after removal of the rubber matting.

The success of this approach highlights the utility of following a public health approach. A similar approach has been adopted with other key risk factors including initial level of aerobic fitness and running distance (see relevant sections below).

Despite evidence to support strategies to prevent injuries in a military setting, effecting change is challenging as in all walks of life.<sup>57</sup> Officers and non-commissioned officers (NCOs) may seek to maintain and

honour traditions, and may resist changes in training regimes or minimum fitness standards. For example, there are conflicting opinions within the military as to whether fitness standards should be different for men and women if they are working in the same trade. One argument is that a combat engineer needs to meet the standards for being a combat engineer regardless of gender.

To summarise, the implementation of changes must consider the cultural environment of the military and a strategic plan implemented in order to ensure a smooth and effective transition.<sup>58</sup> In recent times, Western militaries have moved towards gender-free assessments of physical capability that are valid predictors of work performance. Australia has removed all sex barriers to military employment in 2016. All jobs in the Australian Defence Force are open to women who are able to pass the relevant occupation-specific tests. The effects this change will have on injury type, frequency and severity will be the subject of prospective study and evaluation.

### Sex as a risk factor for injury

In Australian, British and American troops, there are higher rates of injury and illness among female soldiers than their male counterparts.<sup>59-62</sup> Overall morbidity of injury in women is also greater.<sup>63</sup> Medical discharge rates are higher among women in both Australia and Britain.<sup>60, 61</sup>

An increased risk of injury was first identified in 1976 at the US Military Academy at West Point with the introduction of female cadets.<sup>64</sup> On average women had lower aerobic fitness than men ( $\text{VO}_2\text{max}$ , 46 mL/kg/min versus 59 mL/kg/min) and this variable was associated with injury incidence.<sup>65</sup>

When stratified by 1 mile run time, the risk of injury between men and women was comparable, with the highest risk of injury in the slowest group.<sup>63</sup> Of note was that 51% of the women were in the group with the longest run time compared to 1% of the men. Lower peak  $\text{VO}_2$  is also an independent risk factor for time-loss injury.<sup>66</sup> For a standardised level of physical activity, UK male recruits worked at a lower cardiovascular strain than females (24% vs 33% of heart rate reserve), and this additional cardiovascular strain is believed to increase fatigue, thus predisposing to injury.<sup>62</sup> Sex is therefore not an independent risk factor for injury when controlled for aerobic fitness levels among recruits.<sup>61</sup>

### Aerobic fitness

The initial level of aerobic fitness of a recruit has been shown to be a predictor of both injury and successful completion. In an Australian Army recruit cohort, aerobic fitness was measured using the 20 m shuttle run test (SRT).<sup>67, 68</sup> Lower scores on the 20 m SRT were related to

(a)

(b)

**Figure 45.6** (a) The risk of recruit attrition based on 20 m SRT (b) The rate of recruit injury based on 20 m SRT  
REPRODUCED FROM POPE<sup>70</sup> WITH PERMISSION

increased risk of attrition (Fig. 45.6a) as well as increased risk of injury (Fig. 45.6b).<sup>51</sup> The least fit soldiers (20 m SRT score 3.5) were 20 times more likely to not complete training than the fittest recruits (score 13.5). If injured, fit subjects were 25 times more likely to recover from their injury than the least fit subjects with an injury. Similar relationships between fitness, injury rates and attrition have been seen in British Navy and Army recruits.<sup>61, 69</sup>

One and 2 mile run times (both proxies for aerobic fitness) are significant predictors of injury in US Army and infantry recruits, respectively.<sup>12, 63, 71</sup> As mentioned above, recruits of equivalent aerobic capacity have similar rates of injury. However, in a female cohort of US Marine Corps recruits, a slower 2 mile run time was associated with increased incidence of stress fractures. It was suggested that stress fractures may be reduced if women participated in pre-training activities designed to improve aerobic fitness.<sup>33</sup>

It should not be surprising that faster runners get fewer injuries. They are, almost by definition, good runners, and therefore less likely to sustain a running-related injury. Fitter individuals also do not experience

the same level of physiological strain during recruit training as those with lower levels of aerobic fitness. Less-fit individuals work closer to their maximum workload during recruit training and thus are at increased risk of injury.

The situation of a variable aerobic fitness start point and fixed endpoint could be viewed as a recipe for injury.<sup>51,63</sup> Ensuring that recruits arrive at training centres with a minimum level of aerobic fitness is a logical strategy to reduce the risk of injury and subsequent attrition. A screening 20 m SRT test was introduced at all Australian Army recruiting centres in 1997, and only recruits who scored higher than level 7.5 on the 20 m SRT were allowed to proceed to the recruit training battalion. The Royal Navy used a 2.4 km treadmill run to assess initial aerobic fitness.<sup>72</sup> Following introduction of the screening test, the pass rate in recruit training increased by 10%, and the number of recruits applying for voluntary release decreased from 15% to 6%. Overall, pre-enlistment aerobic testing positively impacted on recruit training pass rates.

The US Army tried a slightly different approach, in which they identified recruits with poor aerobic fitness at entry and then provided them with an in-service remedial physical fitness program before starting basic combat training (BCT). Women who undertook this remedial training then began BCT with similar mean 2 mile run times compared with non-remedial women, and had similar graduation success and time-loss injury rates.

Men with poor aerobic fitness (slower 2 mile run time) also undertook remedial training, but they did not improve their fitness to the level of normal entry male recruits. These men began BCT with considerably slower mean 2 mile run times than normal entry male recruits, and were ultimately less likely to graduate and more likely to suffer a time-loss injury.<sup>52</sup> Thus, the remedial program improved initial fitness levels in female, but not male, recruits within a predetermined time period.

These data suggest to us that encouraging potential recruits to achieve a minimum level of aerobic fitness before presenting to a recruit training centre may result in better outcomes than investing in remedial training once enlisted. Regardless of the method employed, overall evidence suggests that improving aerobic fitness levels prior to basic training could help to decrease the risk for injury and attrition.<sup>33</sup>

## Body composition

If aerobic fitness level influences risk of injury and subsequent attrition rates in the military, would body composition also be a contributing factor? It has been noted that, in the US Army's view, 'obesity is associated with being unfit and unsoldierly'.<sup>63</sup> This is a view shared

by many military forces, and most have programs in place to assist members to maintain their weight within prescribed ranges of body mass index (BMI) or percentage body fat.

The US Army weight control program has the stated aims of ensuring that soldiers are physically fit for their combat mission and that they present 'a trim military appearance'. US Army regulations consider body composition to be a subcomponent of fitness.<sup>63</sup> Using defined body fat standards, it has been estimated that 5% of eligible men and 30% of eligible women would be excluded from enlistment in the US military based on failing to meet these standards.

There is a clear relationship between body composition and performance on run tests: 1 and 2 mile run times increase with increasing percentage body fat.<sup>63</sup> For males, the highest percentage body fat group had more injuries; however, in females, the leanest had more injuries.<sup>63</sup>

Current cohorts of young adults are less fit than previous generations of young adults entering military service in the US, as mean times for 1 and 2-mile runs have increased since 1987.<sup>73</sup> US Army recruit height, weight and BMI values have progressively increased, with increases of both body fat and fat-free mass in male recruits. Body composition data on female recruits does not show a consistent trend.<sup>73</sup>

In Norwegian recruits, BMI was an independent risk factor for injury, while height and weight were not associated with injury.<sup>16</sup> In Australian recruits, none of these measures predicted injury.<sup>51</sup> Also, despite the US Army's views on obesity, there were no significant differences in attrition between Army recruits who met body weight standards and those who did not, regardless of sex, provided they met physical fitness standards on entry.<sup>74</sup>

### PRACTICE PEARL

In considering the conflicting evidence available regarding BMI as an independent risk factor for injury, it is important to recognise that efforts might best be served focusing on overall fitness levels rather than body composition per se in assessing suitability for entry into the forces.

## Previous injury

Many studies have linked history of injury and likelihood of a new injury. After adjusting for weekly distance, there was a 65% increased risk of injury in runners with a history of previous injury<sup>75</sup> and a doubling of the risk in those with previous injury.<sup>76</sup> After adjusting for age and sex, previous injury was a strong predictor of injury

with an odds ratio of 1.5.<sup>77</sup> In one study of runners training for a marathon, half of the participants who reported an injury had sustained a previous injury and 42% had not completely rehabilitated before starting a training program.<sup>78, 79</sup> Controlled rehabilitation reduced the number of injuries in soccer.<sup>80</sup>

Previous injury and incomplete rehabilitation are therefore strong risk factors for recurrent injury. Rehabilitation is complete when an athlete is free from pain, muscle strength has returned to the pre-injury level and joint range of motion is restored.<sup>80</sup>

Clinicians responsible for the care of soldiers have a responsibility to ensure that complete recovery from injury has occurred before clearing them to return to full duties. Sports medicine clinicians appreciate that musculoskeletal injuries can only recover fully with adequate functional training.

#### PRACTICE PEARL

Consistent with the principle of specificity, a soldier will only recover sufficiently to return to full duties if given a functional training regime to prepare for full duties.<sup>81</sup>

### Weekly running distance

Overtraining, and in particular, excessive running distance, is the most significant underlying cause of lower limb injuries in athletic populations.<sup>82, 83</sup> The only risk factor for injury consistently identified in running studies is weekly running distance. There is an almost linear relationship between increasing weekly distance and the incidence of injury in both men and women.<sup>75, 76, 84-87</sup> A sudden increase in weekly distance without a gradual build-up (or 'spike' of >10% per week) is considered a training error.<sup>87, 88</sup> Training errors such as running too frequently, too fast or for too long are major causes of injury in both beginner and experienced runners, accounting for up to 60% of injuries.<sup>82, 87, 89, 90</sup> We recommend Dr Tim Gabbett's review of sports injuries and training loads to all who work in the military setting (Chapter 12).<sup>91</sup>

### Reducing weekly run distance

Most military forces use running tests ranging from 1.6 km (1 mile) to 5 km (3 miles) to assess physical fitness. The distance of the Australian Army physical training test has been reduced from 5 km to 2.4 km on the basis that reducing the test distance might reduce the training distances and result in a concomitant reduction in overtraining. However, attempts such as these have met with varying degrees of success worldwide.

**Figure 45.7** Marching has historically been a mainstay of military forces, both in training and in active deployments  
ISTOCKPHOTO

In US studies spanning the Marine Corps, Army and Navy, recruits given lower mileage running programs sustained fewer injuries with no subsequent differences in performance on run tests or other physical fitness tests.<sup>92-95</sup> One study demonstrated a 54% reduction in stress fracture incidence compared to the high-mileage group.<sup>92</sup> The US Department of Defense estimated in 1995 that the reduction in running mileage had saved US\$4.5 million in medical care costs and nearly 15 000 training days annually by preventing stress fractures alone.<sup>96</sup>

### Cross-training and other program modifications

There are effective alternatives to running to condition recruits. Marching with rucksacks in place of running was investigated in Australia with subsequent reduction in injury rates and morbidity, while improvements in performance on run tests and  $\text{VO}_2\text{max}$  were as good as a group given a traditional running program (Fig. 45.7).<sup>14, 97</sup> Load bearing or pack marching is more occupation-specific to the military environment than distance running in a singlet, shorts and shoes. There is considerable gain in aerobic conditioning from shorter, high-intensity training. Given the variety of careers in the military, with varying physical and intellectual demands, imposing a single rigid training regime on all recruits, regardless of physique, sex, age and aspiration, is unrealistic.

Some level of running is essential in military training programs, but the design of running programs may reduce the risk of injury. Interval training and periodisation are other training modifications that have been successfully used to reduce injuries.<sup>60, 94, 98</sup>

In Australia, sport and exercise physician Dr Stephan Rudzki published the results of an intervention that consisted of:

- discontinuing road runs as formed groups
- introducing 400–800 m interval training
- reducing test run distance from 5 km to 2.4 km
- standardising route march speed, and
- introducing deep water running as an alternate aerobic activity.

The incidence of injuries decreased 46% among men but increased in women. Overall, there was a striking cost saving because of the much lower rates of medical discharge and medical investigation.<sup>60</sup>

In a US study, recruits were divided into ability groups based on initial 2 mile run times. Running speed was managed to keep effort at between 70–83% of  $\text{VO}_{2\text{max}}$ . This modified program was compared with a traditional training program. The proportion of recruits who failed the Army Physical Fitness Test (APFT) was lower in the modified program than the traditional training group (1.7% vs 3.3%). After adjustment for initial fitness levels, age and body mass index, the relative risk of an injury in the traditional training group was about 50% greater in both men and women.<sup>99</sup>

Training modifications nearly abolish the incidence of pelvic stress fractures in female recruits.<sup>98</sup> Interventions included a reduction in route march speed from 7.5 km/h to 5 km/h and placing shorter women at the head of the column to reduce stride length. Individual step length was promoted instead of marching in step, march and run formations were more widely spaced, and interval-running training replaced traditional middle-distance runs. The rate of pelvic stress fractures fell from 11% to 0.6%.<sup>98</sup>

Deep water running is an aerobic activity that can rest the lower limbs and periodise impact loading.<sup>100</sup> It is performed in the deep end of a swimming pool, normally with the aid of a flotation vest or belt. This form of training will maintain existing aerobic performance for up to 6 weeks.

To summarise, a comprehensive review of injuries in the US Armed Forces stated that:

*Military and civilian research indicates that high running volume significantly increases the risk for lower extremity injury. During initial military training, about 25% of men and about 50% of women incur one or more training-related injuries. About 80% of these injuries are in the lower extremities and are of the overuse type—a condition brought about by training volume overload (generally excessive running relative to initial fitness level and running capability of the individual).<sup>41</sup>*

#### PRACTICE PEARL

Reducing running distances among recruits is a logical strategy to reduce injury rates while still attaining minimal physical fitness standards. Ideally, recruits come to training in good condition; this has been associated with fewer injuries.<sup>101</sup>

### Running experience

The risk of running injuries declines with increased running experience.<sup>75</sup> This appears contradictory in the context of the clear association between running distance and injury, but may be related to experience (i.e. chronic adaptation of tissues to long-term running programs, improved running mechanics with experience) and/or the 'healthy runner' effect.<sup>82, 90, 102</sup> The 'healthy runner' describes the phenomenon that only those without injury can continue with a running program on a long-term basis. This suggests that 'healthy runners' have the intrinsic characteristics required to become long-term runners in the first place, while others will stop running due to an inability to tolerate the sport. Alternatively, if experience causes reduced injury rates over time, then this would suggest that the reason military recruits tend to have higher injury rates is because they are new to the intensity of the training regime. Either way, runners with less than 3 years of regular running experience have twice the risk of lower limb injury than those with more than 3 years running experience.<sup>76</sup>

### Competitive behaviours

Injury incidence is associated with motivation score.<sup>103</sup> Higher scores correlate with higher incidence of medically treated injury. Runners who compete have higher injury rates than recreational runners, even when adjusting for mileage.<sup>75, 77</sup> More motivated runners may ignore the first signs of injury.

In military populations, every activity is highly competitive. The US Army places great emphasis on the APFT. Better scores influence prospects for promotion and most US soldiers strive to achieve the maximum score. The Australian Army now utilises a pass/fail result instead of a score, to reduce competitive behaviours and subsequent risk of injury.

### Warm-up/stretching

The role of stretching as a component of a pre-activity warm-up, and in preventing injuries in the military, is unclear. As outlined in Chapter 12, in the general sporting population an acute bout of stretching prior to activity results in short-term loss of muscular strength, power and endurance<sup>104, 105</sup> and does not reduce overall injury risk<sup>106</sup>

### Military recommendations for injury prevention initiatives

The evidence base for injury prevention recommendations has been reviewed by a joint US military task force.<sup>41</sup> Six interventions had strong enough evidence to be recommended for implementation in the military services and two interventions were not recommended due to evidence of ineffectiveness or harm.

#### Recommended interventions (sufficient scientific evidence)

1. Prevent overtraining.
2. Perform multiaxial, neuromuscular, proprioceptive and agility training.
3. Wear mouth guards during high-risk activities.
4. Wear semi-rigid ankle braces for high-risk activities.
5. Consume nutrients to restore energy balance within 1 hour following high-intensity activity. (High carbohydrate/protein replacement within 15–30 minutes of finishing high-intensity exercise leads to more rapid muscle and liver glycogen restoration and preservation of muscle mass.)
6. Wear synthetic-blend socks to prevent blisters.

#### Interventions not recommended (evidence of ineffectiveness or harm)

1. Wear back braces, harnesses or support belts.
2. Take anti-inflammatory medication prior to exercise.

While physical training is necessary to condition soldiers for their occupational tasks, the authors noted that 'in classic military tradition, however, efforts to exceed the standards have contributed to the injury epidemic present today'.<sup>41</sup>

In a randomised controlled study in Australian military recruits there was no effect of pre-exercise static stretches on all-injury risk, soft tissue injury risk or bone injury risk.<sup>107</sup> Among Japanese recruits, the total injury rate was the same between those who conducted static stretches and those who did not. However, the incidences of muscle/

tendon injury and low back pain were significantly lower in the stretching group.<sup>108</sup>

As it is clear that traditional static stretches do not reduce overall injury rate, warm-ups today should be incorporating light cardiovascular activities such as jogging and dynamic range of motion activities, and progress to sport-specific drills.<sup>104, 109-111</sup>

#### PRACTICE PEARL

The wise military physician should never assume that all apparent musculoskeletal pain in the young soldier is due to overuse injury.

### Conclusion

Injury is a major problem for most Western military forces, and female recruits bear a disproportionate burden. Although the military population usually is fit and has access to high-quality healthcare, they can still have the systemic, metabolic, infective and neoplastic diseases found in the wider population.

Reducing running distance reduces both the incidence and severity of injury in military recruit populations, without affecting overall physical performance. The entry level of aerobic fitness is a key modifiable risk factor, and screening for physical fitness prior to clearing to participate in basic training programs has reduced both injury and attrition rates. Early identification of injuries and counselling trainees about achievable career paths is an important part of rehabilitation. Not all somatotypes or psyches are suited for infantry, marines or special forces, regardless of pre-recruitment dreams.

Injury prevention strategies should be based on robust surveillance systems using a public health approach to accurately identify risk factors, implement interventions and evaluate outcomes. While the nature of the profession comes with inherent risk, it is possible to reduce injury and improve retention.

# Periodic medical assessment of athletes

with STEPHEN TARGETT and BEN CLARSEN

*To screen or not to screen, that is the question.*

adapted from *Hamlet*, William Shakespeare (1564–1616)

Sports medicine clinicians commonly perform standardised health evaluations of athletes and many different organisations around the world require that athletes undergo a pre-participation evaluation to be allowed to participate in sport. However, organisations rarely provide guidance regarding the content of the required evaluation and the effectiveness of the approach in reducing the risk of injury, illness or sudden death in athletes remains controversial.

There are many different templates available, such as the Fédération Internationale de Football Association (FIFA) pre-competition medical assessment (PCMA),<sup>1</sup> the International Olympic Committee periodic health examination (PHE)<sup>2</sup> and the American Academy of Paediatrics pre-participation physical evaluation (PPE).<sup>3</sup> It should be emphasised, however, that these are designed for different target groups and there is no one universal template that suits all situations.

In order to avoid any confusion in terminology in this chapter, we use the term 'periodic medical assessment' (PMA) to refer to the standardised medical assessment of athletes, without being specific to any group's recommended template.

The development of a template for the PMA of an athlete, whether elite or recreational, requires careful planning, and gives an opportunity for all of the members of the sports medicine team and coaching staff to work in collaboration. Establishing the optimum template for each situation can be achieved by considering the following questions in turn.

- Why perform the medical assessment?
- Who is being assessed?
- When and where should the assessment be performed, and by whom?
- What should be included in the assessment?
- Are there any other issues to consider?

## WHY PERFORM THE MEDICAL ASSESSMENT?

The first step in planning a PMA template is to determine why you are performing the medical assessment. The primary goal of the PMA is to make participation in sport safer, but there are a number of other valid reasons for wanting to perform a PMA such as assessing the status of known injuries and illnesses, screening for risk factors, reviewing medications and supplements, baseline testing, athlete education and establishing rapport with athletes.

## Identification of medical conditions that contraindicate participation in sport

There are some medical conditions that may contraindicate participation in certain sports or recreational activities; for example, uncontrolled epilepsy in motor racing, cycling or swimming; or human immunodeficiency virus (HIV) infection in an amateur boxer. In many cases, such as asthma in a scuba diver, the medical condition is not an absolute contraindication and athletic participation should be decided on a case-by-case basis. It is therefore important that the medical professional performing the PMA understands the physical and mental demands of the sport in question, as well as its regulations. Table 46.1 shows examples of medical conditions that warrant special attention or contraindicate participation in certain sports.

It is important to identify medical conditions that may be made worse by intense exercise; for example, uncontrolled type 1 diabetes, poorly controlled asthma or uncontrolled hypertension. Although such conditions are usually not absolute contraindications to sports participation, optimal control should be established prior to commencing intense training and competition.

**Table 46.1 Medical conditions affecting sports participation (adapted from Bernhardt et al.<sup>4</sup>)**

Medical condition	Sport/activity participation recommendations
<b>Atlantoaxial instability</b>	Medical evaluation necessary
<b>Bleeding disorder, blood thinning medications</b>	Medical evaluation necessary. Contact sport usually discouraged
<b>Cardiovascular disease*</b>	
Myocarditis/cardiomyopathy	All exercise contraindicated
Hypertension	Those with severe hypertension (>99th percentile for age plus 5 mmHg) should avoid heavy weight and power lifting, bodybuilding, strength training and sports with a high static component. Those with sustained hypertension (>95th percentile for age) need medical evaluation
Congenital heart disease	Medical evaluation necessary
Dysrhythmia	Medical evaluation necessary
Heart murmur	Medical evaluation necessary
<b>Structural/acquired heart disease</b>	
Hypertrophic cardiomyopathy	All exercise normally contraindicated
Coronary artery anomalies	All exercise normally contraindicated
Arrhythmogenic right ventricular cardiomyopathy	All exercise normally contraindicated
Acute rheumatic fever with carditis	All exercise normally contraindicated
Ehlers-Danlos syndrome, vascular form	All exercise normally contraindicated
Marfan syndrome	Medical evaluation necessary
Mitral valve prolapse	Medical evaluation necessary
Anthracycline use	Medical evaluation necessary
Vasculitis/vascular disease	Medical evaluation necessary
<b>Cerebral palsy</b>	Medical evaluation necessary
<b>Diabetes mellitus</b>	Participation normally allowed with proper attention to diet, blood glucose concentration, hydration and insulin therapy
<b>Infectious diarrhoea</b>	All sports normally contraindicated, unless symptoms are mild and the athlete is fully hydrated
<b>Eating disorders</b>	Medical and psychological evaluation necessary. Sports participation contraindicated when athlete is not compliant with therapy and follow-up, or where there is evidence of diminished performance or potential injury because of eating disorder
<b>Eye conditions</b>	
Functionally one-eyed athlete	Medical evaluation necessary. Protective eyewear may be appropriate, although in some sports (e.g. boxing, martial arts) it is not permitted
Loss of an eye	
Detached retina or family history of retinal detachment at a young age	
High myopia	
Connective tissue disorder, such as Marfan or Stickler's syndromes	
Previous intraocular eye surgery or serious eye injury	
Infectious conjunctivitis	
	Swimming contraindicated

Table 46.1 Cont.

Medical condition	Sport/activity participation recommendations
<b>Fever</b>	All exercise contraindicated
<b>Gastrointestinal conditions</b>	
Malabsorption syndromes (coeliac disease, cystic fibrosis)	Medical evaluation necessary
Short bowel syndrome or other disorders requiring specialised nutritional support including parenteral or enteral nutrition	Medical evaluation necessary
<b>Hepatitis, infectious</b>	Participation normally allowed in all sports where the athlete's state of health permits. Athletes should receive hepatitis B immunisation and universal precautions should be used when handling blood or body fluids with visible blood
<b>Human immunodeficiency virus (HIV) infection</b>	Participation normally allowed in all sports where the athlete's state of health permits. Universal precautions should be used when handling blood or body fluids with visible blood. Sports with a high risk of viral transmission (e.g. boxing and wrestling) should be avoided
<b>Infectious mononucleosis—acute or with splenic enlargement</b>	Moderate/intense exercise and participation in collision and contact sports contraindicated
<b>Absence of one kidney</b>	Medical evaluation necessary for collision, contact and limited-contact sports. Protective equipment may be available to protect the remaining kidney.
<b>Acute liver enlargement</b>	All exercise normally contraindicated
<b>Chronic liver enlargement</b>	Medical evaluation necessary, particularly for collision, contact and limited-contact sports
<b>Malignant neoplasm</b>	Medical evaluation necessary
<b>Neurological disorders</b>	
History of serious head or spine trauma or abnormality, including craniotomy, epidural bleeding, subdural haematoma, intracerebral haemorrhage, second-impact syndrome, vascular malformation and neck fracture	Medical evaluation necessary
History of simple concussion (mild traumatic brain injury), multiple simple concussions and/or complex concussion	Medical evaluation necessary. Research supports a conservative approach to concussion management, including no athletic participation while symptomatic or when deficits in judgment or cognition are detected, followed by a graduated, sequential return to full activity (see Chapter 20)
Myopathies	Medical evaluation necessary
Recurrent plexopathy (burner or stinger) and cervical cord neuropraxia with persistent defects	Medical evaluation necessary for collision, contact or limited-contact sports; regaining normal strength is an important benchmark for return to play
Seizure disorder with risk of seizure during participation	Athlete needs individual assessment for collision, contact or limited-contact sports. The following non-contact sports should be avoided: archery, shooting, swimming, weight or power lifting, strength training, or sports involving heights or high velocities (e.g. cycling, motor racing). In these sports, occurrence of a seizure during the activity may pose a risk to self or others
<b>Organ transplant recipient (and those taking immunosuppressive medications)</b>	Medical evaluation necessary, particularly for collision, contact and limited-contact sports

Continued

Table 46.1 Cont.

Medical condition	Sport/activity participation recommendations
<b>Pregnancy</b>	Medical evaluation necessary. As pregnancy progresses, modifications to usual exercise routines will be necessary. Activities with a high risk of falling or abdominal trauma, scuba diving and activities posing a risk of altitude sickness should be avoided. Postpartum, physiologic and morphologic changes of pregnancy take 4–6 weeks to return to baseline
<b>Respiratory conditions</b>	
Pulmonary compromise, including cystic fibrosis	Medical assessment necessary, participation normally allowed. Athletes with cystic fibrosis have an increased risk of heat illness
Asthma	Medical assessment necessary prior to scuba diving
Acute upper-respiratory infection	Upper-respiratory obstruction may affect pulmonary function. Athlete needs individual assessment for all but mild disease. If fever is present, all exercise is contraindicated
<b>Rheumatologic diseases</b>	
Juvenile rheumatoid arthritis, juvenile dermatomyositis, idiopathic myositis or systemic lupus erythematosus	Medical assessment necessary
Raynaud's phenomenon	Care should be taken when exposing hands and feet to cold
<b>Sickle cell disease</b>	Medical assessment necessary. In general, if status of the illness permits, all sports may be played; however, any sport or activity that entails overexertion, overheating, dehydration and chilling should be avoided. Participation at high altitude, especially when not acclimatised, also poses risk of sickle cell crisis.
<b>Skin infections</b> —including herpes simplex, molluscum contagiosum, verrucae (warts), staphylococcal and streptococcal infection (furuncle/boils, carbuncle, impetigo, methicillin-resistant <i>Staphylococcus aureus</i> /cellulitis/abscess/necrotising fasciitis), scabies, tinea	During contagious period, participation in gymnastics with mats, martial arts, wrestling or other collision, contact or limited-contact sports is contraindicated
<b>Enlarged spleen</b>	If the spleen is acutely enlarged, participation should be avoided because of risk of rupture. If the spleen is chronically enlarged, individual assessment is needed before collision, contact or limited-contact sports are played

\*All suspected cases should be evaluated by a cardiologist. The 36th Bethesda Conference,<sup>9</sup> the European Society of Cardiology consensus statements<sup>9</sup> and the recommendations from the American Heart Association and American College of Cardiology<sup>40</sup> provide detailed recommendations for sports participation for cardiovascular conditions

## Assessment of known injuries and illnesses

Athletes often have persisting or recurrent injury problems and the PMA is a good opportunity to check that they are receiving optimal treatment. Recent studies of American college athletes and professional footballers in Qatar found that 11% and 17% of athletes had a current injury at the time of the PMA, respectively.<sup>7, 8</sup>

All medical personnel involved in the care of each existing injury should be listed. The current level of symptoms should be ascertained, as well as athlete's

compliance to ongoing rehabilitation or prevention exercises. It is also important to check that exercises are being performed correctly.

It is equally important to address chronic or recurrent illnesses. This involves checking for optimum treatment (e.g. measurement of blood pressure for those with hypertension, asking about breakthrough symptoms in asthma or epilepsy, checking blood glucose control for diabetics), monitoring compliance with treatment (e.g. taking of medication, inhaler technique and attending follow-up appointments) and checking whether the athlete has any questions and/or adequately understands their condition.

## Review of current medications and supplements

This involves checking prescribed medications as well as 'over-the-counter' medications or supplements that an athlete is currently taking, takes occasionally or is considering taking. Athletes sometimes neglect to inform their team medical staff about any changes and these should be checked to ensure compliance with the current World Anti-Doping Agency (WADA) regulations and be updated in their medical records.

While discussing medication, it may also be a good opportunity to remind athletes of their responsibilities under the WADA code ([www.wada-ama.org](http://www.wada-ama.org)). In particular, it should be emphasised that they are ultimately responsible for all substances they ingest and may be required to report their whereabouts to anti-doping authorities. They should also be reminded about the potential hazards associated with taking supplements, minerals and non-prescription medications without first checking with medical staff.

## Education

In addition to providing education about anti-doping, medication use and supplements, other issues may be worth discussing with athletes depending on the local circumstances. Although cardiac screening is a hot topic at present, the leading cause of death in teenagers and young adults is accidents, in particular road traffic accidents, meaning that education on drink driving, wearing seatbelts and safe driving practices should be considered.<sup>9</sup> Other lifestyle practices that may have a negative effect on health and/or performance include abuse of alcohol, the use of recreational drugs or 'legal highs', smoking (tobacco or shisha) and unsafe sexual practices.

Careful consideration should be given to the best mode of delivery of these messages; for example, whether done on a one-to-one basis during the PMA or at a later date as a group lecture or interactive workshop. This will vary from situation to situation.

Other general health topics that may affect performance include basic nutrition advice and the importance of sleep and recovery, and should be discussed.

## Baseline testing

The PMA can be used to perform baseline tests for a range of purposes if appropriate. Examples include:

- neuropsychological testing for athletes involved in contact sports to be used as a baseline following head injury (see Chapter 20)
- tests used in the monitoring of fatigue and recovery in athletes throughout a season, such as blood and/or saliva biochemical, hormonal or haematologic tests, aerobic or anaerobic fitness tests, psychological tests

such as profile of mood states (POMS) or tools to assess sleep and recovery (see Chapter 13)

- physical measures to be used as post-injury reference values (these can be important when making return-to-play decisions; see Chapter 19), such as:
  - muscle strength (Fig. 46.1)
  - single-leg hop tests (see Chapter 35)

(a)

(b)

**Figure 46.1** Strength testing (a) Quadriceps strength testing using an isokinetic dynamometer (b) Testing hip abductor strength with a hand-held dynamometer

**Figure 46.2** The agility T-test<sup>10</sup>

- vertical jump (counter movement jump)
- agility T-test (Fig. 46.2)<sup>10</sup>
- 30 m sprint time
- glenohumeral joint range of motion (Chapter 24).

### Development of athlete rapport

The PMA is often the only time that team medical personnel have an opportunity to have a one-on-one consultation with athletes and to be proactive rather than reactive. It is an opportunity for athletes to ask questions or discuss any matters that they have been hitherto unwilling to discuss and helps in improving rapport and building the clinician-patient relationship.

In some parts of the world, where a pre-participation evaluation is required for recreational athletes, the PPE is the only contact that some athletes will have with the healthcare system and is an opportunity to establish a 'medical home' and discuss general health issues, especially if performed by a family physician.

### Screening

Screening is traditionally defined as the identification of disease among apparently well persons. In 1968, Wilson and Jungner described 10 principles of early disease detection that are still relevant today when considering a screening program for athletes (see box).<sup>11</sup>

Although these principles are universal, two of them are worth considering more closely in the context of sport, as they may be interpreted differently in athletes than in the general population.

### Ten principles of early disease detection

1. The condition should be an important health problem.
2. There should be an accepted treatment for patients with recognised disease.
3. Facilities for diagnosis and treatment should be available.
4. There should be a recognisable latent or early symptomatic stage.
5. There should be a suitable test or examination.
6. The test should be acceptable to the population.
7. The natural history of the conditions, including development from latent to declared disease, should be adequately understood.
8. There should be an agreed policy on whom to treat as patients.
9. The cost of case-finding (including diagnosis and treatment of patients diagnosed) should be economically balanced in relation to possible expenditure on medical care as a whole.
10. Case-finding should be a continuing process and not a 'once and for all' project.

Wilson and Jungner state that the ability to be able to treat the condition adequately when discovered is perhaps the most important. For those conditions where there is no treatment or intervention that will offer a better prognosis, alerting a person to such a condition may cause actual harm. In order to know whether a treatment offers benefit, the natural history of a condition needs to be known.<sup>11</sup>

First, the condition being screened for should be deemed 'important'. For athletes, particularly elite competitors, anything that negatively affects performance or leads to lost training time may be seen as very important, particularly during crucial periods of the season. In the general population, however, a 2% reduction in 5 km time or a 10% loss of strength may be insignificant.

Second, the screening program must be cost-effective. In professional sport, where athletes are often paid many thousands of dollars per week, even short periods of time loss or small performance reductions can be very costly. Prevention of minor injuries and illnesses among professional athletes may therefore be highly cost-effective.

Screening is therefore commonly considered to be a valuable process for athletes and is standard practice in many elite sports. However, the actual preventive value of mass screening programs for athletes has been questioned.<sup>12–15</sup> We will examine this in greater detail in the following section where we review the most common types of athlete screening: cardiac screening, screening for unknown injuries and illnesses, and screening for risk factors for future injury.

## Cardiac screening

Several high-profile cases of sudden cardiac death in athletes over recent years, such as that of Norwegian swimmer Alexander Dale Oen, as well as the case of English professional footballer Fabrice Muamba, who survived a sudden cardiac arrest after prolonged resuscitation, have stimulated a healthy debate in both the medical community and the popular press about the pros and cons of cardiac screening.

Despite all this debate, there is no universal consensus on whether or how cardiac screening should be performed. The lack of agreement is because the context in which the PMA is being performed will affect the decision on whether or not to offer cardiac screening and thus this decision will likely remain an individual one for each organisation or country.

Some of the many factors that have to be considered when deciding whether or not to offer cardiac screening and/or how to screen are the population being studied (numbers, age group, gender, prevalence of conditions predisposing to sudden cardiac death), the screening tests being used (sensitivity and specificity) and the resources available (money, equipment and access to cardiologists with expertise in conditions that predispose to sudden cardiac death).

When considering mass screening funded by the public purse, the cost-benefit of screening for conditions predisposing to sudden cardiac death versus other demands for the health dollar also needs to be considered. Many countries simply do not have the resources to be able to offer a large-scale screening program particularly if it might place barriers to people partaking in exercise, which will actually reduce public health costs.

Cardiac screening usually consists of the following elements:

- targeted history for symptoms suggestive of cardiac disease, and for personal or family history of cardiac disease
- physical examination of the cardiovascular system
- special tests such as electrocardiograph (ECG), echocardiograph or stress test.

As mentioned, there is no international consensus on which special tests should routinely be used. Most of the debate, however, centres on the routine use of an ECG as part of cardiac screening. Those against the routine use of ECG in cardiac screening point out that there is a high false positive rate, there may be undue stress associated with further investigations of 'abnormal' results, expertise is required to interpret the ECG and the costs are high. Those in favour of the routine use of ECG argue that:

- ECG is more sensitive and specific than history and examination alone; a study of college athletes showed that 30% responded positive to at least one of the American Heart Association cardiac questions, which reflects the high rate of false positives<sup>8</sup>
- the use of standardised ECG criteria to interpret ECGs can improve the accuracy of ECG interpretation<sup>16</sup>
- athletes feel reassured by ECG screening, not unduly stressed.<sup>17, 18</sup>

Echocardiograph and stress tests are usually only routinely used as part of cardiac screening by professional sporting teams with sufficiently large budgets and access to expertise, or when further investigation is indicated by an initial screening assessment.

### PRACTICE PEARL

An important part of the topic that often gets overlooked when considering cardiac screening is being adequately prepared for a sudden cardiac arrest should one occur. Even a comprehensive cardiac screening program will not identify all persons with conditions predisposing to sudden cardiac death.

High school studies in the United States clearly show the benefit of having an automated external defibrillator (AED) on site (Fig. 46.3) and that sudden cardiac arrest (SCA) is survivable with an AED program. A study published in 2013 looking prospectively at 2149 US high schools, 87% of which had an AED program, reported that 89% of the athletes (including students and older athletes) survived to hospital discharge because of prompt CPR and early defibrillation.<sup>19</sup> Being prepared for SCA involves more than just having an AED on site.

## Screening for unknown illnesses

In some situations, screening for the presence of unknown or subclinical medical conditions may be worthwhile. For example, these include any medical conditions that:

- have a negative effect on performance, such as iron deficiency anaemia or exercise-induced asthma
- predispose athletes to injury; for example, there is an association between vitamin D deficiency and stress fractures in military populations<sup>20</sup>
- might be hazardous to other athletes or medical staff, such as hepatitis B.

## Screening for risk factors for future injury

A comprehensive musculoskeletal examination is among the most common elements of a PMA. Typically,

(a)

(b)

**Figure 46.3** A functioning automated external defibrillator (AED) is essential equipment at venues that host sporting events. (a) AED closed, showing on/off switch (b) AED open, showing simple instructions on the flap and electrodes ready to be placed on the patient's chest

COURTESY OF PROFESSOR JONATHAN DREZNER, UNIVERSITY OF WASHINGTON CENTER FOR SPORTS CARDIOLOGY, WITH PERMISSION FROM PHYSIO-CONTROL, INC.

athletes' strength and flexibility are measured and compared to normative values or pre-determined cut-off values to determine whether the athlete is at risk of future injury. Specific orthopaedic tests may also be performed in order to identify unknown existing injuries. In recent years, however, there has been a trend away from static clinical measurements towards dynamic screening of the athletes' ability to perform a range of functional tasks. A number of similar systems are currently popular, all of which aim to identify 'weak links' in strength, flexibility or motor control, which can be targeted by individualised injury prevention programs. These include the Functional Movement Screen (FMS),<sup>21–23</sup> the United States Tennis Association High-Performance Profile<sup>24</sup> and the 9+ test battery developed by physiotherapists at the Swedish Sports Confederation (Fig. 46.4).<sup>25</sup>

Irrespective of whether traditional clinical measurements or a qualitative approach are used, the goals of musculoskeletal screening remain the same—to identify athletes at risk of specific injuries and guide the development of individualised injury prevention training programs. Although this is a theoretically appealing approach, there are several reasons why it may not deliver the desired results in practice.

First, for most injuries very few intrinsic modifiable risk factors have been identified and screening cut-off values are often based on expert opinion or assumed associations with injury risk. For example, athletes with poor hamstring flexibility are commonly advised to stretch in order to avoid hamstring strains. However, research into the link between hamstring flexibility and injury is inconclusive, and there is no cut-off value for hamstring flexibility that can identify players at risk for future injury.<sup>26, 27</sup> This is the case for the majority of physical measures currently used to screen athletes.

Second, even in cases where significant associations between risk factors and injury have been established, such as eccentric knee flexor weakness for hamstring strains<sup>28</sup> or glenohumeral joint stiffness for shoulder injuries in throwing athletes,<sup>29–32</sup> intrinsic risk factors are poor predictors of future injury. This is because they typically only explain a small part of an athlete's overall injury risk and because cut-off values are likely to have low sensitivity (many false negatives) and/or low specificity (many false positives), depending on which value is used.<sup>15</sup>

Clearly, more high-quality research into injury risk factors is required, in particular into the combination of test findings in order to maximise their predictive value. It is likely that dynamic predictive models are necessary before athletes at risk of future injury can be successfully identified.<sup>33</sup>

**Figure 46.4** Examples of tests within the 9+ test battery. A full description of the tests and scoring criteria can be found in Frohm et al.<sup>25</sup>

COURTESY OF A FROHM, SWEDISH SPORTS CONFEDERATION

Nevertheless, musculoskeletal screening remains a popular and potentially valuable tool, particularly in helping sports medicine personnel familiarise themselves with each athlete's physical attributes and limitations. Care should be taken, however, in telling athletes that they are not at risk of injury or that they don't need to perform injury prevention training, because they passed a particular screening test.

### WHO IS BEING ASSESSED?

There are numerous factors to consider about the population being assessed that can affect the content of the PMA.

### Sport and position

The incidence and type of injuries or medical issues varies widely between sports. For example, in soccer the major injuries are knee injuries (ligament and meniscal tears), ankle ligament sprains, thigh muscle strains (hamstrings and quadriceps) and groin injuries; this is different to many other sports.<sup>34</sup> In some sports such as rugby, the incidence of injuries differs between positions. A study of professional rugby union players in the United Kingdom showed that anterior cruciate ligament (ACL) injuries caused the most time loss for forwards and hamstring injuries for backs.<sup>35</sup>

It is important to know about the injury and illness epidemiology for the particular athlete's sport and position as the PMA should specifically look for any risk factors associated with the important injuries or medical issues associated with each athlete's sport, and seek to address any of those that are modifiable. Some sporting bodies require athletes taking part in international competitions to undergo a medical assessment prior to competing, such as the FIFA football World Cup, the World Rugby (IRB) World Cup and the Olympics. A set template will usually be provided and should be followed.

### Geographical location

In some countries, legislation dictates that some athletes require a medical assessment prior to playing sport. The Italian Government has required the screening and medical clearance of athletes since 1971 with an annual physical examination, personal and family history, and 12-lead ECG for all athletes aged 12–35 years participating in competitive sport.

Local patterns of disease, both infective and genetic, vary around the world and should be taken into account when designing a PMA. For example, in certain parts of the world there is a high prevalence of hepatitis B. The most recent guidelines from the US Preventive Task Force recommend mass population screening for hepatitis B in areas with a prevalence of over 2% in the

general population.<sup>36</sup> However, screening for hepatitis B immunity in order to be able to offer immunisation to those who are non-immune may be appropriate, even in countries with a lower prevalence rate for athletes involved in contact sports.

Extreme environmental conditions such as heat, cold and altitude can be experienced by some athletes as part of their sport when played in some geographical locations. Any previous history of complications associated with such conditions should be explored in the history when athletes are likely to encounter such environmental stresses.

## Age

There is no consensus on what age to start performing PMAs. The American Academy of Paediatrics recommends annual routine health screening for all healthy children and adolescents from age 6, but there is no evidence to support starting PMAs in sporting groups at any particular age. As mentioned previously, in Italy an annual cardiac screening is mandatory for all competitive athletes from age 12. The European Society of Cardiology recommends pre-participation cardiac screening from ages 12 to 14, and Cardiac Risk in the Young (CRY) in the UK recommends screening from age 14.

Some sports have an increased risk of overuse injuries to certain growth plates (epiphysitis or apophysitis); for example, the proximal humeral epiphysis or medial humeral epicondyle epiphysis in pitchers and the distal radial epiphysis or calcaneal apophysis in gymnasts (Chapter 44). Symptoms of growth plate injuries associated with the particular sport being played should be enquired about during the PMA in young athletes who are between the ages at which these different conditions occur and a change in technique or training load may be required. Although the majority of these heal with adequate rest, there have been case reports of growth arrest of epiphyses when not treated properly.

If at all practicable, a parent or legal guardian should accompany a child to the PMA. Studies of high school students undergoing a PPE have shown that only 19–33% of athletes' responses were the same as those given by their parents or legal guardians when completing the same form.<sup>37, 38</sup> If a parent is unable to attend, then the previous medical history and family history sections of the questionnaire should be completed by them prior to the consultation.

## Sex

Female athletes will generally have the same basic PMA template as males playing the same sport; however, the range of conditions associated with relative energy

deficiency needs to be considered in female athletes, particularly in those who are involved with high-risk sports (those with weight categories to meet or where the aesthetic can be judged, such as gymnastics or ballet).<sup>39</sup> Several screening tools have been proposed to identify the athlete with relative energy deficiency. However, none have been validated and a high index of suspicion is required. It should be noted that, although much less common, relative energy deficiency may also occur in male athletes.

It is known that female athletes have a 2–3-fold higher incidence of ACL injury than their male counterparts and that male athletes have a higher incidence of hamstring injuries. Such differences in injury rates, when present, should be reflected in the medical assessment.

## Available resources

At the end of the day, the available budget will usually dictate the content of the PMA, irrespective of the desired components. A major hurdle for organisations considering developing a publicly funded PMA cardiac screening program for large numbers of athletes is the availability of cardiologists with expertise in sports cardiology who will be needed to follow up those with cardiovascular symptoms, abnormal physical examination findings or abnormal ECGs.

In elite or professional sport, where money may be less of an issue and there are often full-time medical staff available to perform medical assessments, access to equipment (e.g. for isokinetic or  $\text{VO}_2\text{max}$  testing) or expertise (cardiologists with expertise in sports cardiology) may instead limit the content of the PMA.

## WHEN TO PERFORM A PMA

The PMA is typically performed in the pre-season period. This is often the first time that the medical staff get to meet any new members of the squad who have joined in the off-season and is a good opportunity to develop a working relationship with new players.

It is a good idea for medical staff to engage coaching staff and management in the development and planning of the PMA so that they understand the goals (and limitations) and are encouraged to think about injury prevention. This makes them more likely to allow adequate time for medical staff to perform the medicals and be supportive of the delivery of any recommendations that might come out of the PMA, such as individual or team-wide injury prevention programs.

The value of engaging coaching staff has been clearly shown with the ACL injury prevention program in elite female handball players in Norway.<sup>40</sup> Despite an

intervention study showing that a series of rehabilitation exercises done routinely as a part of team training significantly reduced the incidence of ACL injury, most teams stopped performing the exercises once the study was completed and the study personnel driving the injury prevention exercises were removed from the clubs; ACL rates consequently rose in subsequent seasons. A reduction of injury rate was seen after the introduction of education sessions for coaches and a sport-specific website on injury prevention.<sup>40</sup>

Ideally, a shorter modified PMA is also performed at the end of the season to review any injuries that might have occurred during the season (including ones that may not have been reported to medical staff), to possibly repeat some of the baseline musculoskeletal and/or laboratory measurements that were performed earlier in the season and to formulate a treatment or rehabilitation program over the off-season.

No research has conclusively shown that more frequent PMAs reduce the incidence of death or injury and recommendations on frequency vary. The most common recommendation is that a comprehensive assessment be performed every 2-3 years with a shorter, annual questionnaire and targeted examination in between. However, practice varies depending on the context and available resources.

## WHAT TO INCLUDE IN THE TEMPLATE

The basic structure of the medical template will consist of history, examination and investigations. A detailed history is an important part of the assessment because the most consistent risk factor for injury across injury types is a previous history of injury. Defining the goals of the PMA (which, as referred to earlier, can vary depending on the stage of the season) and taking into account the unique factors associated with the population in question (including the available resources) will allow you to select the appropriate tools for the task.

The PPE monograph from the American Academy of Paediatrics is an excellent resource for anyone designing a PMA. It contains sections on the history and a systems-based examination, and has an example of a PMA form.<sup>3</sup>

The temptation when designing a PMA template is to include too much, particularly in the musculoskeletal examination. For example, taking reliable measurements of strength or joint range of movement is time consuming and may be a waste of time if no action is going to be taken for 'abnormal' results (what is 'abnormal' is often not even considered), if the data are not going to be used as a baseline post injury or if the data are not being used as part of a research project.

## OTHER ISSUES TO CONSIDER

### Consent

The PMA form should contain a consent section that the athlete should sign covering the following points, if appropriate:

- the athlete consents to undergo a medical assessment to assess their fitness to safely participate in sport
- the athlete understands that clearance may not be given if any significant medical issues or injuries are discovered
- the athlete certifies that their answers to all PMA questions are true to the best of their knowledge
- the athlete agrees to inform the medical professional if their medical situation changes significantly after the completion of the PMA
- the athlete consents to the use of data collected as part of the PMA for research purposes as long as the results do not in any way identify the athlete
- a parent or legal guardian should sign the consent form for athletes under the age of consent (18 in most countries).

### Clearance or restriction from play

A very small percentage of athletes undergoing a PMA will be diagnosed with a medical condition that is associated with an increased risk of sudden cardiac death. In such cases, a cardiologist with the appropriate experience should review the athlete. The assessment of risk, however, is not a precise science and may differ between physicians. In order to make the decisions more consistent, guidelines have been produced for participation in sport with different cardiovascular conditions; however, the guidelines do differ in places and the decision on whether to allow the athlete to participate should be individualised once all the relevant information is available.<sup>6, 41</sup>

If clearance to participate is not given, the athlete may ask to sign a 'risk release' acknowledging that they have been fully informed of the risks and assume the risk of participating against medical advice; however, this may not be appropriate in all cases. It is important that documentation of any risk release is completed correctly and some experts recommend that the athlete and/or parents write in their own words their understanding of the risks of continued participation to prove that they have been fully informed of the risks. A decision to withhold clearance from participation may be subject to legal challenge. The success of a challenge will depend on the circumstances of the individual case and the local legislation, which varies widely from country to country.

## Who should perform the PMA?

Although some parts of the PMA are often performed by other health professionals (e.g. nurses may take history and vital signs, physiotherapists may perform musculoskeletal assessments), the overall responsibility to review all the PMA components and make recommendations on clearance and follow-up should lie with a medical doctor who has the clinical training to deal with the wide variety of issues that might arise as part of the assessment.

## Pre-employment medical assessment

Many professional athletes will be required to undergo a medical before their employment contract becomes valid. The principles for creating a template for the medical assessment are the same as for any PMA; however, there are some differences that are worth considering.

The biggest difference is the doctor-patient relationship. The person performing the medical assessment is often the athlete's team physician, with whom they have a normal doctor-patient relationship. When completing a new contract medical assessment, the doctor is acting on behalf of a third party (the club/employer). The fact that the athlete understands this difference and that that athlete agrees to the doctor providing a report on the athlete's ability to play sport to the employer using medical information from the assessment needs to be reflected in the consent form.

Even though the consent form requires athletes to promise to provide honest answers, there is a temptation for athletes to be economical with the truth (or even to lie) during a new contract medical, especially if the contract is worth large amounts of money. The physician performing the assessment should bear this in mind and if possible attempt to see the previous medical records. For some sports, injury information as well as matches and minutes played is freely available on the internet and is a valuable source of information and should be obtained if possible.

For high-value contracts, some clubs routinely ask for multiple magnetic resonance imaging (MRI) scans as part of the new contract medical (e.g. both knees, ankles, groin and lumbar spine in soccer players). The value of this approach is unknown as an MRI scan often picks up asymptomatic findings, such as a chondral defect in a knee that may have little or no practical prognostic value when taken in the context of a 1-year contract, but can be useful as a baseline when repeating imaging at a later date. Clubs can also use this information to negotiate a clause in the contract to protect themselves against prolonged future time loss from identified abnormalities.

In addition to the usual goals of a standard PMA, the role of the medical team performing a new contract medical is to provide the potential employer with an

estimated level of risk that any identified medical and/or injury issues might preclude the athlete from being able to perform at their best for the duration of their contract. Some studies show a link between previous injury and future playing ability or length of career, such as the reduced performance of running backs in National Football League (NFL) after ACL reconstruction,<sup>42</sup> or the effects of previous injury history noted at the NFL Combine medical assessment on future career length.<sup>43</sup> The Combine study also showed, however, that athlete talent was a big factor that also had to be taken into account.

The prediction of future injury risk is complex and likely depends on a number of different factors in addition to injury history. This was highlighted by a recent pilot study at the Aspetar Orthopedic and Sports Medicine Hospital in Qatar (as yet unpublished), where a group of experienced sports physicians were asked to predict the risk of future injury for a series of case scenarios. The responses showed markedly different estimations of risk (from high to low) for almost all cases.

Once the risk has been conveyed to the potential employer, which is best done verbally so that any questions can be answered, it is up to the employer to decide whether they offer the athlete a contract. This can be quite a complex decision and involves many different factors such as depth of squad in the athlete's chosen position, the experience and talent of the athlete, the contract cost and duration, and the sport or position played.

## Insurance medical assessment

Many athletes take out income protection insurance and will require a medical certificate to be completed by a doctor. In the majority of occasions, the insurance company will provide a form with the required template. If the athlete does not provide a form, they should be instructed to contact their insurance company to provide one as the requirements can vary between different companies.

It is important that the form is completed accurately as any incorrect answers can render the insurance void and may place the doctor at risk of legal action if there is any suggestion that there was any attempt to be economical with the truth. If the athlete is putting undue pressure on the team doctor to withhold certain information, the medical might be better performed by an independent doctor.

## Action points from the PMA

Any action points identified as a result of the PMA should be discussed with the athlete and written on a discharge summary, which is then given to the athlete. This should also clearly indicate who is responsible for initiating the various action points and when follow-up is required (if possible, a follow-up appointment should be given at the

same time). If appropriate, the discharge summary could also be sent to any relevant stakeholders, such as team medical staff or the athlete's personal physician. However, it is important to get the athlete's consent prior to sharing any health information.

For some athletes who spend a lot of time travelling and/or are members of several teams, there can be some challenges around distribution of the results of the PMA to the various medical teams looking after them to avoid any unnecessary duplication of tests or to refer to when required. There is no one solution that will suit all athletes and this should be dealt with on a case-by-case basis.

## SUMMARY

The PMA can have many uses that have been outlined in this chapter. There is no one PMA that suits all situations. Care should be taken when designing a PMA to ensure that it meets the required goals for your particular situation and also avoids performing unnecessary (and possibly time consuming and expensive) examinations or tests. Communication of the results to the athlete and an action plan to address any identified issues are important to maximise the benefits of the assessment.

# Working and travelling with teams

with LIAM WEST

*Talent wins games, but teamwork and intelligence win championships.*

Michael Jordan

Within sports medicine, involvement in team care is a very rewarding yet challenging experience. Working alongside other clinicians and disciplines enables individuals to build upon their own skills and translate this into their everyday practice. Working with athletes on a regular basis helps the clinician to understand the psychological pressures placed upon them and appreciate the physical demands of the particular sport.

Clinicians working in a team environment must adapt and fit into the 'team chemistry'. This involves adhering to team rules and customs while appreciating that the clinician is a small cog in a very large wheel, where the players and the coach are the key people.<sup>1</sup> To be accepted by the coaches, athletes and other members of the medical team, the clinician needs to be in regular attendance during training sessions and competition. This in return offers the relatively unique opportunity to closely observe and understand mechanisms of injury before monitoring the progress of these injuries during rehabilitation.

Travelling with a team presents the sports medicine clinician with a considerable challenge.<sup>2</sup> In order to provide quality medical support on the road, clinicians must be flexible, innovative and fulfil a number of roles, as not all members of the medical team will be able to travel and less equipment will be available. Travelling with a team often involves working long hours in less than ideal conditions with sportspeople and coaches who are under great stress due to the demands of competition and travel.<sup>3</sup> Nonetheless, travelling with a team is fun, a great opportunity to learn, and offers the chance to broaden your horizons by seeing the world.

## THE MEDICAL SUPPORT TEAM

The size and make-up of the medical support team often depends on the size of the sporting team, the competition standard and financial considerations. Frequently, the support team will consist of just one individual, who may be a physiotherapist, physician, massage therapist or trainer. Specialists from various branches of medicine can contribute to the sports and exercise medicine (SEM) team.<sup>4-6</sup> It is imperative that a solo clinician develops a network of colleagues who can assist where additional specialised management is indicated. Not all members of the medical support team will be remunerated and the ethical issues facing professional teams' clinicians are slightly different from those of volunteer clinicians.<sup>7-10</sup>

## KEY ATTRIBUTES OF A SUCCESSFUL MEDICAL TEAM

In order to add value to athletes, the medical team often consists of representatives from different health disciplines. In an ideal scenario, the professional sporting team should have access to the services of an SEM physician, physiotherapist, massage therapist, podiatrist, dietitian, psychologist, orthopaedic surgeon, cardiologist and sports trainer as well as the coaching, sports science and fitness staff. Whoever is responsible for assembling such a support team must ensure that all individuals have high professional standards and work well collectively.<sup>11</sup> This leader does not necessarily need to be the team physician; often the physiotherapist or sports scientist is better placed to lead the medical team as they work full time with the sporting team. The appointed medical team lead should take ultimate responsibility for difficult management decisions and the smooth running of the group.

The best medical teams have clearly defined roles and duties that help to avoid conflict. The clinician has a primary responsibility to the athlete, but must determine and define his or her responsibilities to the coach, the team management and the fellow support staff before taking up the position. Medical teams should actively encourage the 'cross pollination' of ideas from different medical disciplines. Effective communication with each other, the athletes and the coaching staff is the cornerstone of success for a medical team.

## **MEDICAL INDEMNITY AND TRAUMA TRAINING**

We live in a world of litigation, and the sports medicine arena is not exempt. It is imperative that sports clinicians arrange medical indemnity to cover their entire scope of practice. Without this cover, the financial and reputational risks can be devastating. It is the responsibility of the team clinician to ensure that his or her medical indemnity is not only current, but also indemnifies them in any state, county or country to which team competition may take them. In addition to indemnity, it is important that medical team members (not just the physician) undertake an appropriate advanced resuscitation and emergency aid course for their sport so that they can competently care for a seriously injured or ill athlete. Without adequate training, indemnity may be null and void.

## **WHERE DOES THE MEDICAL TEAM WORK?**

The medical team is required to operate in various settings including at the training ground, at competition venues, and during travel. At each location the team must ensure that it has adequate equipment for each member to perform his or her role—see below for information on the pitchside medical bag. The club medical room should ideally be a clean room that has a door that can be locked to enable privacy and confidentiality. It should have at least one examination couch, facilities to enable the clinician to clean his or her hands at a sink or with alcohol hand gel, and all the medical equipment required for the particular sport.

The team clinician must ensure that medications and other medical equipment, such as oxygen, are stored safely and securely. If the clinician is expected to perform procedures such as suturing, he or she should aim to have an area to do so under sterile conditions while being able to safely dispose of sharps and blood-contaminated products. Clinicians should consider decorating the medical room with anatomy posters to help explain injuries, and evidence-based infographics to educate athletes about various topics within sports medicine such as the importance of sleep or adequate hydration.

## **MEDICAL EQUIPMENT**

The contents of the medical bag will vary depending on the type of sport, access to other facilities, and the clinician's own preferences. It is often impossible to carry all required items in one bag and therefore equipment should be organised into storage within the medical room, a pitchside suitcase, a medical bag and a hip bag that contains the essentials to provide athletes with symptom relief or immediate care until a more comprehensive kit can be accessed.<sup>12</sup> An exhaustive list of contents of medical equipment for a contact sports team without immediate access to more sophisticated facilities can be found in the box below. When travelling with a team, the contents of the medical kit will vary depending on the make-up of the medical support team, the size of the overall team and the local facilities available.

## **TEAM CARE THROUGHOUT THE SEASON**

The team clinician must tailor athlete care according to the stage of competition – pre-competition, during competition and post-competition. In the pre-competition phase there should be a full assessment of all team members based around a comprehensive history and examination (Chapter 46). This screening should evaluate for medical illness and musculoskeletal conditions that may need further follow-up. This screening will often be carried out in conjunction with a fitness assessment. A similar assessment should be performed on new team recruits and also on the entire team at the end of a season to plan appropriate individual off-season treatment and rehabilitation programs. Arrangements for how this will be monitored by the sports clinician should also be made. During the season, post-game/competition injury clinics help to diagnose and plan treatment of acute injuries and illnesses. Where possible, these clinics should be attended by both a team physician and physiotherapy staff.

## **Core principles providing care for a team**

The medical team should look to develop various core 'team principles' that underpin good sports medicine care. An athlete's right to confidentiality must be strictly adhered to by ensuring that their medical problems are not discussed with other team members, officials or the media without the player's permission.<sup>13</sup> Good record keeping is important for patient care and medico-legal purposes. There are many excellent software programs that allow practitioners to maintain records on a laptop computer, which is particularly useful when travelling with a team. The sports clinician should consider keeping two sets of password-encrypted notes: one for musculoskeletal injuries that can be seen by other members of the treating medical team, and the other for medical and mental health issues to which only

## Contents of the medical bag

### Diagnostic instruments

Oral/rectal thermometer  
 Stethoscope  
 Blood pressure cuff  
 Ophthalmoscope  
 Otoscope (auroscope) & ear pieces  
 Pencil torch  
 Tongue depressors  
 Oxygen saturation (SATS) probe  
 Tendon hammer  
 Portable ultrasonography device  
 Snellen eye chart & Ishihara plates  
 SCAT3™ forms

### Medications

Oral analgesics (e.g. paracetamol [acetaminophen], aspirin, codeine, tramadol)  
 Intravenous analgesics (morphine, tramadol)  
 Adrenaline (epinephrine) for anaphylaxis (& hydrocortisone)  
 NSAIDs (nonsteroidal anti-inflammatory drugs)  
 Antibiotics (e.g. amoxycillin, erythromycin, flucloxacillin, doxycycline, metronidazole)  
 Antacid tablets  
 Anti-nausea tablets (e.g. prochlorperazine [oral/IM], metoclopramide)  
 Antidiarrhoeal agent (e.g. loperamide)  
 Faecal softeners  
 Antihistamines  
 Bronchodilators (e.g. salbutamol inhaler, beclomethasone inhaler)  
 50% glucose solution  
 Sedatives and hypnotics  
 Nasal spray decongestants  
 Eye and ear antibiotic solutions  
 Ear wax softener  
 Throat lozenges  
 Cough mixture  
 Creams/ointments: antifungal, antibiotic, corticosteroid, anti-inflammatory  
 Tetanus toxoid  
 GTN sublingual spray  
 Corticosteroid injections

### Sutures/dressings

Needle holders

### Forceps

Scissors: nail clippers, small sharp scissors, tape scissors  
 Syringes (various sizes)  
 Needles (various sizes)  
 Sutures (various sizes), absorbable & non-absorbable  
 Suture cutters  
 Scalpels  
 Local anaesthetics: lignocaine (lidocaine) with and without adrenaline (epinephrine)  
 Steri-strips™ (various sizes)  
 Alcohol swabs  
 Gauze swabs  
 Dressings packs  
 Antiseptic solution  
 Tincture of benzoin  
 Dressing pads (various sizes)  
 Low-adherent dressing (e.g. Jelonet™)  
 Band-Aid® plastic strips  
 Crepe bandages  
 Tube gauze (Tubigrip™)  
 Sterile gloves, goggles & mask

### Resuscitation and emergency equipment

Defibrillator  
 Resuscitation medications (e.g. adrenaline, amiodarone)  
 Oropharyngeal & nasopharyngeal airways (various sizes)  
 Bag valve mask (BVM)  
 Oxygen with suitable delivery masks  
 Emergency cricothyroid set  
 Portable suction device  
 Cannulation equipment  
 Intravenous (IV) sodium chloride  
 Intravenous (IV) giving set  
 Rectal diazepam (for seizures)  
 EpiPen®

### Blood management

Gauze swabs  
 Klatostat® for lacerations  
 Klatostat strings & Rapid Rhino™ for epistaxis  
 Blood tape (Coban™)  
 Co-phenylamine/tranexamic acid nasal spray  
 Betadine® spray  
 Vaseline®

### Other equipment

Bolt cutters/screwdriver  
 Air/box splints  
 Triangular bandages (sling)  
 Cotton-tipped applicators  
 Rigid sports tape (various sizes)  
 Elastic adhesive tape (various sizes)  
 Compression bandage (various sizes)  
 Adhesive foam pad  
 SAM splint  
 Blister pads  
 Coolant spray  
 Crutches  
 Deep Heat® muscle warming spray  
 Finger splints  
 Adjustable cervical collar (soft & hard)  
 Spinal board with straps  
 Eye kit: irrigation solution, fluorescein, eye patches, local anaesthetic/dilating eye drops, contact lens container  
 Sunscreen  
 Bonjela mouth ulcer cream  
 Massage oil/heat rubs  
 Electrotherapy (e.g. TENS, portable laser)  
 Portable couch  
 Alarm clock  
 Plaster of Paris/thermoplastic casting equipment

### Miscellaneous equipment

Pen and paper  
 Urine reagent strips and urine sample pots  
 Safety pins  
 Tampons  
 Condoms  
 Contaminated needle container  
 Acupuncture needles  
 Foam rollers & rehabilitation equipment  
 Spare shoelaces  
 Spare mouth guard  
 Flexible orthoses  
 Batteries  
 Safety razor  
 Plastic bags & cling film for ice  
 Transformer & dual voltage connector (if appropriate)  
 Glucose sweets (for hypoglycaemia)  
 Alcohol hand gel  
 Heel-raise foam pads  
 List of WADA banned substances

C

the clinician has access. A simple overview of player availability using a traffic-light coloured coding system (green = available, orange = available with conditions, red = unavailable) can help communication with coaching staff while maintaining confidentiality.

Working with a team provides an ideal opportunity to educate sportspeople and coaches. The medical team should look to create 'teaching moments' throughout the season during opportunities such as the pre-season health assessment, treatment sessions or team presentations. Experienced team clinicians have found that relevant topics of education include the following.

- **Sexual activity.** Team members should be warned of the dangers of acquiring sexually transmitted infections such as chlamydia, gonorrhoea, hepatitis B and HIV. Abstinence guarantees prevention, but condoms should be made available.
- **Hygiene.** Players should be encouraged to wash their hands regularly with alcohol hand gel and to avoid contact with any ill team members or loved ones. Travelling to foreign countries or participating in large sporting events places both athletes and support staff at risk of endemic disease and outbreaks of infectious diseases.<sup>14</sup>
- **Vaccinations.** Team members should be educated about the need for vaccinations depending on the countries they will compete in. Immunisations for the athlete are listed in Table 47.1. Team clinicians should use websites to gain up-to-date information on vaccination and illness prevention, especially in destinations where disease pattern is rapidly evolving.<sup>15</sup>
- **Anti-doping.** Team members must ensure they have a sound appreciation of those medications that are currently banned by the World Anti-Doping Agency (WADA). Up-to-date information can be obtained from national sporting organisations and Olympic

federations—some useful contacts are listed in Table 47.2. Medical team members need to educate players so they understand that many over-the-counter medications used in the treatment of coughs and colds are banned, and they should not take any medications or supplements without consulting their medical team.<sup>16</sup>

## EMERGENCY ACTION PLANS

Emergency action plans (EAPs) are extremely useful documents that can help the sports clinician prepare for difficult scenarios that can arise within sports medicine. EAPs containing, but not limited to, the below information should be created for home training and competition venues in addition to all the locations you may travel to with your team:

- Contact details of the entire medical and coaching staff
- Address and contact details of all sporting and accommodation venues
- Distances from these locations to various specialist medical services and their contact details:
  - emergency department
  - trauma unit
  - orthopaedic surgery
  - plastic surgery
  - cardiac services
  - neurosurgery
  - burns unit
- National consulates and embassies are useful for foreign travel to source information on the quality of local medical personnel and facilities
- For each venue, entry points for emergency services (i.e. ambulances) should be determined so that clear instructions can be given to locate the team

**Table 47.1 Immunisations suitable for the athlete according to the World Health Organization in May 2016**

Routine vaccination	Selective use for travellers	Mandatory vaccination in particular countries
<ul style="list-style-type: none"> <li>• Diphtheria, tetanus, pertussis</li> <li>• Hepatitis B</li> <li>• Haemophilus influenzae type b</li> <li>• Influenza (seasonal)</li> <li>• Measles, mumps, rubella</li> <li>• Pneumococcal disease</li> <li>• Human papillomavirus (females)</li> <li>• BCG</li> </ul>	<ul style="list-style-type: none"> <li>• Cholera</li> <li>• Hepatitis A</li> <li>• Japanese encephalitis</li> <li>• Meningococcal disease</li> <li>• Rabies</li> <li>• Tick-borne encephalitis</li> <li>• Typhoid</li> <li>• Dengue (CYD–TDV)</li> </ul>	<ul style="list-style-type: none"> <li>• Yellow fever (depending on the country)</li> <li>• Meningococcal disease and polio (required by Saudi Arabia for pilgrims; updates are available on <a href="http://www.who.int/wer">www.who.int/wer</a>)</li> </ul>

**Table 47.2** Contact details for obtaining drug information in various countries

Country	Drug information website address

United States	US Anti-Doping Agency (USADA), www.usada.org

- All medical team staff should have completed an emergency life support training course that involves education regarding cervical spine immobilisation and transferring the athlete from the pitchside to hospital safely. The team should then make, and frequently practise, plans for caring for a medically unstable athlete in various situations
- A pitchside extrication plan should be created and practised regularly throughout the year. This plan should be exhaustive and address questions such as:
  - Who will perform what duties during pitchside extrication (such as cervical spine immobilisation, positions within a log roll, and positioning the spinal board)?
  - What will the instructions be during a log roll?
  - Does the defibrillator have scissors attached to it to facilitate quick removal of a jersey so pads can be applied to the chest?
  - Where are the defibrillator and other emergency equipment located is this equipment locked and if so who has the key?
  - Who will call for an ambulance?
  - How do you carry the athlete off the pitch?
  - Where will the athlete be taken to once on the spinal board?
  - Is this designated place warm or do blankets need to be stored there?
- Consider which member of the medical team will stay with an athlete during drug testing procedures or in the event that he or she is unable to travel back from a destination due to injury or illness.

## PREPARING TO TRAVEL

When travelling to any venue away from home, the usual medical support structure is lost and the nature of existing medical support services in different countries varies substantially.<sup>17</sup> In order to become self-sufficient, a detailed plan must be constructed before travelling with sports teams.<sup>18</sup> Team clinicians may find it useful to split preparation into the following four stages;

### 1. Before travel

- *Travel destination.* The team clinician needs to have a good understanding of the climate, altitude, level of pollution, water supplies, security, recent health epidemics and natural disasters at the destination.<sup>19-21</sup>
- *Accommodation.* In hot climates, air conditioning may be advantageous for comfort although it may delay heat acclimatisation. It may also cause respiratory issues if used excessively as it can dry out the upper respiratory tract mucosa. Particularly tall athletes will require extra-long beds. Try to have a dedicated medical room when travelling with a large team to allow for privacy and confidentiality.
- *Vaccinations.* As discussed earlier (Table 47.1), vaccinations and malaria prophylaxis must be considered before embarking upon travel.<sup>15</sup>
- *Equipment and travel logistics.* It is important that the weight allowance for travel is considered when packing medical equipment so that everything can be transported to the destination. The local destination

medical services should be researched to decide whether medical equipment and medications can be sourced locally or need to be transported. It is important to note that medications may have different compositions in different countries. An advance visit to the competition location is extremely advantageous, if feasible, for the team physician to inspect local medical facilities, hotel kitchens and the like.<sup>22</sup> Formulas exist within the literature to assist in estimating the pharmacological needs for a trip,<sup>23</sup> and it is important that all the medications be accompanied by a prescription or doctor's letter as well as being kept in the original containers.<sup>24</sup>

- **EAPs.** As discussed above, creating EAPs to prepare for travelling with a team is invaluable.
- **Fitness to travel assessments.** Contact all team members, including coaches and officials, to ask about present and past injuries or illnesses. Often officials are older than the athletes and can cause anxiety for a travelling clinician because of medical conditions such as coronary artery disease. These individuals must be reminded to bring their own medications. Attempts must be made to treat injuries or illnesses prior to departure.
- **Nutrition.** It is challenging for athletes to maintain good dietary habits when travelling and they should be counselled on wise food choices before travel.<sup>25</sup> At large competitions, athletes often eat in village communal restaurants where buffet-style dining practices may lead to overeating. In addition to food intake, adequate hydration—especially when travelling to warm climates—is important.<sup>21</sup> To minimise the risk of traveller's diarrhoea, athletes should eat only food that has been cooked, and avoid shellfish, salads, unpasteurised milk products and unpeeled fruit.
- **Jet lag.** This is discussed in the following section.
- **Insurance and indemnity.** As described earlier, your policies must cover you to practice at your destination. If any minors are in attendance, it is important to travel with the appropriate permission documents to treat them, as well as their guardian's contact information.<sup>26</sup>
- **SAMPLE forms.** It is useful to create a history and treatment sheet for each athlete prior to travel in case she or he should need to be transferred to hospital during the trip. This sheet can be pre-filled with certain details such as their past medical history, regular medications, allergies, personal details and next of kin details. The SAMPLE format is a useful format for this sheet: **S**igns and symptoms, **A**llergies, regular **M**edications, **P**ast medical history, **L**ast meal/drink and **E**vents (including examination and treatment/intervention).

- **Injury prevention.** It is important to ensure that despite travelling, the team conduct proper warm-ups, stretching/yoga and strength maintenance, and receive regular soft tissue therapy.

## 2. During travel

Sports physicians should create a medical travel bag that contains medications to deal with travel sickness and simple analgesic medications. They must ensure that the athletes have sufficient water and food for the duration of their trip, especially if they are to compete soon after reaching their destination. If travelling long distances via road or aeroplane, the use of thromboembolism-deterrent (TED) stockings, electronic calf stimulators, earplugs, eye masks and facemask air humidifiers can help athletes to sleep in comfort and reduce the risk of venous thrombosis.

## 3. On arrival

A medical room should be established soon after arrival. Ideally, this should be a large room separate from any bedrooms. Treatment hours should be specified using an appointment sheet so that the practitioner has adequate time for meal and exercise breaks. This must be strictly enforced as athletes have a tendency to extend these hours. The clinician should ensure that athletes know the room number of the medical staff in case of emergencies. It is important that the team manager know how to contact the medical staff if the room is unattended. It also helps to obtain an athlete room list from the team manager.

For trips involving a single venue, a portable examination couch (treatment table) is invaluable for the comfort of both the athlete and the treating clinician. A low, soft bed may not be an appropriate site for massage or spinal mobilisation. On trips involving multiple venues, the advantage of having a treatment couch must be weighed up against the inconvenience of transporting it.

Traveller's diarrhoea is very common when travelling for sports,<sup>27</sup> and while the infection is usually self-limiting, team physicians should institute oral fluid replacement as the mainstay of treatment.

## 4. Journey home

Preparation for the return journey is important as some injuries or illnesses incurred while away may need specialist arrangements for travel or referral for specialist follow up.<sup>28</sup> Thought must be given to the thromboembolic risk of various injuries, such as fractures, and whether anticoagulation should be used prior to return travel. Once back in the home country, the medical staff should have a debriefing session to review any issues during the trip to enable changes to be implemented for future medical care.<sup>18</sup>

## JET LAG

Jet lag presents a major challenge for clinicians travelling long distances with teams.

### Air travel and jet lag

Air travel is an important part of professional and international sports. Short-distance air travel (up to 3 hours) does not appear to present any problems for the athlete.<sup>29</sup> However, extended air travel, often required for major events such as Olympic Games or World Championships, can provide significant problems.<sup>30</sup> Thus travelling athletes, team officials and team physicians will benefit from education on how to decrease the harmful effects of long-distance travel, such as jet lag, on performance (Table 47.3).

Jet lag is when the body is unable to adapt rapidly to a time zone shift and normal body rhythms lose synchrony with the environment. In general, it is a benign and self-limited condition. The major complaints of the condition are poor sleep, daytime fatigue and poor performance.<sup>31</sup> The sleep deprivation secondary to the flight can be mostly made up in a day, whereas jet lag lasts much longer.<sup>32</sup> A number of factors influence the severity of jet lag symptoms.<sup>33-34</sup> These include: individual differences, number and direction of time zones crossed, temporal and seasonal timing of flight, age, impaired health, lack of previous travel experience, sleep deprivation, dehydration, stress, alcohol and excessive food intake.<sup>35</sup>

### Pathophysiology

The suprachiasmatic nuclei (SNC), located in the hypothalamus, produce a timing signal that modulates circadian rhythms of sleep and alertness, core body temperature and certain hormonal secretions such as melatonin and cortisol. The SNC, via the eyes, senses darkness and sends a timing signal to the pineal gland. This maintains the nocturnal secretion of melatonin for 10-12 hours. Beta blockers can inhibit melatonin secretion. Although the SNC signal is important, melatonin secretion requires darkness. Light intensity of >50 lux can cause some melatonin inhibition and light of >2000 lux completely suppresses it. Therefore, summer's long days and short nights will suppress melatonin secretion despite the 12-hour SNC 'on' signal.

The 12-hour SNC 'on' signal, despite melatonin inhibition by light, is considered an operational definition for biological night. Therefore, the nocturnal SNC signal synchronised to home night time (biological night) may result in melatonin secretion if the unadapted, jet-lagged traveller is placed in a dimly lit room. Melatonin can be measured in saliva, plasma and urine.<sup>31</sup>

The circadian rhythm is regularly synchronised to the 24-hour day by environmental time cues, termed 'zeitgebers', such as alternation of light and darkness, ingestion of melatonin, sleep/awake schedules, physical activity and meal timing.<sup>31, 35</sup>

Travelling across multiple time zones (>3 time zones) causes a temporary misalignment between the circadian clock (lag) and the sleep/wake schedule at the destination time zone, that is slow to reset. The symptoms of jet lag dissipate as the circadian clock gradually resets (adjusts) to the time cues at the new destination time zone.<sup>31, 32, 35, 36</sup> Although there is considerable individual variability, it is estimated that it takes about 1 day per time zone for the biological clock to resynchronise with the sleep/wake schedule.<sup>25, 31</sup>

### Prevention of jet lag

The faster the biological clock adapts to the new time zone, the shorter the symptomatic period. Thus, speeding up the adaptation is the primary goal.<sup>35</sup> When travelling in more than three time zones for a stay longer than five days, circadian adaptation is desirable (Table 47.3).<sup>35, 37</sup> Pre-flight adjustment to travel may speed up adaptation and is discussed below.<sup>38</sup> Experienced practitioners and many successful athletes also suggest that low-intensity physical activity early after arrival helps promote adjustment to the new time zone. Seasoned air travellers have developed a series of guidelines to minimise the adverse effects of long-distance travel (Tables 47.3 and 47.4).

### Timed light exposure and avoidance

Light intensity and timing are the two most important factors that influence phase shift. Exposure to bright light (sunlight at approximately 3000-100 000 lux, light box at 1500-3500 lux or room light at 100-550 lux) can help phase shifting. The magnitude of shift is greater as we get closer to the Tmin (the body's minimum core temperature, which is estimated to occur at 3-5 am in most individuals). Light has more shifting effect at night when bright light is absent.

#### PRACTICE PEARL

Light exposure late in the sleep episode or in the early morning (i.e. after the Tmin phase advances) will promote phase shifting. The same light stimulus, when applied early in the sleep episode (i.e. before the Tmin) will delay phase shifting.<sup>31, 32, 35, 39</sup>

**Table 47.3 General guidelines for adaptation strategies based on the length of stay at destination and numbers of zones crossed<sup>35</sup>**

Length of stay at destination	Recommended strategy
Long (>5 days)	<ul style="list-style-type: none"> <li>• Pre-travel adaptation of sleep schedule to that of the destination</li> <li>• Timed light exposure and avoidance</li> <li>• Timed melatonin intake</li> </ul>
Intermediate (3–4 days)	<ul style="list-style-type: none"> <li>• Work around sleep and alertness times</li> <li>• Schedule critical activity to daytime in the departure zone</li> <li>• Airplane light exposure/avoidance strategy</li> <li>• Short-term measure to maintain alertness (caffeine) and sleep (naps and short-acting hypnotics)</li> </ul>
OR	
Short (1–2 days)	
OR	
Game aligned with circadian time of peak performance	

**Table 47.4 General principles to help clinicians customise jet travel schedules for athletes travelling in any direction across multiple time zones**

**Goal:** Get Tmin within sleeping episodes and avoid being awake at the sleepest time (Tmin)

Eastward jet lag	Westward jet lag
<b>Differences</b>	
<ul style="list-style-type: none"> <li>• Requires advancing the circadian clock</li> <li>• Harder and slower to adjust (1 h/day)</li> <li>• Abrupt 12-h time zone shift, takes 8–9 days to adjust</li> <li>• Destination Tmin = origin Tmin + number of time zones crossed</li> </ul>	<ul style="list-style-type: none"> <li>• Requires delaying the circadian clock</li> <li>• Easier and quicker to adjust (1.5–2 h/day)</li> <li>• Abrupt 12 h time zone shift, takes 4–5 days to adjust</li> <li>• Destination Tmin = origin Tmin – number of time zones crossed</li> </ul>
<b>Similarities</b>	
<ul style="list-style-type: none"> <li>• Maximum or largest shift is 12 h time zones</li> <li>• Traveller feels sleepy in hours surrounding Tmin and difficulty sleeping at hours far from the Tmin</li> <li>• Traveller will experience impaired daytime activity near Tmin</li> <li>• Phase shifting needs to be applied daily for several days to produce results</li> </ul>	

Tmin origin = minimum core temperature, estimated to occur at 3–5 am (hours before wake-up time) for most individuals, 2–4 am for larks (morning type, M-type), and 5–7 am for owls (evening type, E-type) based on the sleep pattern for the last week. Tmin coincides roughly with the maximum nocturnal melatonin level in the circulation

Timed light avoidance is equally important. Light avoidance can be achieved by staying in a dim light room (<10 lux) or wearing dark sunglasses.<sup>39</sup> Light exposure should be augmented with light avoidance during flight or on arrival to a new destination as it ensures a unidirectional phase shifting. For instance, an eastward-travelling athlete needs to maximise light exposure after Tmin and avoid or minimise light before Tmin to ensure phase advancement of the circadian clock, and vice versa for the westward travelling athlete.<sup>38</sup> On the other hand, exposure to light before and after Tmin would result in no phase shifting.

### Timed melatonin pills

Despite being marketed as an over-the-counter sleep aid, melatonin is not associated with sleep or increased sleepiness. Instead, melatonin is considered a darkness signal. The timing of melatonin pills is more important than dose. It has more of a phase-shifting effect when there is less endogenous melatonin in the circulation. Therefore, a timed melatonin pill (3 mg) can help produce the greatest phase advance of the circadian clock when taken in the afternoon (approximately 5 hours before dim light melatonin onset [DLMO] or 12 hours before Tmin) while phase delays occur when taken in the morning.<sup>32, 35</sup>

**Pre-travel sleeping schedule**

Adjusting sleep schedule in 1-2 days (depending on the number of time zones to be crossed) prior to travel to gradually match the destination schedule may help with phase shifting. Sleep on flights should be avoided unless it is night at destination.<sup>40</sup>

**Synergistic approach**

When combined with a pre-travel sleep schedule for the destination, timed light exposure/avoidance and melatonin pills can have a synergistic phase-shifting effect.

**Symptomatic treatment for jet lag**

If the travelling athlete still suffers jet lag symptoms despite the gradual shifting, stimulants such as slow-release oral caffeine (300 mg) could be helpful to induce daytime alertness, and hypnotics such as oral zolpidem (10 mg) could be used to counteract night insomnia.

# Career development

by MICHAEL DAVISON

*If you don't build your dream, someone else will hire you to help them build theirs!*

Dhirubhai Ambani

The first thing to realise is that, irrespective of the industry in which you work, the fundamental responsibility for your career lies with you. You are in charge. Of course you can let fate play its part, and without certain qualifications and experience you may find obstacles in your path. All of this considered though, it will be your determination and persistence that creates your career opportunities. It is important to think big about where you would like to be and to have the dream, but within this dream you need both a plan (which can change over time) and the stepping stones to achieve it.

In this chapter we explore the context in which careers in sport and exercise medicine (SEM), sports therapy and physiotherapy operate. This landscape has changed greatly in the past decade and is set to evolve even further in the next. The main driver has been the globalisation of medicine to support sport which has mirrored the globalisation of sport.

Furthermore we want to focus readers' attention, in particular that of future sports clinicians, on the key behaviours that are important to both potential employers and other people who will help with career progression.

We then reflect on some career advice provided by five members of the SEM community: two international sports physiotherapists; a young SEM doctor; one of the most controversial characters in SEM; and finally, a leading figure in injury prevention. All of their stories and advice provide invaluable real life guidance and inspiration.

## DEVELOPMENT OF SPORT AND EXERCISE MEDICINE

Sport and exercise medicine has become an all-encompassing term for many subdisciplines and types of practitioners. Sports medicine is a multidisciplinary way of thinking based around three core themes or approaches:

1. Work as a team.
2. Communicate internationally.
3. Reach the top with your patients or athletes, where you seek to achieve the maximum functional recovery possible.

Across the world, SEM has developed at different rates and with different styles of leadership and personality. Now, however, the effect of globalisation is felt more strongly through the diaspora of the playing talent in sport and increased global travel to compete in both professional and amateur events, such as marathons and triathlons. Following this pattern, clinicians have begun to move internationally to practise and so cross-pollination is taking place. There has never been a better time for an international career in SEM.

The internationalisation of the discipline is not constrained to the travels of individual athletes. In fact, in the past decade international governing bodies such as FIFA (Fédération Internationale de Football Association) and the IOC (International Olympic Committee) have created international networks of clinics and scientific research centres or hubs (48 in the case of FIFA and nine in the case of the IOC), with the key driver of promoting international collaboration. Both groups also support large conferences, such as the annual Football Medicine Strategies Conference organised by Isokinetic Medical Group and the IOC World Conference on Prevention of Injury and Illness (held every three years). More than 1000 sports medicine practitioners from more than 70 countries come together at these conferences to share their experiences, network and seek collaboration for future multicentre studies.

This explosion in interest in the discipline has led to the need to establish a common method of communication,

and sports medicine has adopted English as its base language. To support and stimulate further cross-border sharing of information and experience, the *British Journal of Sports Medicine* (BJSM) has been proactive in co-opting well over 20 professional member bodies from countries as diverse as The Netherlands, South Africa, Australia and Switzerland, and has extended its editorial board to embrace 35 nations (at the time of publication).

Against this backdrop of movement of people and information, two other macro trends are positively impacting upon the cultural development of the discipline and the number of career opportunities. These are an increase in televised sport and its associated investment, and a growing understanding of the dangers of physical inactivity, which has led to the view that 'exercise is medicine'.

### **The adoption of exercise medicine in the sports medicine movement**

In many countries, sports medicine has become known as 'sport and exercise medicine'. This term provides an apt description of the discipline, blending management of sports injuries and medicine in the sporting population with promotion of the beneficial effects of exercise and its positive contribution to world health.

Treatment of the effects of physical inactivity is outside the scope of this volume (see Volume 2: *Exercise Medicine*), but it is widely recognised that insufficient physical activity is a key risk factor for non-communicable diseases (NCDs) such as cardiovascular disease, cancer and diabetes.<sup>1</sup> There is mounting scientific evidence that physical activity may be a most important public health intervention to prevent NCDs. Evolving national health systems and structures, and public health policies, will increasingly shape the way in which investment is targeted to deal with the mounting burden of NCDs. This will lead to wider and more specialised career opportunities. The private sector will support this, especially where there are sporting injury comorbidities or a patient wishes to regain functional capacity. Additionally, as the population ages and the importance of sporting activities and participation among the older generation increases, the demand for specialised, private sports medicine services will increase.

### **Increased resources in sport**

Television companies are now able to access global markets through digital and internet-based channels, resulting in a huge inflow of money into sport. This has triggered an increase in investment in both SEM and research. Not only are there now more resources available to club management to spend on player support and welfare, the economic rationale and business case for the role of SEM is better understood. Now, in a premier league football clinical team you would expect to see at least:

- a full-time SEM doctor
- two or three part-time doctors across all teams
- a ratio of one physiotherapist to five first team players
- osteopaths and chiropractors
- a sessional sports psychologist, a dietitian/nutritionist and a podiatrist
- sports therapists and other soft tissue specialists
- a medical administrator.

These roles, although they may be well paid, are also very demanding, often requiring availability across the full week. (See also Chapter 1.)

### **Proficiency in a second or third language**

Another trend, in European football clubs in particular, is that language skills within the SEM team are increasingly required and valued. Considering that the playing group of most UEFA Champions League football teams is drawn from more than a dozen countries and mother tongues, it is difficult for SEM practitioners to communicate and build a bond of trust if they do not fully understand the cultural heritage of the players and their medical history. Added to this is the requirement to communicate effectively with the national team SEM staff for acute injury management, workload modifications and return-to-play (RTP) considerations. This additional workload on top of normal day-to-day club commitments is becoming more common in football as there are more international 'friendlies' and larger national team squads. Within football, Spanish and French are probably the most valuable second languages to learn. This allows for better communication with players from North and West Africa, and Central and South America.

### **Widening the scope of practice—dual qualifications and subspecialist courses**

In addition to the increased demands that are placed upon SEM teams in professional sport, employers expect practitioners to have a wider vision than would be provided by a single educational experience. For example, within a rehabilitation-focused setting, classical physiotherapy training is not considered sufficient to help a patient to reach the maximum functional recovery possible.

If a practitioner has a secondary qualification, the scope of practice widens and there is a greater benefit for both the patient and the team. Among the staff at the Isokinetic Clinic in London practitioners hold the following dual qualifications: sports therapy BSc and fast-track physiotherapy BSc; physiotherapy BSc and sport and exercise medicine MSc; engineering science BSc and physiotherapy BSc; human movement science BSc and sports physiotherapy MSc. After the base university

education, the next development steps are in specialist courses and certification. For example, a SEM physician, doctor, or physiotherapist may be able to add value by doing an MSc in ultrasound or injections. This is a way of adding value to patients' treatment and at the same time becoming more employable. Another example might be a physiotherapist undertaking a course in the management of non-specific low back pain, if this is what is being seen in their clinical practice.

### Sports therapy, sports and exercise science, and sports rehabilitation

There is a well-identified need for a blended skill-set and perspective, whether as an individual practitioner or among the wider SEM team. After graduating from undergraduate physiotherapy or physical therapies degree courses, the clinician has not yet received sufficient training to be effective in SEM settings. To meet this need, many clinicians undertake sports physiotherapy masters degrees.

There has also been an explosion in the number of new courses designed specifically to train students in the management and treatment of sports injuries. In the United Kingdom, sports therapy, sports and exercise science and sports rehabilitation courses have been among the fastest growing university courses over the past five years.

Overall, however, systems in public and private medicine and in team sports have not kept pace with this change, especially in the areas of state registration, professional indemnity insurance and identifying where they fit in the clinical governance model. In the United Kingdom, for example, because of a lack of state registration by the Health and Care Professions Council, (HCPC) sport and exercise clinicians are unable to be registered with private medical insurers (PMI) for work in the private sector and cannot always assume highly responsible roles in team settings. Fortunately it does seem that change is just around the corner and future accreditation processes will open up new avenues of career opportunities.

### Men and women have a place in sport and exercise medicine

One final but important dimension to the development of SEM over the past decade has been the increasing participation of female doctors, physiotherapists, osteopaths and other clinicians in the discipline. Sport has historically been male-dominated and resistant to change. Women were (and many still are) disadvantaged in many settings. This is beginning to change, not simply in an age of equal opportunities, but as sporting teams recognise that medical teams need to be selected on merit and not prejudice.

## KEY BEHAVIOURS FOR A SUCCESSFUL AND INTERESTING CAREER

My personal career path in sports medicine has been far from traditional. Three key points that contributed to my being in the position of responsibility I have are: (i) gaining skills that would *add value* to a sports medicine setting (business management in my case), (ii) adopting a *flexible attitude*—embracing change, and (iii) working to develop a network of top experts who support me and to whom I contribute. Turning the mirror to face the reader, I suggest the following five key behaviours are critical to developing a successful career:

- willingness to make yourself available to patients and colleagues
- open, honest and timely communication
- problem solving
- determination to reach the optimal result
- attention to detail.

Surrounding this is the development of self-awareness, which is built through an evolutionary process of maturation. These phases do not have to be sequential and they often run in parallel. There may be times when you reflect and revisit an earlier phase, especially as your self-awareness grows. Don't be afraid to go back to run forward.

In the first phase of your career you should seek to develop your technical skills and knowledge. This knowledge increases over time, but mainly as a result of practice. 'Miles on the clock' are important (Fig. 48.1).

Being an 'expert' is a dangerous time for a clinician. It may be a time of making clinical errors in advance of developing greater insight into one's limitations (Fig. 48.2).

A positive next step and second phase of your career is to develop your 'softer' skills, such as effective communication, negotiation, conflict resolution and problem solving (both through specific courses and also by talking with those close to you). To really develop in this area you

**Figure 48.1** A schematic of how we can describe different levels of development as a health professional

**Figure 48.2** Depicts a common feeling where a learner's feeling of knowing nothing changes into feeling that he or she knows everything, before soon realising that even the most expert really knows very little

need not to be afraid of making mistakes and you need to seek out constructive criticism.

This then leads you into a critical SEM phase—that of understanding what it really means to work in a team. It means *collective action over self-interest*. Much easier said than done. There are countless examples of dysfunctional medical teams due to the inability of team members to find a simple working consensus.

At all times in your life and particularly as you start making your own decisions, you need to recognise the role of others close to you in your career development. This can be your parents, but is more likely to be your partner or spouse. Including that individual(s) in any decision making and being very clear about the likely impact on your time together (especially as sports medicine often involves travel with a team or long or anti-social hours in the working environment), will provide stability for you to grow. It is not a normal career that you are looking to develop, so you will need extraordinary support, understanding and encouragement around you.

Last, and while this sounds the easiest, the greatest challenge you will have is working on yourself. This is not in relation to developing knowledge or skills, nor is

it the teamwork that is required inside and outside work. It is about making sure you have a good relationship with yourself. One where you actively critique and score yourself, and drive yourself to live in the present, understanding the importance of the past and how it seeds the future. You need to have a relationship with yourself where you reflect on your actions honestly and with humility.

Complementing my perspective, here is an American perspective on how you could break into the world of sports medicine, especially team medicine, and succeed:<sup>2</sup>

- *Pay your dues.* Start working with local sports teams to gain experience.
- *Create visibility.* Make yourself known to team decision makers.
- *Communicate clearly.* Professional communication training is a plus.
- *Build relationships.* Sport is like life: it's all about relationships.
- *Create protocols.* A disorganised doctor is an ineffective doctor.
- *Establish a chain of command.* Let others know who to talk to and when.

- *Direct the flow of information.* A team needs to speak with one voice.
- *Clarify expectations.* Determine the needs and wants of each stakeholder.
- *Let the coaches coach.* Don't stick your nose where it doesn't belong.
- *View each player as an individual.* That goes for visiting players, too.
- *Be wary of the media.* If you must talk to them, stick to the facts.

## LESSONS FROM AROUND THE WORLD

Below, five members of the international sport and exercise medicine community offer their advice to others about developing a career in sports medicine.

### Ummukulthoum Bakare—football medicine enthusiast and sports injury prevention strategist West Africa

Ummukulthoum Bakare is based in Lagos, Nigeria. She is a member of the Medical and Scientific Commission of the Nigerian Olympic Committee. Alongside this role she is a senior physiotherapist at Lagos Teaching Hospital and one of the few accredited FIFA 11 For Health and FIFA 11+ (injury prevention program) instructors in Africa.

Like many successful SEM professionals before her, she understands that it is important to engage in continuous self-improvement and professional development.

Her advice to aspiring SEM clinicians is:

- *Practice makes perfect.* Be willing to shadow, undertake work experience, learn and do a large amount of volunteer work to get the necessary hands-on exposure and experience.
- *Never be tired of being a part of the knowledge continuum and always share information.* It does not make you any less intelligent!
- *Don't think you know everything and want to be in the spotlight.* Even professors are still learning—so should you. The light will shine on you when the time is right.
- *Procrastination is the thief of time.* Poor time management is the bane of any professional.

### Dr Liam West—the rookie doctor Northern Europe and Australia

Liam is based in Melbourne, Australia, but completed his junior medical jobs in Oxford, England, and his undergraduate medical training in Cardiff, Wales. At the time of publication he was planning to start his specialist training in SEM medicine. He has a passion

Ummukulthoum Bakare

COURTESY OF OBE TOLUOPE CROSSHAIRS PHOTOGRAPHY

*Once you identify what goal you want to achieve as an upcoming sports physiotherapist, you have to seek out and surround yourself with senior colleagues who can help you on your path—mentors in the profession or a related field. An orthopaedic surgeon acted in this role early in my career (undergraduate university) and helped me identify my interest of specialisation in sport and exercise medicine. Let passion be your driving momentum and all the glitz and glamour may follow, but it is not guaranteed unless you make it count! Ummukulthoum Bakare*

for increasing the opportunities and education in SEM for undergraduates and junior doctors. To help achieve this he founded societies: at local level while at Cardiff Medical School; at national level in the UK with USEMS (Undergraduate Sport & Exercise Medicine Society)—and at European level, with ECOSEP (European College of Sports

Dr Liam West

& Exercise Physicians). He is a Senior Associate Editor for the BJSM, produces insightful podcasts for the journal, and coordinated the BJSM 'Undergraduate Perspective on Sport and Exercise Medicine' blog series.

Liam recognises the value of developing an international network. During his undergraduate elective, he gained experience at the Olympic Park Sports Medicine Centre, Melbourne and the Stadium Orthopaedic and Sports Medicine Centre, Sydney, followed by time at the Aspetar Orthopaedic and Sports Medicine Hospital, Qatar.

Liam's suggestions for juniors wanting to develop a career in SEM include the following.<sup>3</sup>

- *You need energy and motivation, especially to seize opportunities.*
- *How do you get these opportunities?* By approaching medical or physiotherapy schools in the first instance

to see what they can offer. Ask if they have lectures on SEM and if they have faculty working there who are involved in sport.

- *When you are there, find out if there is a local student society.* If there is, then get involved. If not, make one. Aim to get on the committee to learn valuable skills while meeting key individuals in SEM.
- *Networking is key.* You can network in a general way (i.e. online) but the most effective way is at conferences—choose five names on the program and don't leave until you have their email addresses. Email them that night explaining it was nice to meet them and include something interesting about either what you said or did while with them. Then in the no-so-distant future, when you're looking for SEM experience, reply to that initial email and they will remember who you are from your story. This will help your request stand out from the weekly emails for shadowing opportunities the clinician receives. Wait until your chosen contacts are with at least two of their colleagues—you will meet more people this way for less effort. Networking should be fun!
- *Offer to work at conferences for free admission—pack bags, etc.* This gets you networking opportunities and plenary education for free!
- *Remember to network within your peer group, not just the big guns.* In 15 years time, hopefully you and your colleagues will be the leaders of the clinical and research arms of SEM so forge lasting relationships early.
- *Once networked, get your hands dirty and try to get as much experience as possible in sport.* You need to start viewing long weekends in the rain as good things. When shadowing, be polite, gently inquisitive, energetic and offer to help at every opportunity—do NOT be a burden and, importantly, do NOT be a fan. Doctors are employed to provide clinical care for athletes, not to scream abuse at a referee or celebrate a goal.
- *People don't owe you this experience.* You don't get it handed to you like cardiology or respiratory medicine during your undergraduate studies—you need to offer value to those giving the experience. Sitting in on a clinic may be achieved by doing an audit for the company, etc. Create your self-directed study modules or elective placements in SEM. Travelling for these experiences should not put you off.
- *Adding value can also be in the form of targeted learning.* If you are interested in a certain sport, learn about the common injuries—spines and fingers in cricket, groins and ankles in football, anterior cruciate ligament injuries in netball, etc.

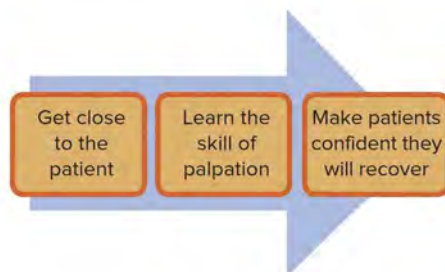

### Hans-Wilhelm Müller-Wohlfahrt—the team and celebrity doctor Bavaria, Central Europe

The oldest of our interviewees, Müller-Wohlfahrt (or MW as he is often referred to) is one of the most renowned sports doctors in the world. Aged in his 70s, he has been challenging the status quo and the orthopaedic medicine paradigm over the past 40 years. Often talked about with an air of controversy (due to his use of homoeopathic medicine to treat players), there is no doubt that he has pushed forward SEM's understanding of muscle injuries in particular. Along with his roles with Bayern Munich and the German national team, he has been a magnet for many celebrities from the world of sport and beyond. This includes Usain Bolt, Paula Radcliffe, Ronaldo, Steven Gerrard, Michael Owen and many more. Orthopaedically trained with a specialisation in sports medicine, his approach is one of conservative management and the avoidance of surgery until there is no other option.

For him, the advice for career development is simple and summed up in three principles shown in Figure 48.3. He believes that your career is defined by your ability to manage and win with patients.

Hans-Wilhelm Müller-Wohlfahrt

**Figure 48.3** Dr Müller-Wohlfahrt's keys to career development

### Rod Whiteley—sports physiotherapist who has moved across continents for his career Middle East via Australasia and Major League Baseball

Rod Whiteley is a sports physiotherapist working at Aspetar Orthopaedic and Sports Medicine Hospital in Qatar as a research and education physiotherapist. His primary clinical interest is in upper limb injuries, stemming in large part from having played baseball for over 30 years, from which point his PhD in throwing-related injury seemed almost inevitable. He was physiotherapist to the Australian Baseball Federation for 20 years prior to joining Aspetar and recently was the first non-American to be an invited keynote speaker at Major League Baseball's Winter Medical Meeting.

For him, the overall perspective to share is that 'there is no formula'. Reflecting on his career, he says the underlying theme 'is that you will need to very early suck up the idea that you are not going to be driving a Porsche, so if that's your motivation, get out while you can. If, on the other hand, your motivation is curiosity, an open ended career where things are constantly evolving, and the opportunity to be around other people who are also striving to get as far as they can largely through hard work, then come in, the water's fine'.

He also has some cautionary tales regarding fan syndrome, and losing sight of clinical and professional objectivity. He believes in the importance of honest and frequent self-appraisal and addressing one's own deficits. He is not sure if you could work properly in sport medicine if you are not athlete-centred rather than it all being about how wonderful you are as a clinician.

Finally he also recognises the phenomenon of 'How much I actually know'. He reflects: 'I keep reminding myself of whatever I was doing five years ago and how embarrassed I am about this now, which of course makes me realise that in five years from now I will think exactly the same about what I am now doing'.

Rod Whiteley

## Roald Bahr—Professor of Sports Medicine The Nordic countries

Last but far from least, is one of the editors of this book, Roald Bahr, Professor of Sports Medicine in the

Roald Bahr

Department of Sports Medicine at the Norwegian School of Sport Sciences and the Chair of the Oslo Sports Trauma Research Center. He is also the Chief Medical Officer for Olympiatoppen and Chair of the Medical Department at the National Olympic Training Center. Additionally he is the Head of the Aspetar Sports Injury and Illness Prevention Programme.

Roald is more than these titles though. Professionally he is a world leader in sports injury prevention research having published more than 300 original research articles, review papers and book chapters, in addition to several books. More importantly though he is one of the most warm and generous human beings you could meet.

As is so often the case with those who have been very successful in their careers, the simple advice is built on a deep understanding of those things that really work. For him, the advice he would wish to share is shown in Figure 48.4.

**Figure 48.4** Professor Roald Bahr's keys to success

## Chapter 3

*After feeling discomfort in my hamstring after the first round last night and then again in the semi-final tonight, I was examined by the Chief Doctor of the National Championships and diagnosed with a grade 1 tear.*

Usain Bolt, posted on Twitter 6 weeks before the Rio 2016 Olympic Games

## Chapter 4

*During training, I suffered a stress fracture. It was madness that I carried on and ran the 800 metres and 1500 metres, but because it's the Olympics, you run through the pain. You never know if you'll have another chance at the Olympics, so unless you can't actually walk you carry on, because you don't want to be asking yourself, 'What if?'*

Dame Kelly Holmes, MBE, DBE, 800 and 1500 m gold medallist, Athens 2004 Olympic Games

## Chapter 5

*... then, [Mr Hammerhead Shark] his shirt covered in blood, spun around and hit his knee on the table, at which point he swore and yelled 'My knee! My knee!', the whole time unfussed about the hammer stuck in his neck.*

G Lorimer Moseley, *Painful Yarns. Metaphors and stories to help understand the biology of pain*, Dancing Giraffe Press 2007

## Chapter 6

*Understanding pain biology changes the way people think about pain, reduces its threat value and improves their management of it.*

David Butler & Lorimer Moseley, *Explain Pain*, 2nd ed, Noigroup Publications 2013

## Chapter 7

*Belgian decathlete Thomas Van der Plaetsen had testicular cancer diagnosed because abnormal levels of the HCG*

*hormone were detected on a routine doping test in 2014. After treatment, 2016 saw him win the European Championships and compete at the Rio 2016 Olympic Games.*

Authors

## Chapter 8

*Mo Farah has nine key elements to his running technique that have allowed him to become Britain's greatest ever runner.*

R Gray, 'The secrets of Mo Farah's success', [www.telegraph.co.uk](http://www.telegraph.co.uk), 16 September 2013

## Chapter 9

*Nothing compares to the simple pleasure of riding a bike.*

John F Kennedy (1917-1963)

## Chapter 10

*In football as in watchmaking, talent and elegance mean nothing without rigour and precision.*

Lionel Messi, [www.thewatchquote.com](http://www.thewatchquote.com), 7 September 2012

## Chapter 11

*Core strength and stability is very important to me. Tennis is all about rotation of the body and my ability to create power. I incorporate a lot of abdominal, back and glute exercises into my gym sessions.*

Samantha Stosur.  
A Prosenko, 'New attitude, new Sam', [www.smh.com.au](http://www.smh.com.au), 6 June 2010

## Chapter 12

*An ounce of prevention is worth a pound of cure.*

Benjamin Franklin (1706-1790)

## Chapter 13

*Paul Quantrill will never forget the feeling of pure exhaustion at the most important moment of his career. It was the fourth game of the 2004 American League Championship Series, at Fenway Park, with the Yankees trying to finish a sweep of the Boston Red Sox. The teams were tied, 4-4, heading into the bottom of the 12th. It was Quantrill's 100th relief inning of the season. 'We were done', Quantrill said. 'We were wrecked. We battled, but we just weren't where we needed to be.'*

T Kepner, 'The Endangered Species of Baseball' *New York Times*, 31 March 2016

## Chapter 14

*Listen: the patient is telling you the diagnosis.*

Sir William Osler, Canadian physician (1849-1919)

### Chapter 15

*Wherever the art of medicine is loved, there is also a love of humanity.*

Hippocrates (c.460-370 BCE)

### Chapter 16

*The operation was entirely successful, but the patient succumbed.*

*Manual of Operative Surgery*, published 1887

### Chapter 17

*Healing is a matter of time, but is sometimes also a matter of opportunity.*

Hippocrates (c.460-370 BCE)

### Chapter 18

*The pearl of long-term rehabilitation is to build a small team of core people who collaborate with other professions. Never walk alone!*

Kjetil Jansrud, alpine skiing gold medallist at the 2014 Sochi Winter Olympic Games, 13 months after rupturing his anterior cruciate ligament

### Chapter 19

*Perhaps the most common question for every active but injured patient is 'When can I return to play?'*

Authors

### Chapter 20

*I've been knocked out a few times in there, but I have no idea how many concussions I've ever had.*

Hulk Hogan, *Ewrestling News*, 2 January 2015

### Chapter 21

*In the beginner's mind there are many possibilities, in the expert's mind there are few.*

Shunryu Suzuki, *Zen Mind, Beginner's Mind*,  
T Dixon and R Baker (eds), Weatherhill NY, 1970

### Chapter 22

*Having looked at it on YouTube, I don't like to look at it too much because it freaks me out a bit. The bail hit me in the eye and went two centimetres back.*

South African cricket player Mark Boucher  
on his career-ending eye injury  
F Moonda, 'Boucher finally says goodbye',  
[www.espnricinfo.com](http://www.espnricinfo.com), 16 February 2013

### Chapter 23

*It makes your arm very hot, heavy and difficult to move. Stingers don't tend to last too long; you get pins and needles down your arm as the heaviness goes away. Sometimes it's 10 seconds, sometimes maybe a minute.*

England Rugby star Jonny Wilkinson, who required  
neck surgery after recurrent injuries  
P Rees, *The Guardian*, 7 February 2004

### Chapter 24

*When I dislocated my shoulder back in 2005 and (went through) rehab throughout 2006, I was told by Dr Andrews 'you're always going to have to stay on top of that shoulder. You're always going to have to do a little bit extra to keep it at the level you want to keep it at'. In a lot of ways it was the best thing that ever happened to me because I started doing things that I'd never done before. So I learned so much about my shoulder and how to manage my shoulder.*

Drew Brees, NFL quarterback  
J Bennett, 'Drew Brees updates shoulder injury',  
[www.raycomgroup.worldnow.com](http://www.raycomgroup.worldnow.com), 24 September 2015

### Chapter 25

*Throwing warmup pitches to start the bottom of the second inning, Hudson felt some tightness around his elbow. On the second pitch that inning, he felt that something was seriously wrong. His fastball dipped to about 85 mph, and he became hittable. He stayed in the game and completed the inning . . . but that . . . would be Hudson's last pitch for another year.*

Report on major league baseball pitcher Daniel Hudson's  
return from two ulnar collateral ligament surgeries  
M Hendley, 'After Two Tommy John Operations, Daniel Hudson  
Hopes to Rejoin the D-backs' Starting Rotation',  
[www.phoenixnewtimes.com](http://www.phoenixnewtimes.com), 1 April 2015

### Chapter 26

*Laura Robson admits she will have to start her career all over again after she recovers from major wrist surgery. Robson said she 'felt like a child again' in the aftermath of her operation, struggling to dress herself and cut her own food. Itching to return to action, Robson said she has been reduced to tears, at times frustrated with rehabilitation while her peers train and compete.*

Sky Sports, 20 June 2014

### Chapter 27

*Star midfielder Daniel Kerr says he's willing to risk permanent damage to his injured finger if it means helping the Eagles reach and win another Grand Final. West Coast's bid for a third straight grand final, and back-to-back premierships, was dealt a shattering blow last week when Kerr had to undergo surgery on a ruptured tendon in the ring finger of his left hand.*

T Clarke, 'Daniel Kerr willing to risk permanent damage to  
finger', *Superfooty AFL*, [www.Perthnow.com](http://www.Perthnow.com), 29 August 2007

### Chapter 28

*I want to apologise to my fans. I broke my rib and again I am out of the fight. I really wanted to come back, I'm not sure if I will ever come back.*

Khabib Nurmagomedov, UFC, October 2015

### Chapter 29

*My MRI shows I have a damaged disc at L5/S1. I am disappointed that I can never play basketball, golf and go for a*

*run ever again. A neurosurgeon says he can perform a fusion. Is there anything else I can do?*

24-year-old athlete with disabling low back pain

### Chapter 30

*Running has substantially shaped human evolution, it is one of the most transforming events in human history. We have literally evolved to run and our big incredible butts are evidence of this.*

Professor Dan Lieberman, evolutionary biologist, Harvard University, *Nature*, November 2004, p.345

### Chapter 31

*... Lionel Messi returned to Barcelona early from international break due to an inflammation in his hip, pain that has also plagued other players such as Raul, Xabi Alonso, Aduriz, Busquets and a host of Athletic Club's current squad. There are different options in terms of treatment, and each player has undergone their own decision towards recovery to get back onto the pitch as quickly as possible.*

J Rincón, 'Messi not the only one to suffer from hip pain', [www.Marca.com](http://www.Marca.com), 4 September 2016

### Chapter 32

*Soccer was my first love, and I enjoyed playing on the left wing until a groin injury forced me out of the game in 2008.*

Chad le Clos, South African swimming gold medallist 'Chad's in le Clos of his own', *City Press*, [www.News24.com](http://www.News24.com), 19 November 2011

### Chapter 33

*It was the quad in my right leg, the tendon just kept tearing. I couldn't get back to the point of playing and obviously after having a really good start last season, and not playing again, it was frustrating.*

Joel Paris, promising Australian cricket fast bowler L Jolly, 'Paris primed for Warriors' campaign', [www.cricket.com.au](http://www.cricket.com.au), 1 October 2015

### Chapter 34

*You know, this is a different hamstring—I did my left hamstring, I've done the right side of my back, I've just done my right hammy ... obviously I've got injury concerns at the moment, now I have to go back and do what the experts tell me to give myself the best chance of being fully fit.*

Michael Clarke, Australian cricket captain A Burnett, 'Clarke openly ponders playing future', [www.cricket.com](http://www.cricket.com), 13 December 2014

### Chapter 35

*The thing is I have no ACL. So unless I get surgery, there's nothing really magical that I can do that's going to make it better. I just can get my leg stronger, my muscle stronger and try and support it a little more. But that has a small impact.*

*My knee is loose and it's not stable and that's the way it's going to be from here on out.*

Lindsey Vonn, Olympic gold medal skier 'Vonn: Knee fine after skiing off in downhill', [www.abclocal.go.com](http://www.abclocal.go.com), 21 December 2013

### Chapter 36

*The New York Knicks announced today that Carmelo Anthony will have season-ending left knee surgery. The procedure, which will be performed by Team Orthopedist Dr. Answorth Allen, includes a left knee patella tendon debridement and repair.*

[www.NBA.com](http://www.NBA.com), 18 February 2015

### Chapter 37

*When I listened to other people—who seemed to have trouble even though their [knee replacements] went well—[I learned that] they didn't make the commitment to rehab ... I can walk forever now—pain-free ... I can hit a tennis ball again.*

Billie Jean King, 6 years after her 2010 knee replacements M Cartel, 'Billie Jean King: Life after knee replacements', [www.lifescrpt.com](http://www.lifescrpt.com), 23 January 2016

### Chapter 38

*I saw it once like two years ago ... And that was it, I didn't need to see any more after that.*

Kevin Ware, commenting on his gruesome complete tibial fracture that occurred while contesting a loose ball in NCAA in 2013 R Barrigon, 'Kevin Ware: "I saw the injury once two years ago, I didn't need to see any more after that"', [www.Hoopshype.com](http://www.Hoopshype.com), 27 March 2016

### Chapter 39

*Kompany remains sidelined with a calf injury, sustained after just seven minutes of City's goalless draw with Dynamo Kiev one month ago. Remarkably, it is the 14th time he has suffered a problem with his calf since joining the club in 2008 – with five of them occurring this season – and his 32nd injury overall during the past eight years.*

PhysioRoom, 12 April 2016

### Chapter 40

*The anger is rage. Why the hell did this happen?!? ... Now I'm supposed to come back from this and be the same player or better ... How in the world am I supposed to do that?!? ... Maybe this is how my book ends. Maybe Father Time has defeated me ... Then again maybe not!*

Kobe Bryant, LA Lakers shooting guard and five-time NBA champion, after rupturing his Achilles tendon in a game against the Golden State Warriors in 2013. He returned to play until his retirement in 2016 [www.kobebryant.com](http://www.kobebryant.com)

#### Chapter 41

*Total rupture of left ATFL (ankle ligament) and associated joint capsule damage in a soccer kickabout with friends. Continuing to assess extent of injury and treatment plan day by day. Rehab already started.*

World golf number 1 Rory McIlroy on Instagram,  
nine days before the British Open, 6 July 2015  
[www.instagram.com](http://www.instagram.com)

#### Chapter 42

*Dance is the hidden language of the soul.*

Martha Graham, dancer and choreographer (1894-1991)

#### Chapter 43

*Plantar fasciitis sucks. It feels like you have needles underneath your feet while you're playing.*

Joakim Noah of the Chicago Bulls (NBA)  
D.L. Moore, 'Plantar fasciitis knocking top athletes  
off their feet', [www.usatoday.com](http://www.usatoday.com), 21 August 2013

#### Chapter 44

*Youth is full of sport,  
Age's breath is short;  
Youth is nimble,  
Age is lame;  
Youth is hot and bold,  
Age is weak and cold;  
Youth is wild, and age is tame.*

From William Shakespeare, 'Crabbed Age and Youth'

#### Chapter 45

*The limbs of soldiers are in as much danger from the ardor of young surgeons as from the missiles of the enemy.*

Confederate surgeon Julian John Chisholm's observations on  
the limitations of medical care for military personnel in the  
American Civil War (1861-1865)

#### Chapter 46

*To screen or not to screen, that is the question.*

Authors (adapted from *Hamlet*, William Shakespeare)

#### Chapter 47

*Talent wins games, but teamwork and intelligence win championships.*

Michael Jordan

#### Chapter 48

*If you don't build your dream, someone else will hire you to help them build theirs!*

Dhirubhai Ambani

A G KRISHNAMURTHY, 'Against all Odds:

A story of courage perseverance and hope',  
McGraw-Hill Education Leadership Essentials Series, 2008
